- Application: This UFC is applicable to military installations worldwide.
- Need: This UFC is needed to bring uniformity to many different types of signage used at military installations across the DoD.
- Reasons for Revised UFC: The previous version of this UFC addressed only Air Force sign standards. That document included outdated information that provided little assistance in the implementation of new or replacement signs.

Impact: The following direct benefits will result from publication of this UFC:

- Initial Costs: The costs of implementing new or replacement signs may be lower due to the synergies found in the design guidance of this UFC.
- Life Cycle Costs: Effective application of the design guidance provided will reduce maintenance and minimize overall life cycle costs.
- Safety: Effective application of the strategies in this UFC will improve safety and help ensure building code compliance.
- Convenience: Service members, civilian employees, contractors, and visitors will enjoy improved wayfinding and less stress associated with poor signage.
- Public Image: Compliance with the Service branch identification guidelines in this UFC will help contribute to the positive reinforcement of the brand identity for each Service branch.

CHAPTER 1 GENERAL INFORMATION

1-1 PURPOSE AND SCOPE.

This UFC provides criteria for new and replacement signage appropriate for each Service branch. It establishes requirements for the graphic identification of registered trademarks that are easily recognized in the community. It also provides criteria for standardizing sign materials, colors, styles, and placement throughout an installation. Information on unique sign programs and design requirements of local projects must be obtained at the installation level. Some installations may deviate from these general standards in order to be compatible with their existing signage. Alteration and renovation projects should update existing signage to meet the guidance and criteria provided in this UFC where possible. Non-conforming signs should be replaced when their useful life has ended or modified as required to be compatible with the intent of these standards where practical and economically justifiable.

1-1.1 Background.

This UFC was developed through the collaborative efforts of the U.S. Army Corps of Engineers (USACE), the Air Force Civil Engineer Center (AFCEC), and Naval Facilities Engineering Command (NAVFAC). The intent of this UFC is to provide comprehensive criteria for evaluating, planning, programming, and implementing interior and exterior signs for all military and other Department of Defense (DoD) installations worldwide. This UFC uses non-government standards to the greatest extent possible.

1-1.2 Intended Use.

This UFC applies to the design of all new construction projects, including additions, alterations, and renovation projects on military installations of the Army, Air Force, Navy, and Marines, in the continental United States (CONUS) and overseas (OCONUS). This UFC may also apply to off-installation facilities of these four Service branches, such as recruiting stations or other similar facilities. This UFC does not apply to visual air navigation facility signs placed in and around airfield environments to provide information for operating aircraft. Some installations may require unique sign solutions that reflect their cultural heritage or historical significance, as appropriate.

1-2 GENERAL.

Signs are a highly visible component of the built environment and the public impression expressed by military installations. Each installation must establish both interior and exterior sign standards as part of their Installation Planning Standards (IPS), which include Navy Installation Appearance Plans (IAP), Army Installation Design Guides (IDG), and Air Force Facilities Excellence Guides (FEG). These standards will help provide visual and functional signage consistency for all installations. This consistency will also help improve wayfinding by providing familiar signage components and directional information. Sign programs should be designed with materials and fabrication techniques that maximize the durability of signs and minimize maintenance. Effective sign programs will reduce the number of signs on each installation to the absolute minimum required for directions, identification, and customer service. This eliminates visual clutter and results in an efficient, cost-effective, and attractive system that creates a unified professional appearance for all military installations. Efficient signage and wayfinding programs help provide support for installation-specific mission requirements. Using sign standards will simplify the design/procurement process and reduce construction/maintenance costs.

1-2.1 Sustainability.

The sign contractor must coordinate with the project team to ensure signage materials and components comply with current DoD or Service-specific sustainable design policies, as applicable.

1-3 CODES AND STANDARDS

This UFC is intended to supplement, not replace code requirements and standards, which continue to be the authority for the issues to which they apply.

1-3.1 Exterior Sign Codes and Requirements.

Most exterior signs require approvals and/or permitting at the installation level before installation. Exterior signage programs require compliance with a wide variety of sometimes conflicting criteria, such as:

- American Association of State Highway and Transportation Officials (AASHTO) *Roadside Design Guide*
- Architectural Barriers Act Accessibility Standard for Department of Defense Facilities (ABAAS)
- Federal Highway Administration (FHWA) *Manual on Uniform Traffic Control Devices* (MUTCD)
- FHWA *Standard Highway Signs*
- Institute of Transportation Engineers (ITE) *Traffic Control Devices Handbook*
- Surface Deployment and Distribution Command Transportation Engineering Agency (SDDCTEA) DoD supplement to the MUTCD
- SDDCTEA Pamphlet 55-14
- SDDCTEA Pamphlet 55-15
- SDDCTEA Pamphlet 55-17
- UFC 2-100-01
- UFC 3-535-01
- Unified Facilities Guide Specifications (UFGS) 10 14 01

The location and placement of all exterior signs must comply with guidance provided in the MUTCD.

1-3.2 Interior Sign Codes and Requirements.

Interior signage programs require compliance with a wide variety of different code issues and requirements, such as:

- ABAAS
- *International Building Code* (IBC)
- National Fire Protection Association (NFPA) 101
- UFGS 10 14 00.20

These building codes have specific requirements regarding signage and vary with the building design and other details.

1-3.2.1 ABA Accessibility Standard.

The ABAAS has many requirements that specifically address interior signage, such as:

- Permanent room and space identification
- Requirements for Braille and tactile characters on certain signs
- Sign mounting height and location requirements
- Utilization of the international symbol of accessibility (ISA)
- Specialized elevator signage requirements

These specialized requirements have been considered for the interior sign design parameters provided in Chapter 4.

1-3.2.2 International Building Code.

The IBC has many requirements that specifically address interior signage, such as:

- Stair identification
- Two-way communication systems
- Elevator life safety signs
- Means of egress signs
- Maximum occupancy signs

1-3.2.3 National Fire Protection Association.

Comply with the interior signage requirements of NFPA 101. These requirements address life safety issues, such as:

- Stair identification and stairway landing information
- Tactile level identification requirements (in specific circumstances)
- Tactile exit sign requirements

- Egress identification and information requirements
- Fire extinguisher identification and information
- Elevator sign requirements

1-3.2.4 UFGS 10 14 00.20.

This UFGS addresses such issues as:

- Sustainability requirements
- Submittals
- Warranty
- Various types of interior signs
- Installation requirements
- Protection and cleaning

CHAPTER 2 DESIGN STANDARDS

2-1 GRAPHICS STANDARDS.

Standardization of graphic and text information used on military installation signs helps establish consistent visual communication and brand identity. The graphic standards in this chapter provide general guidelines for most sign message requirements, such as the use of logos, seals, fonts, and colors.

2-1.1 Service Branch Logo Identification.

Service branch logo identification includes seals, symbols, and text that are registered trademarks. Use the approved Service branch seals and text of the Army, Navy, and Marines on installation identification signs as specified in this UFC in Figures 2-1 through 2-5. Use the approved Air Force symbol and text on installation identification signs as specified in this UFC. Restrict the use of these logos to installation identification signs and water towers. There are no such restrictions on the use of these logos on interior signs. The logos must not be altered or modified in any way.

Figure 2-1 Army Logo Identification.

Figure 2-4 Marine Corps Logo Identification.

U.S. MARINE CORPS

Figure 2-5 Joint Base Logo Identification.

U.S.ARMY®

U.S. JOINT BASE

2-2 FONT STANDARDS.

The term “font” is used in this UFC for references to typography. Most sign messages should use upper- and lowercase text for optimum readability. Use the Helvetica Neue family of fonts. The font standards for sign message content include the following:

- Helvetica Neue – 95 Black
- Helvetica Neue – 85 Heavy
- Helvetica Neue – 75 Bold
- Helvetica Neue – 65 Medium
- Helvetica Neue – 55 Roman

This family of fonts provides a hierarchy for messages used on signs. Use the Adobe OpenType family of fonts to provide the maximum flexibility on both the Macintosh and PC operating systems. Traffic control signs must follow the *Standard Alphabets for Highway Signs and Pavement Markings* published by the FHWA and used in conjunction with the MUTCD.

2-2.1 Helvetica Neue – 95 Black

Use the font Helvetica Neue 95 Black (see Figure 2-6) in all applications for letter descriptions of the Air Force, Army, Navy, Marines, and joint bases on installation/gate identification signs and water towers.

Figure 2-6 Helvetica Neue – 95 Black.

Helvetica Neue - 95 Black
ABCDEFGHIJKLMNOPQRSTUVWXYZ
abcdefghijklmnopqrstuvwxyz0123456789

2-2.2 Helvetica Neue – 85 Heavy

Use Helvetica Neue 85 Heavy (see Figure 2-7) for the names of military units on freestanding primary building identification signs and building-mounted identification letters.

Figure 2-7 Helvetica Neue – 85 Heavy.

Helvetica Neue - 85 Heavy
ABCDEFGHIJKLMNOPQRSTUVWXYZ
abcdefghijklmnopqrstuvwxyz0123456789

2-2.3 Helvetica Neue – 75 Bold

Use Helvetica Neue 75 Bold (see Figure 2-8) to identify the installation name on installation/gate identification signs. This font may also be used as the larger font where a hierarchy of typestyles is beneficial.

Figure 2-8 Helvetica Neue – 75 Bold.

Helvetica Neue - 75 Bold
ABCDEFGHIJKLMNOPQRSTUVWXYZ
abcdefghijklmnopqrstuvwxyz0123456789

2-2.4 Helvetica Neue – 65 Medium

Helvetica Neue 65 Medium (see Figure 2-9) is the approved font for primary or "headline" messages on both interior and exterior signs unless otherwise specified.

Figure 2-9 Helvetica Neue – 65 Medium.

2-2.5 Helvetica Neue – 55 Roman

Helvetica Neue 55 Roman (see Figure 2-10) is the approved font for secondary or "body text" messages on both interior and exterior signs unless otherwise specified. **\1** This font should also be used for all tactile messages on interior signs. **/1/**

Figure 2-10 Helvetica Neue – 55 Roman.

2-2.6 Alternative Fonts.

Alternative fonts may be used on signs for historic buildings or installations with unique architectural character. Alternative fonts must comply with ABAAS when used for tactile characters associated with Braille requirements.

2-2.7 Letter Spacing.

Appropriate letter spacing is important for consistency and the visual appearance of message content on signs. Kerning refers to the spacing between letters and optical kerning of letters is desired for digital sign message layouts. Comply with the letter spacing examples provided below for all installation and gate identification signs. All other sign message requirements will use optical kerning and zero letter spacing. Refer to Figures 2-11 and 2-12 for examples.

Figure 2-11 Installation Name Letter Spacing.

Figure 2-12 Letter Spacing Standards.

Optical Kerning, 0 (zero) Letter Spacing

CHAPTER 3 EXTERIOR SIGN STANDARDS

3-1 EXTERIOR SIGN DESIGN GUIDANCE.

Provide exterior signage as part of a total wayfinding system that includes directional guide signs, building identification signs, pedestrian directional signs, street signs, and orientation maps. Develop installation-specific sign designs in accordance with this UFC, giving consideration to the existing IPS, cultural heritage, regional influences, and historical significance. Signs should coordinate with nearby landscape and structures. Design exterior signs for maximum durability and sustainability based upon regional weather impacts. Sign message panels should be easy to update or replace to allow for flexibility of future message updates. Integrate new signs with existing signs to provide the most cost-effective and practical solutions for each facility or installation. A standardized sign system ensures consistency, improves wayfinding, and is compatible with existing base standards.

3-1.1 Exterior Sign Types.

Develop a standard family of installation-specific sign designs in accordance with this UFC and any specific requirements defined in the IPS. Integrate new signs with existing signs to provide the most cost-effective and practical solutions for each facility or installation. There are six basic categories of exterior signs:

- Installation and gate identification
- Building identification
- Traffic control devices
- Directional and wayfinding
- Mandatory and prohibitory
- Informational and motivational

3-1.2 Prohibited Exterior Signs.

Prohibited signs include any sign with animated, blinking, chasing, flashing, or moving effects. Other types of prohibited signs include rotating signs, windblown or inflated signs, neon signs, and portable signs. Specific prohibitions on certain sign types may also be established at the installation level. These restrictions do not apply to traffic control devices.

3-1.3 Historic Signs.

Specialty historic signs for facilities on the National Historic Register or within a historic district must be coordinated and approved through the state historic preservation office (SHPO). These are freestanding and wall-mounted exterior signs that may use a special typeface, materials, or fabrication techniques to complement the character of historic buildings.

3-1.4 Exterior Color Standards.

The goal of this UFC is to establish a consistent color scheme for all installation and building signs that works for all Service branches. A consistent dark background should be used for standard installation and gate identification signs, with light text to provide sufficient contrast, to meet all visibility and required legibility objectives. Accent colors help reinforce the brand identity of the Service branch.

Service branch-specific color schemes are permitted exceptions to the standard color scheme where needed to maintain consistency with existing sign programs, IPS, or other special considerations at some installations. These color standards and special Service branch exceptions do not apply to traffic control signs that have color and material requirements specified in the MUTCD.

3-1.5 Engineering and Shop Drawings.

All signs, foundations, and connections must be engineered to resist wind loads and thermal movement according to the local climate requirements without distortions and excessive deflections. Shop drawings submitted by the sign contractor must include fabrication details such as elevations, message layouts, sections, side views, plan views, mounting details, and electrical or communication details. Submittals for all freestanding signs must include design calculations and the signed seal of a registered structural engineer licensed in the required area or follow approved state department of transportation standards to ensure compliance with all design and load requirements. Shop drawings must illustrate all means of mounting and attachment for proper coordination for connections to building structures.

3-2 INSTALLATION AND GATE IDENTIFICATION SIGNS.

Provide installation and gate identification signs according to the design guidelines provided in this UFC to help provide consistency for installation identification signs among all Service branches. These sign designs also address joint Service installation identification issues.

3-2.1 Message Content.

These signs may contain graphic information on one or both sides, depending upon the orientation of the sign and visibility requirements. These signs contain only the following information:

- **\4** "Service branch and Component logo or Seals" identification text in all caps. **/4/**
- Service branch or "U.S. Joint Base" identification text in all caps. The font must be Helvetica Neue 95 Black. The logo for the lead Service branch **\4** or Component **/4/** of a joint base must be mounted on the left side of the sign.
- Installation name in upper- and lowercase letters. Font must be Helvetica Neue 75 Bold. The name for the lead Service branch **\4** or Component **/4/** of

a joint base must be mounted on the left side of the sign and must match the logo placement.

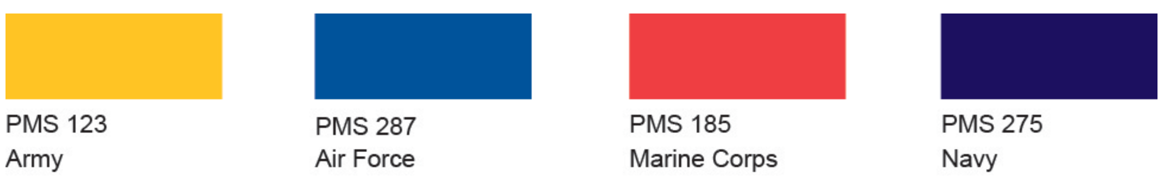
- Optional gate identification information may be added to the base of the sign. The font must be Helvetica Neue 65 Medium.

3-2.2 Materials and Colors.

The sign and background material should be fabricated from aluminum with a painted finish. All logo symbols and seals must be 0.5 inch (13 millimeters [mm]) thick and fabricated from highly durable materials with full color graphics, except the Air Force logo must be brushed aluminum. All letterforms must be constructed of 0.5-inch (13-mm) -thick aluminum. Use a paint to match a “brushed aluminum” finish for the center part of the sign cabinet. Provide a dark bronze painted finish for the background of the sign face unless there are installation-specific color standards. The supporting structure materials may vary to match the architectural character of the surrounding environment or installation-specific standards.

Service branch-specific color schemes are permitted exceptions to the standard color scheme where needed to maintain consistency with existing sign programs. These special considerations should be established in the IPS. Provide a vertical brushed finish with a factory-applied coating to aluminum letterforms on dark backgrounds. Provide dark painted letterforms if using a light-colored sign background to provide sufficient contrast and allow these signs to meet all required visibility and legibility objectives. These color standards and special Service branch exceptions do not apply to traffic control signs that have color and material requirements specified in the MUTCD. Accent colors shown in Figure 3-1 are used to help reinforce the brand identity of each Service branch.

Figure 3-1 Installation and Gate Identification Sign Accent Colors.



3-2.3 Illumination.

Provide external illumination for all primary, secondary, and wall-mounted installation entrance signs where required for visibility. Use high-efficiency floodlights. Minimize the use of illuminated signs to reduce initial costs, prevent maintenance issues, and avoid driving distractions.

3-2.4 Primary Installation and Gate Identification Signs.

The structure supporting the sign may vary to complement the predominant architectural style of the installation, but the design of the sign itself must conform to Figures 3-2 through 3-9 to the maximum extent practical. Installation and gate identification signs at the entrances to installations are the only signs that will incorporate the brand identity of each Service branch.

Figure 3-2 Primary Installation and Gate Identification Sign Fabrication.

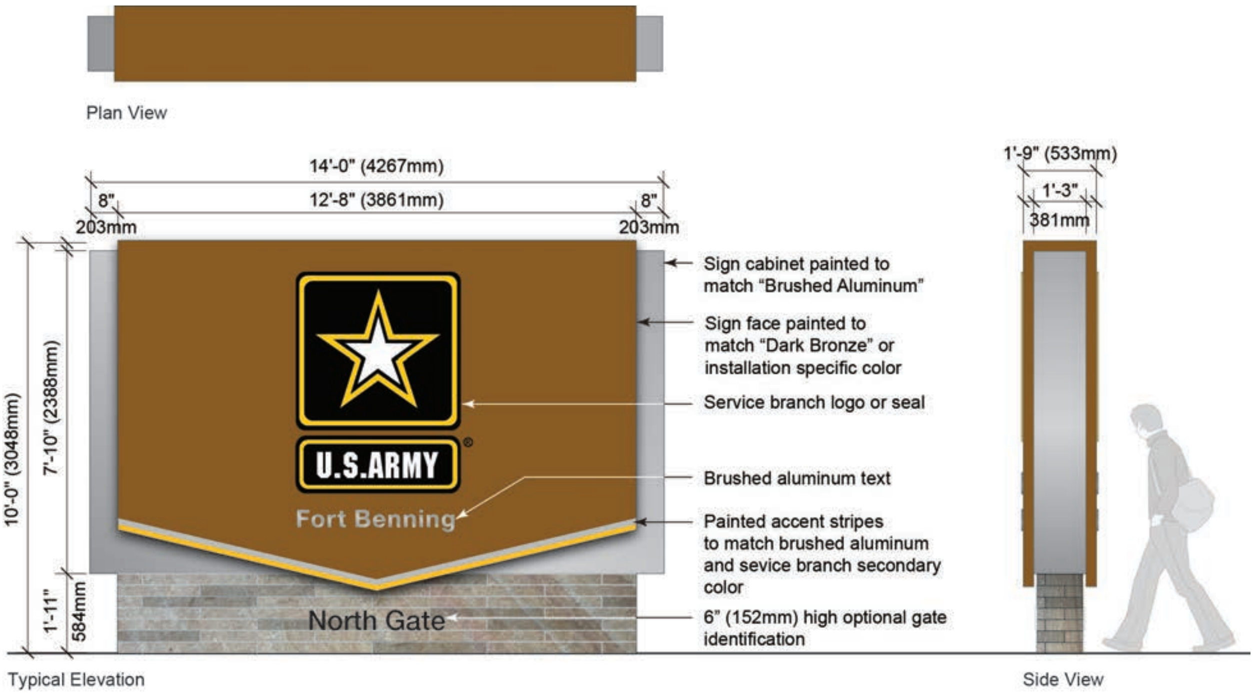


Figure 3-3 Primary Installation and Gate Identification Signs.

Figure 3-4 Primary Installation and Gate Sign Layout Details.

Figure 3-5 Primary Joint Installation and Gate Identification Signs.

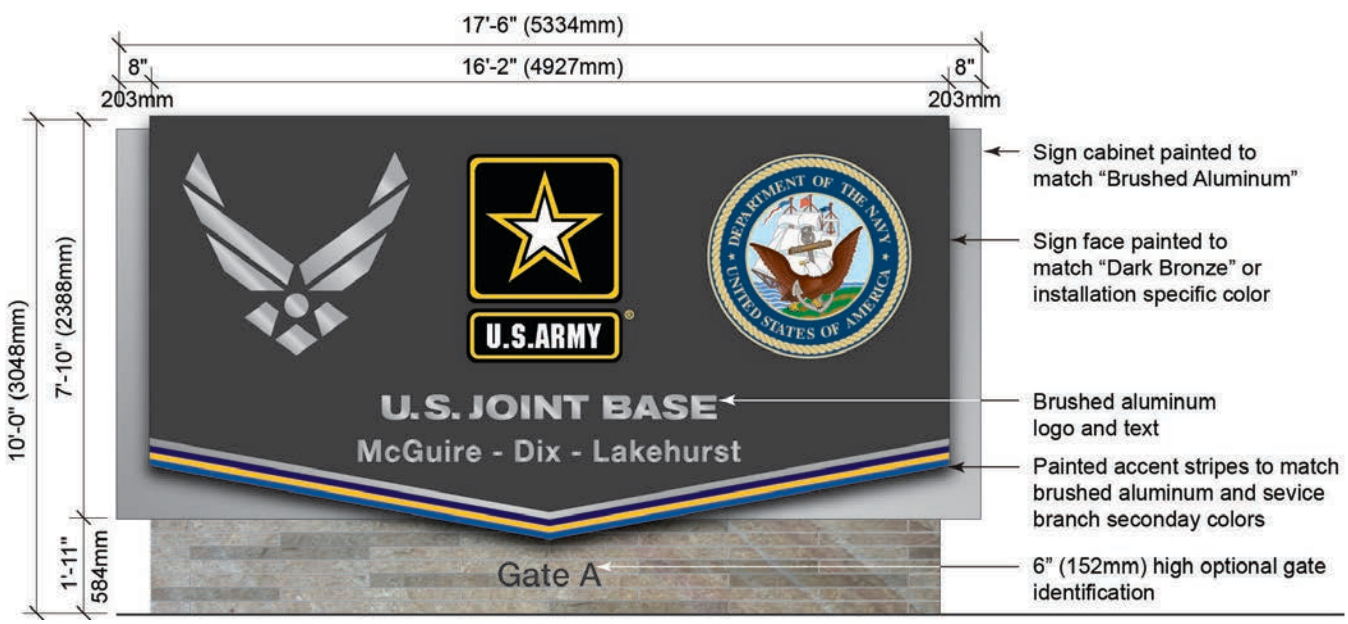

Figure 3-6 Primary Joint Installation Sign Layout Details.

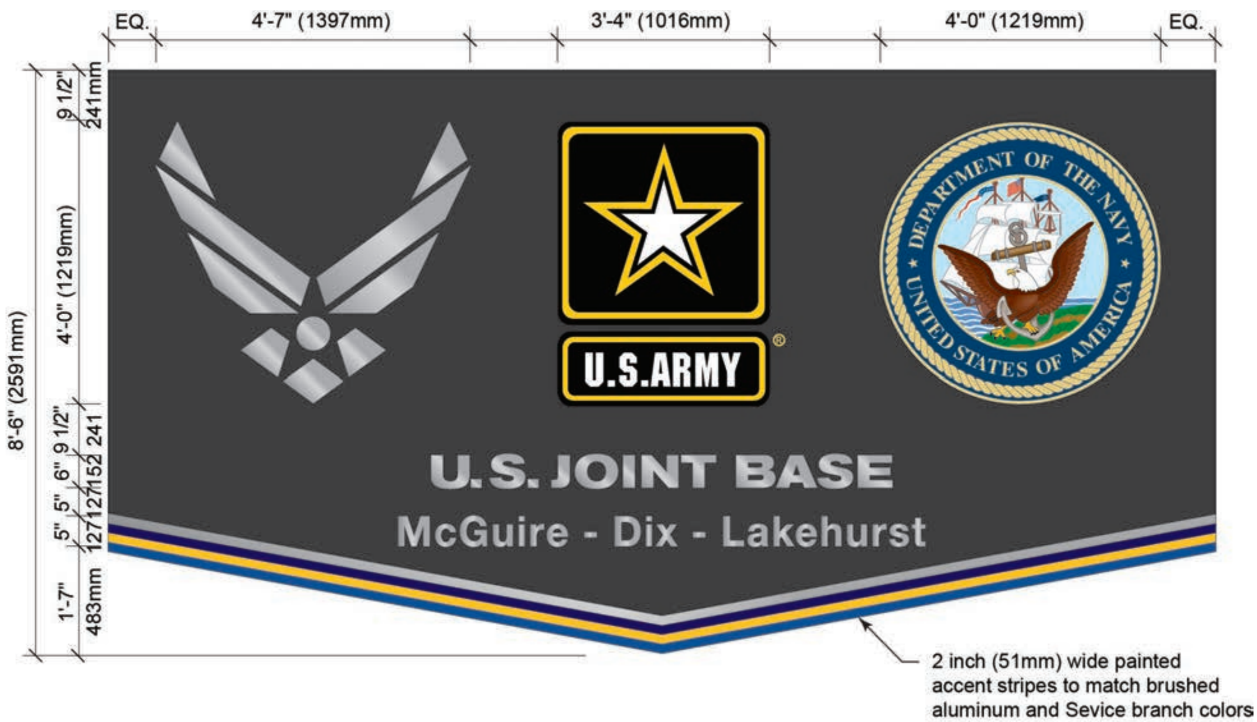
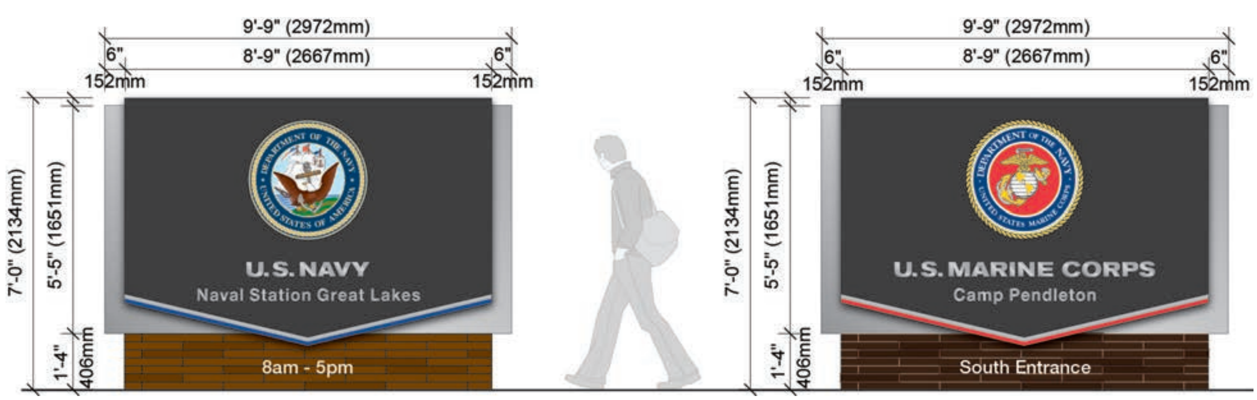


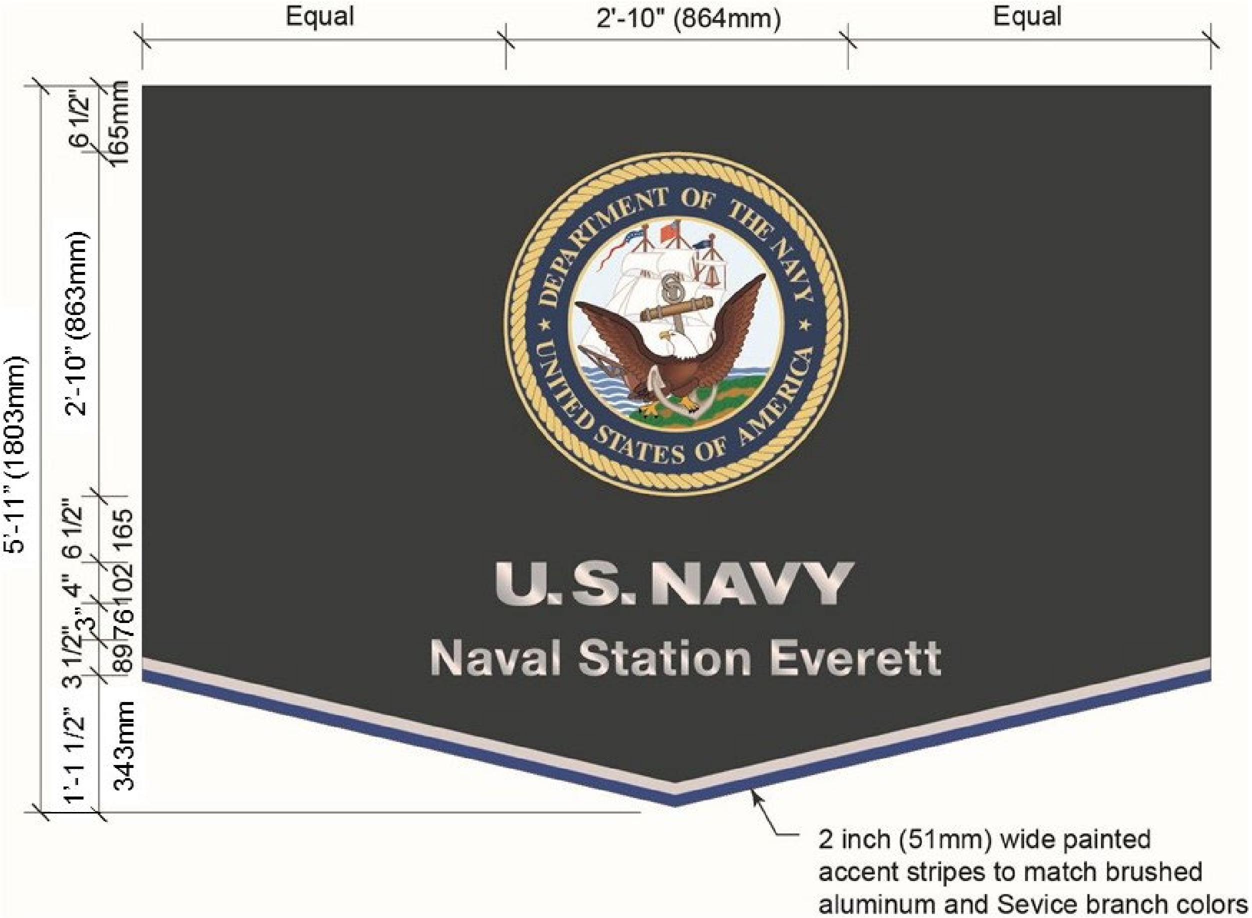
3-2.5 Secondary Installation and Gate Identification Signs.

Secondary installation and gate identification signs are used to identify secondary installation entrances that receive high volumes of traffic (see Figures 3-7 through 3-9). These entrances are primarily for active duty and other DoD personnel with proper identification. These signs must use the same materials and information as the primary installation identification signs except they must be slightly smaller in size. Supplemental messages may be provided on the sign base, such as gate identification or hours of operation.

Figure 3-7 Secondary Installation Identification Signs.



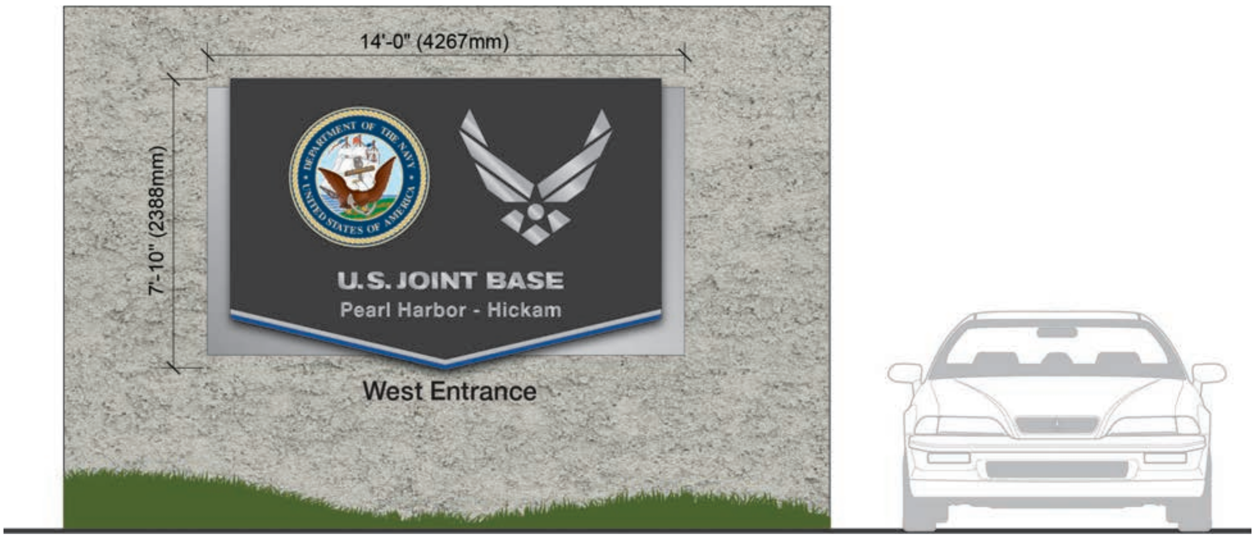
\3\ Figure 3-8 Secondary Installation Sign Layout Details. /3/



3-2.6 Wall-Mounted Installation Identification Signs.

Installation identification signs may need to be placed on existing walls, gates, or buildings at or near the main installation entrances to identify and introduce the installation to visitors. The fabrication techniques, materials, and colors should be consistent with freestanding installation identification entrance gate signs. These signs should use the background materials as shown to provide a consistent background for the symbols and letterforms regardless of the color of the object where it may be installed. Provide installation identification mounted on an aluminum sign panel because it requires fewer holes to be drilled into the existing structure than individual logo symbol/letters, resulting in less damage to the structure in the event of a future name change.

Figure 3-9 Wall-Mounted Installation Identification Sign.



3-2.7 Tertiary Gate and Entrance Signs.

Tertiary gate and installation entrance signs are used to identify non-public access control points, such as commercial/delivery gates. Use MUTCD standard guide signs to direct vehicles to these entrances. Message content should include the installation name and the function of the tertiary entrance.

3-3 BUILDING IDENTIFICATION SIGNS.

Building identification signs are used inside the installation to provide information about buildings, major tenants within buildings, areas within the installation, and organizational or functional units. Different sizes and design elements are used to identify the different organizational levels. The signs should carry one unit name and any secondary information to identify the unit component (such as headquarters) and may also include a street address. No unit mottoes, names, or titles of individuals are permitted.

3-3.1 Freestanding Building Identification Signs.

Most buildings can be best identified by using a freestanding building identification sign in front of the building near the main entrance or at the main entrance to the associated parking area (see Figures 3-10 and 3-11). There are three basic types of freestanding building identification signs:

- Primary - These signs identify high-level organizations such as command, squadron, or unit headquarters.
- Secondary - These signs identify lower-profile buildings. These signs use the same basic principles as primary facility signs, only these are somewhat smaller.
- Tertiary - These signs identify buildings or other miscellaneous facilities that do not require a street address or building number, such as recreational facilities, training areas, and maintenance or storage facilities.

The appropriate sign type required is based upon the importance of the building or tenant identification required. Place primary identification signs as close as possible to the building entrance and perpendicular to the roadway to permit viewing by traffic moving in both directions. If the building is set back from the roadway and is not visible or is only partially visible from the roadway, place the sign next to the entrance driveway and on the side of the driveway closest to the building. Provide one sign for each building unless additional signs are required due to unique site conditions. Consider intersection sight distances provided in AASHTO *A Policy on Geometric Design of Highways and Streets* (Green Book), in addition to the lateral offsets included in the MUTCD.

Figure 3-10 Freestanding Building Identification Signs.

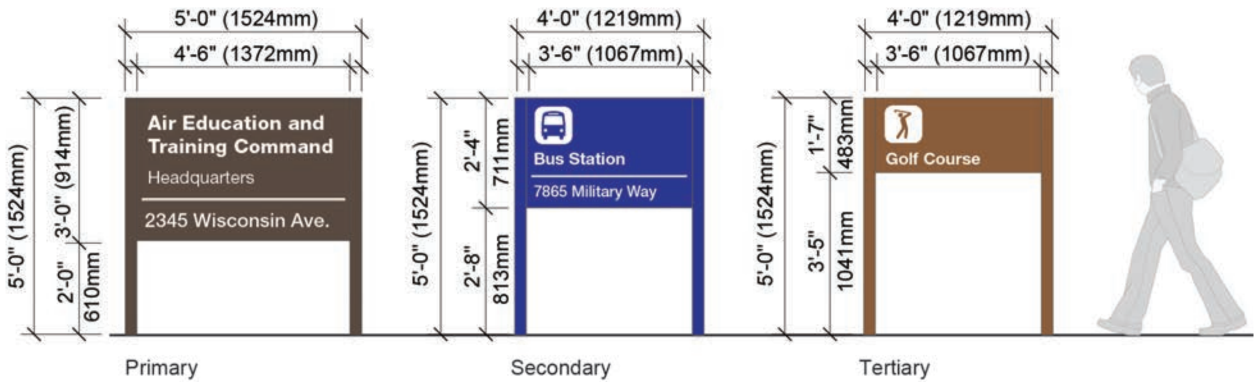


Figure 3-11 Freestanding Building Identification Sign Layouts.

3-3.1.1 Materials and Colors.

Freestanding building identification signs must be non-illuminated and use a standard post-and-panel type construction. Use extruded aluminum square posts with flat aluminum sign message panels that are removable for easy replacement. Sign post and panel sizes must be engineered by the sign contractor according to wind loads and other requirements at each installation. Minor deviations from these general specifications are permitted where needed to align with installation-specific standards and pre-existing sign programs.

Provide a dark bronze painted finish for the background of the message panels and support posts. Sign message content must be white reflective engineering-grade vinyl. Use these standard materials and colors unless there are specific requirements established in the IPS. These color standards and special Service branch exceptions do not apply to traffic control signs that have color and material requirements specified in the MUTCD.

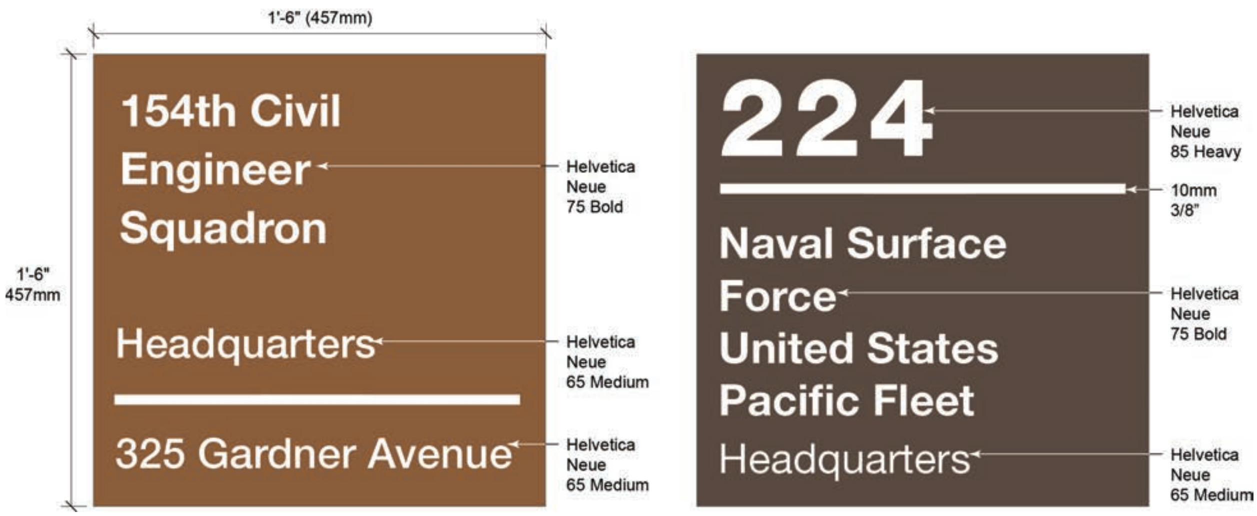
3-3.1.2 Street Address and Building Numbers.

Include the street address or building numbers (if used) on all building and facility identification signs, where possible. Include this information at the main entrance to the building and on other exterior portions of the building as necessary for wayfinding.

3-3.2 Building Entrance Signs.

Only one identification sign is permitted at each building entrance (see Figures 3-12 through 3-14). Place the building entry signs directly on the wall next to the entry point. If the building is set back from the roadway and is not visible or only partially visible from the roadway, place the sign next to the main entrance of the building to confirm the information shown on the sign at the entrance driveway. Some buildings have more than one primary entrance. Use building-mounted entry signs to identify organizations that are reached through the alternate entries of these types of buildings.

\2\ Figure 3-12 Building Entrance Signs. /2/



\2\ Figure 3-13 Building Entrance Sign Layouts. /2/

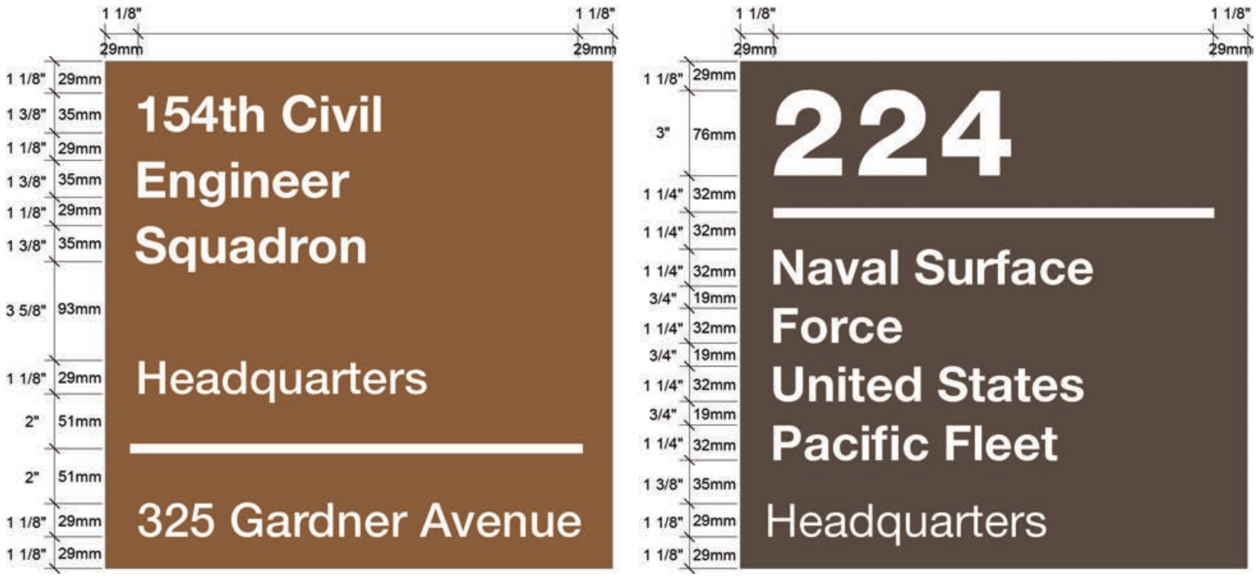


Figure 3-14 Building-Mounted Entry Sign Placement.

3-3.2.1 Materials and Colors.

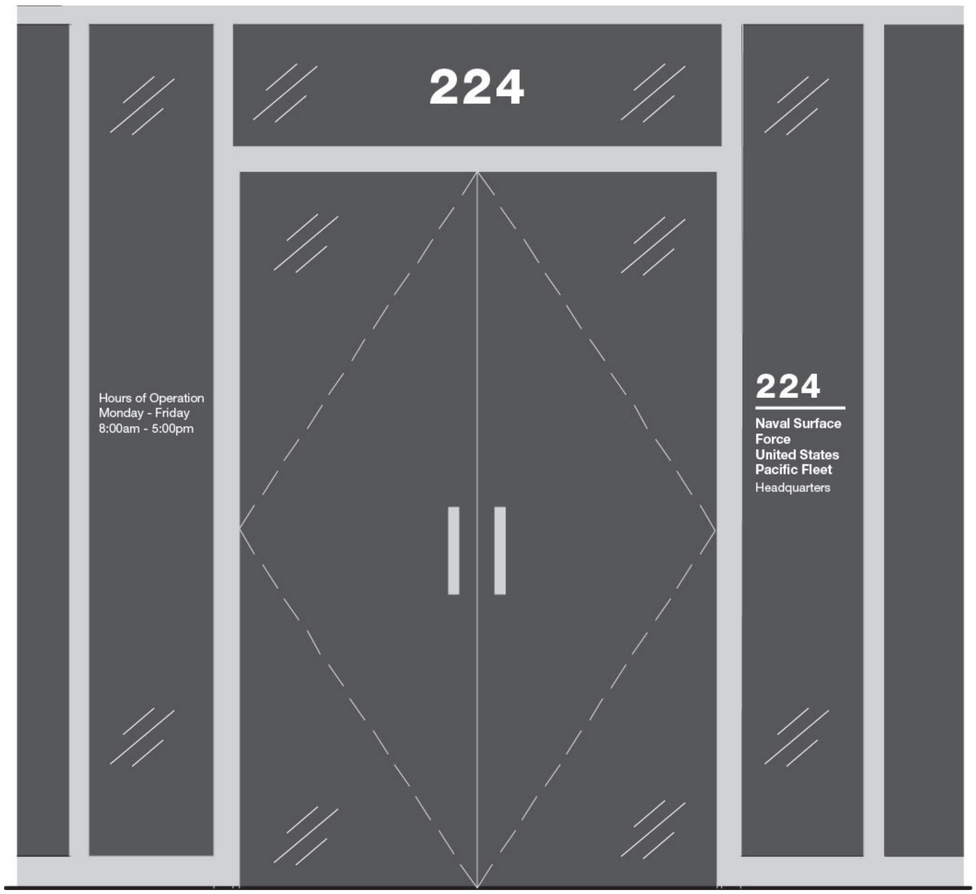
Building-mounted entry signs must be non-illuminated and must be painted aluminum with white vinyl messages. Signs must be wall-mounted where possible and attachment methods may vary depending upon building conditions. The dimensions of the signs are 1.5 feet x 1.5 feet (457 mm x 457 mm). If building numbers are used they should be located at the top of the sign. If the required message on a building entry sign is too long to fit on the standard layouts shown, reduce the size of the text as required.

Provide a dark bronze painted finish for the background of the message panels or other background color that is consistent with the installation standards. Minor deviations from these general specifications are permitted where needed to align with installation-specific standards and pre-existing sign programs. Use these standard materials and colors unless there are specific requirements established in the IPS.

3-3.3 Building Entrance Signs on Glass.

Customized solutions may be designed for buildings with glass entrances. Provide frosted or white vinyl building identification on glass entryway signs where required. Provide building numbers or the street address that are appropriately sized for the average viewing distance. As a guide, use letters 1 inch (25 mm) high per 25 feet (7.62 meters) of viewing distance and establish an installation standard based on the average door size and the average viewing distance. Include limited additional information such as tenant identification information and hours of operation where appropriate (see Figure 3-15).

Figure 3-15 Building Identification for Glass Entrances.



3-3.4 Building-Mounted Identification.

Minimize the use of building identification signs to only high-profile buildings, except where building identification numbers are used. Signs mounted on prominent buildings may include the building name, primary function, and/or building identification number when the facility needs identification from long distances. Building number signs may be used in addition to the primary facility identification sign where required.

3-3.4.1 Materials and Colors.

Individual dimensional letters applied directly to the surface of the wall are discouraged. The preferred fabrication details should include an aluminum sign panel mounted to the building with letterforms applied to the panel. Use the Helvetica Neue 85 Heavy font for typical building identification letters or numbers where required. Provide a dark bronze painted finish for the background of the message panels or other background color that is consistent with the installation standards. The color or finish of the letters should complement the predominant color of the building while providing enough contrast with the background for visibility. Use light-colored letters on dark sign panels and dark-colored letters on light sign panels. Use these standard materials and colors unless there are specific requirements established in the IPS. Minor deviations from these general specifications are permitted where needed to align with installation-specific standards and pre-existing sign programs.

3-3.4.2 Placement.

Building-mounted identification signs should be coordinated and compatible with the building's design and applied consistently across the installation. They are often most effective near the main building entrance or on a covered drop-off canopy. Signage may be required on the back or side of the building to provide better visibility and wayfinding cues for visitors or customers. The installation engineer should select the most appropriate solutions for the architectural style of the buildings and apply them consistently.

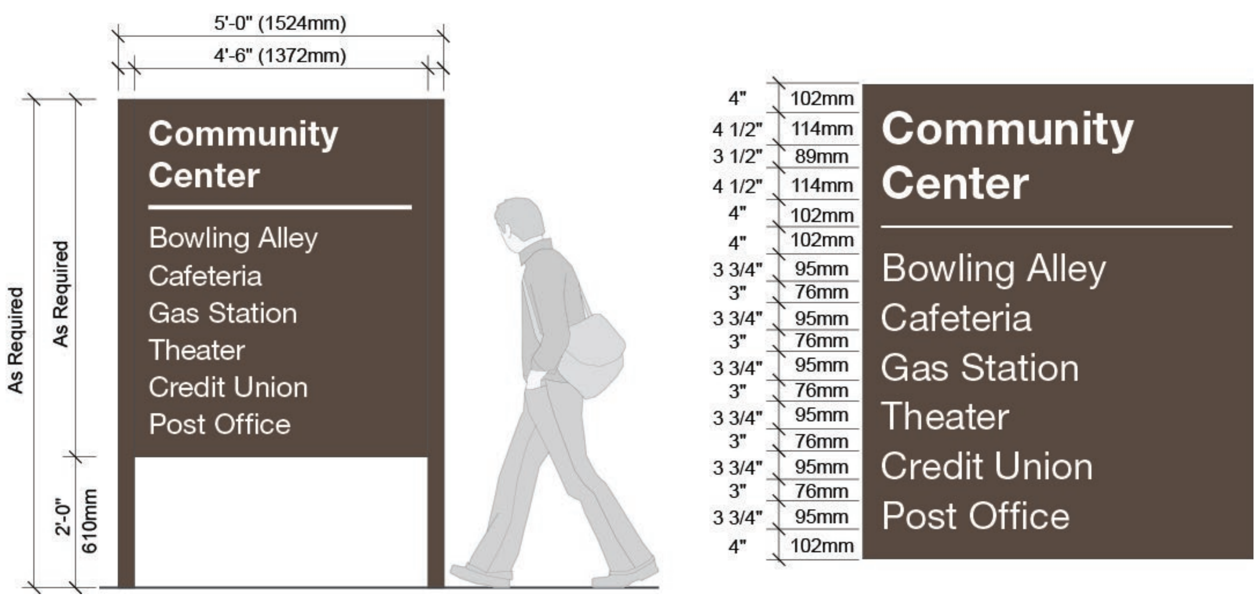
3-3.5 Commercial Signs.

Many commercial entities on military installations have standard image symbols or unique logos that may be used to provide identifiable images and/or wording that is easily recognizable to potential users. Commercial organizations, such as the base exchange, Defense Commissary Agency (DeCA) stores, and restaurants may display their registered trademark logos. The size, placement, and material composition of these signs must be consistent with installation-specific standards. The use of neon signs is prohibited.

3-3.6 Centralized Facilities Freestanding Identification Signs.

Centralized facilities signs may be designed to address multiple buildings or services that use a common roadway entrance or parking area. Set the sign to permit viewing by traffic moving in both directions. The size, placement, and material composition of these signs must be consistent with installation-specific standards. See Figure 3-16.

Figure 3-16 Centralized Facilities Freestanding Identification Signs.



3-3.6.1 Specialty Community Identification Signs.

Limited use of specialty community identification signs is permitted to identify communities, housing areas, districts, or other installation-specific specialty facilities. These signs may be customized to align with the unique architectural characteristics of each area or installation, as required. Use the general guidance and design principles provided in this UFC for these types of non-standard signage options.

3-3.7 Water Tower Signage and Graphics.

Water towers must comply with UFC 3-535-01 for marking and lighting requirements for airfield obstructions. Service logos and shields are not required for all water towers. When applied, these guidelines apply only to water towers and may not be used for other highly visible structures. The face of the water tower tank must display only the Service branch seal or logo and the approved font identification; no additional graphics or lettering will be applied (see Figure 3-17). The paint scheme for the symbol and letterforms must be consistent with the approved colors associated with the appropriate Service branch logo. The application of each logo template may vary in overall size but must maintain the composition and proportions as provided by the digital artwork. The shapes of the seals, symbols, or letterforms must not be altered in any way.

Only apply Service logos and shields to water towers with a background color for the body of the tank that is a uniform light tone consistent with installation standards. Due to the diversity of water tower tank shapes, configurations, and orientations, the following guidelines are provided to facilitate consistent and effective implementation:

- Avoid a cluttered appearance by having no more than two applications of the symbol and letterforms on one tank.
- Orient the symbol and letterforms on the side(s) of the tank that provide the best visibility for the public.
- Size the symbol and letterforms to be easily read from a reasonable distance.
- Position the symbol and letterforms in a manner that minimizes visual interference by railings or other structural elements and minimizes distortion due to any vertical curvature of the tank surface.

Figure 3-17 Water Tower Signs.

3-4 TRAFFIC CONTROL DEVICES.

All traffic control devices must conform to the requirements specified in the latest versions of the MUTCD and the SDDCTEA DoD Supplement to the MUTCD. The MUTCD defines the standards used to install and maintain all traffic control devices. Exceptions to the MUTCD must be approved by SDDCTEA. SDDCTEA executes DoD's overall transportation engineering program on behalf of the Services.

3-4.1 Fabrication and Installation.

All sign colors for traffic control devices will be in accordance with the MUTCD. Material selection and installation must consider the effects of local climatic conditions. Painting sign posts and the backs of signs is prohibited. Wood for sign faces is prohibited.

3-4.2 Access Control Point/Entry Control Facility Signs.

The required traffic control devices required for access control points and entry control facilities (ACP/ECF) are detailed in the MUTCD, the SDDCTEA DoD Supplement to the MUTCD, and SDDCTEA Pamphlet 55-15.

3-4.3 Speed Limit Signs.

Speed limit signs must display the limit established by law, ordinance, regulation, or as adopted by the authorized agency. Speed zones (other than state statutory speed limits) will only be established on the basis of an engineering study performed in accordance with traffic engineering practices. The speed limits displayed must be in multiples of 5 miles per hour (mph) (8 kilometers per hour [kph]).

3-4.4 Street Name Signs.

Provide street identification signs in accordance with the guidelines established in the MUTCD. Pictographs and logos are prohibited on street name signs. Use double-faced street name signs.

3-4.5 Reserved and Accessible Parking Signs.

Reserved and accessible parking should be kept to a minimum and assignment of reserved spaces should be established at the installation level. The use of freestanding and building-mounted signs is discouraged. Acceptable space identification methods include curb markings, pavement markings, or identifying the entire reserved area with a sign at each entrance. The requirements for reserved parking do not apply to accessible parking. The guidelines and requirements for accessible parking and signs are detailed in ABAAS and the MUTCD.

3-5 DIRECTIONAL AND WAYFINDING SIGNS.

There are two types of directional and wayfinding signs: pedestrian and vehicular. Pedestrian circulation is separate from vehicular circulation and requires its own wayfinding system. Vehicular directional and wayfinding signs are detailed in the MUTCD and paragraph 3-4 of this UFC. A cohesive signage plan is important and both sign systems must work together. See Figure 3-18.

3-5.1 General Guidelines.

Provide pedestrian directional signs at critical points where decisions are necessary for movement to a destination. It is very important for these signs to meet the information needs of visitors and other installation users. There are too many potential destinations on any military installation to list on directional signs, but effective directional signs help visitors find their destinations more easily. Directional signs, proper street identification, and effective installation maps form the basic keys to visitor orientation and effective wayfinding. Graphics and messages must appear on both sides of the sign if visible and meaningful to people moving in both directions. Separate the destinations with white rule lines. Place no more than six, and no fewer than two, destinations on pedestrian directional signs.

3-5.1.1 Materials and Colors.

Pedestrian directional signs must be non-illuminated and use a standard post-and-panel type construction. Use extruded aluminum square posts with flat aluminum graphic sign message panels that are removable for easy replacement. Sign post and panel sizes must be engineered by the sign contractor according to the wind loads and other requirements at each installation. Minor deviations from these general specifications are permitted where needed to align with installation-specific standards and pre-existing sign programs.

Provide a dark bronze painted finish for the background of the message panels and support posts. Sign message content must be white vinyl. Use these standard materials and colors unless there are specific requirements established in the IPS.

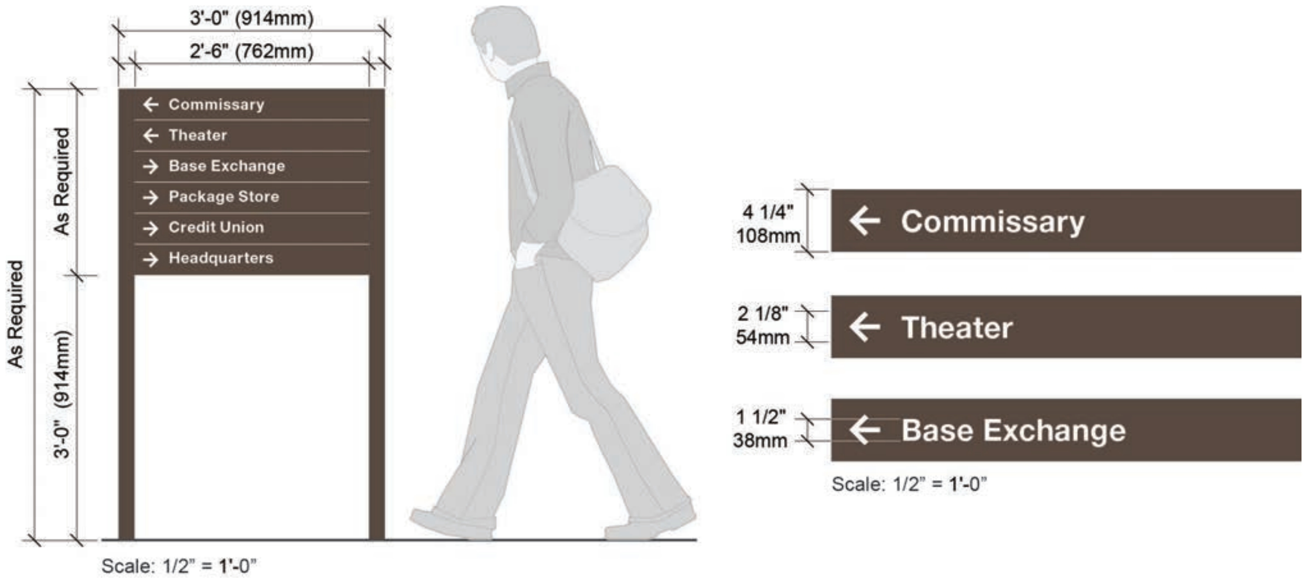
3-5.1.2 Message Limitations.

The destinations most often sought by people new to the installation should be clearly named on orientation maps and directional signs. Other major destinations should be listed in a map legend keyed to building address numbers. Area designations should be used only if they are meaningful. No more than six destinations should appear on one directional sign. If it is necessary to show more than six destinations then add a second sign, but do not use more than two directional signs in any situation.

3-5.1.3 Sign Placement and Installation Details.

Signs should be placed where they can be clearly seen by the user. Check sight lines before signs are erected. Place signs to take advantage of indirect light from existing light sources for good night visibility. A series of signs requiring pedestrian decisions should be placed far enough apart to allow enough time for the user to make the required decisions.

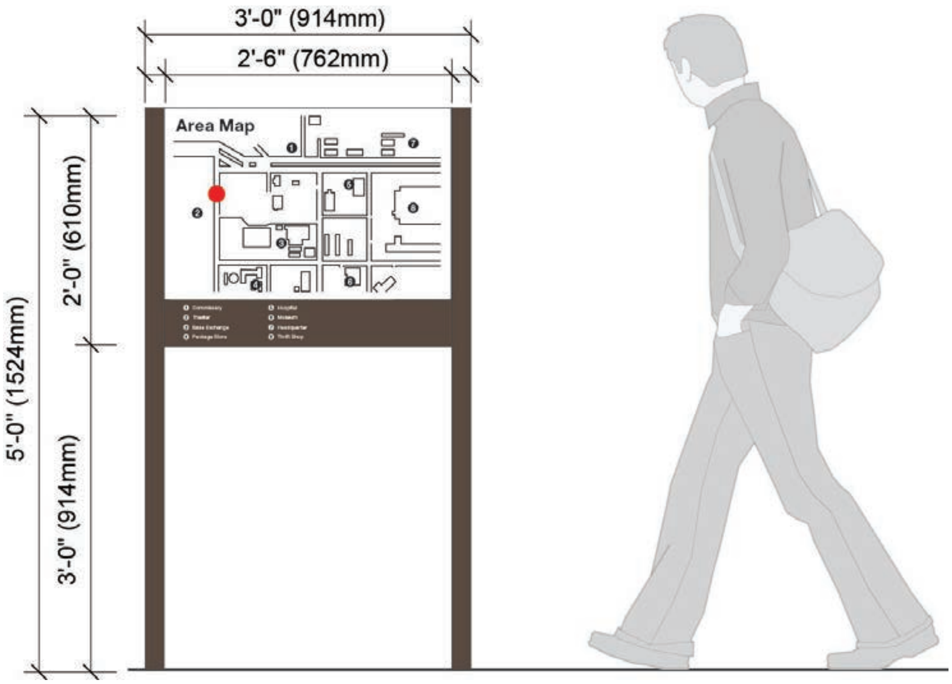
Figure 3-18 Pedestrian Directional Signs.



3-5.2 Orientation Map and Wayfinding Signs.

Most first-time visitors to a military installation receive verbal information at the entry gate, but may also need wayfinding/orientation map information. Provide installation maps at strategic locations to orient visitors and help them find destinations (see Figure 3-19).The installation map, directional signs, and building and street identification signs comprise the total wayfinding system outlined in this UFC. It is essential to use consistent nomenclature throughout the system. For example, the community center should be indicated by the same name on the map, directional signs, and the building identification sign. Design maps for clarity and ease of use. Maps created by merely reducing the installation site plan are usually too difficult to read, so the site plan must be simplified to emphasize major circulation routes and destinations. Use a halftone screen to indicate roadways. Emphasize important buildings by increasing the scale of the buildings in relation to other buildings or by adding color. Maps should be drawn from the perspective of the main entrance to aid visitor orientation and include “You Are Here” orientation information.

Figure 3-19 Orientation Map Signs.



3-6 MANDATORY AND PROHIBITORY SIGNS.

There are many different types of mandatory and prohibitory signs required for military installations that inform visitors and personnel of physical hazards and unsafe practices. These signs are required to define areas of restricted access to maintain proper levels of security. Other signs are required to address many types of specialized issues (e.g., hazardous or flammable materials, ordnance, fuel storage tanks). Utilization of these sign types should be kept to the minimum number and size required to meet safety regulations and avoid visual clutter. Refer to the design criteria and specification provided in the SDDCTEA DoD Supplement to the MUTCD for all traffic-related mandatory and prohibitory sign requirements.

3-6.1 Accessibility Pathway and Entrance Signs.

Provide signs as required by the ABAAS and to indicate the accessible routes from parking areas, public transportation stops, and public streets or sidewalks to building entrances. The signs must include the ISA and may require arrow indicators, as needed.

3-7 INFORMATIONAL AND MOTIVATIONAL SIGNS.

Informational signs may be used to address a wide variety of communication initiatives. These signs may include promotional advisories, general information, or temporary campaigns. Use signs that complement the standard morale signs and avoid visual clutter. Informational signs may be used alone or in combination with morale signs. Consider the need for message panels that can be easily updated or replaced using digital output sources like printed vinyl graphics.

The design of motivational signs may vary depending upon the installation standards and what types of signs are selected. Place signs at a prominent location on the installation, in an open area free from other signs or obstructions. Avoid haphazard placement and odd sizes. There are two types of exterior motivational signs: installation and standard. Unit morale signs should be used only inside buildings and are addressed in paragraph 4-8. The installation commander is responsible for controlling the quality, content, and placement of motivational signs. Minimize the number of motivational signs to avoid a cluttered appearance and do not use motivational signs at ACP/ECFs. Sign faces may be finished in a variety of materials, but sign structures must conform to the design requirements provided in this UFC.

3-7.1 Motivational and Morale Signs.

These signs are typically placed inside the main gate or at a central location on the installation, and may show the command shield, organizational emblems, mottoes, awards, and other elements related to installation morale. The design parameters of these signs may vary. There are no restrictions on the use of color or the character of the specific design, but these signs should be professionally designed and fabricated. Morale signs are used to support safety campaigns, fundraising drives, and special events. The design and fabrication should reflect the overall design principles outlined in this UFC. The dimensions should not exceed 4 feet x 10 feet (1219 mm x 3048 mm).

3-7.2 Electronic Message Signs.

Electronic messaging must be limited to the locations listed below:

- Primary entrance/entrances to the installation or at a central location in the community area
- Single location at the VIP entry point along the flight line
- Wing commander's office (serves as the wing commander's board)
- Electronic sortie board

When utilized at Air Force installations, an electronic message board that tracks the number of sorties flown will also serve as the base commander's message board. The size of this board depends on the total number of units being tracked. Information on the board is laid out with the flying unit designations across the top and "Goal," "Flown," "Remaining," and "Ahead/Behind" along the left side. The board should have the same layout on the opposite face (two-sided board). For initial planning purposes, anticipate a board size of 12 feet (3658 mm) long by 5 feet (1524 mm) high, supported on a 2.5 foot (762 mm) high masonry base.

Existing electronic messaging signs not in compliance with this UFC must not be grandfathered or replaced in kind and must be removed or brought into full compliance at the end of their useful life. Electronic messaging signs are limited to the locations identified above. **\2** The electronic message area, with the exception of the electronic sortie board, must be up to a maximum 10 feet (3048 mm) wide by 6 feet (1829 mm) high. Electronic message signs must be carefully located to avoid visual distraction and obstruction of vehicle and pedestrian traffic. ***/2/*** It is recommended to place the electronic message board on a masonry base to help protect the board from damage by grounds equipment and to conceal the electrical and control wiring. Electronic message sign hours of operation should be controlled by a timer so signs are turned off when vehicular traffic is minimal.

3-7.3 Exhibit Signs.

Use exhibit signs to display information relating to large-scale exhibits, such as aircraft, tanks, missiles, and specialty equipment. Place these informational signs in the vicinity of the exhibit they describe, oriented to the roadway or to the principal direction from which a visitor will approach. Informational text should appear on only one side of the sign. The materials should be selected to be compatible with the expected lifespan of the exhibit.

3-7.4 Specialty Informational Signs.

Specialty informational signs may be used to provide supplemental information regarding a building or organization, such as hours of operation or similar public information. Message information may use vinyl cut out by computer and applied with pre-spacing tape, or digitally output graphics on glass or on removable sign message panels, as required.

3-7.5 Construction Project Identification Signs.

Construction project identification signs must be utilized as temporary signs that provide information regarding construction projects with performance periods of 120 days or more. See UFGS 01 58 00 for details regarding all construction project identification signs.

CHAPTER 4 INTERIOR SIGN STANDARDS

4-1 INTERIOR SIGN DESIGN REQUIREMENTS.

This UFC is intended to provide requirements for the design of all interior signs. Design details for interior signs will vary due to many factors, such as existing installation standards, installation-specific colors, interior or architectural design details, and manufacturer-specific fabrication techniques. Interior signs must complement interior architecture and color schemes. Each interior sign system must be flexible enough to adapt to frequent personnel changes and office relocations. Coordinate room numbers and sign message text with the project team during the design phases through the completion of the project to ensure changes during the project development are addressed by the sign program.

Provide directional signs to guide visitors through a building from the entrance point to the correct floor, the correct area of a floor, the correct office, and (if appropriate) the correct desk. All interior signs must follow the requirements in this UFC for system organization, sign types, and sizes. Variations in types of hardware, materials, and colors are permitted. Design interior signs for minimum maintenance and maximum durability.

The general requirements for interior sign fabrication details include high-quality materials, workmanship, and fabrication techniques. Flexibility is included in the standard design direction provided in this UFC to allow for minor fabrication and material differences. Include extra “attic stock” or surplus signs when specifying a large project for future use and changing needs. Provide additional blank paper stock as appropriate for the size of the project for future use by the installation to print additional or replacement inserts, as required.

4-1.1 Interior Sign Types.

Interior sign types are standardized by function. Each sign type addresses specific requirements for wayfinding, codes, life safety, or other facilities management purposes. The seven main sign type categories include the following:

- Room, space, and workstation identification
- Life safety
- Interior directional
- Building directories
- Interior mandatory and prohibitory
- Interior informational and motivational
- Unit identification and morale

4-1.2 Interior Signage Objectives.

The primary objectives of interior signage programs include the following:

- Identify rooms and areas in conformance to ABAAS requirements.
- Address life safety code requirements.
- Develop a room numbering system for new facilities.
- Establish appropriate terminology for Services, departments, entrances, units, and other information required for each building. Avoid use of terminology that is likely to change (e.g., department codes).
- Provide effective directional information that guides visitors to their destinations and reduces the need for staff to help visitors.
- Establish and document new sign standards to be implemented in each facility.

4-1.3 Materials and Colors.

The fabrication methods used for interior signs may vary depending upon the manufacturer selected and existing sign systems at each installation. Interior signs should use primarily neutral colors and materials that blend with the interior finishes. Exact colors, materials, and finishes must be determined on a project-by-project basis. All interior signage colors must comply with the color contrast requirements of message content and sign backgrounds as specified in the ABAAS.

Where possible, maintain consistency with existing sign systems. Minor deviations from these general specifications are permitted where needed to align with installation-specific standards and pre-existing sign programs. Example layouts have been provided for general guidance but layout specifications will vary according to the unique message content requirements of each sign. Unacceptable fabrication techniques for interior signs include surface-applied vinyl letters or graphics that can be rubbed off or damaged and exposed paper inserts with no protective covering such as non-glare glass, clear acrylic, or other clear plastic-type product. Exterior-grade signs with durable plastic or other insert materials should be located in open areas (such as hangars or workshops), and interior grade signs should be located inside buildings, where required (e.g., offices, labs, and corridors).

4-1.4 Room Numbering.

Room numbering strategies are critical to wayfinding and facilities management. A master plan strategy of room numbering and workstation identification is required to ensure the numbers used on the architectural and interior plans will align with the wayfinding and signage objectives. This coordination will allow information in the architectural model to be extracted directly into the sign message schedule database that will be used to implement, maintain, and manage the sign program in the future.

4-1.5 Medical-Related Facilities.

The design guidance provided in this UFC is applicable for medical-related facilities as needed. Refer to UFGS 10 14 00.20 for additional information and guidance.

4-1.6 Owner Education and Maintenance Manuals.

The sign contractor must provide owner education services for any components that may require future actions by the installation. This often includes templates for replacing sign message inserts developed in specific software specified in the contract documents that will allow the facility to produce their own in-house message inserts. Maintenance or owner's manuals are required for any complex or electronic signs.

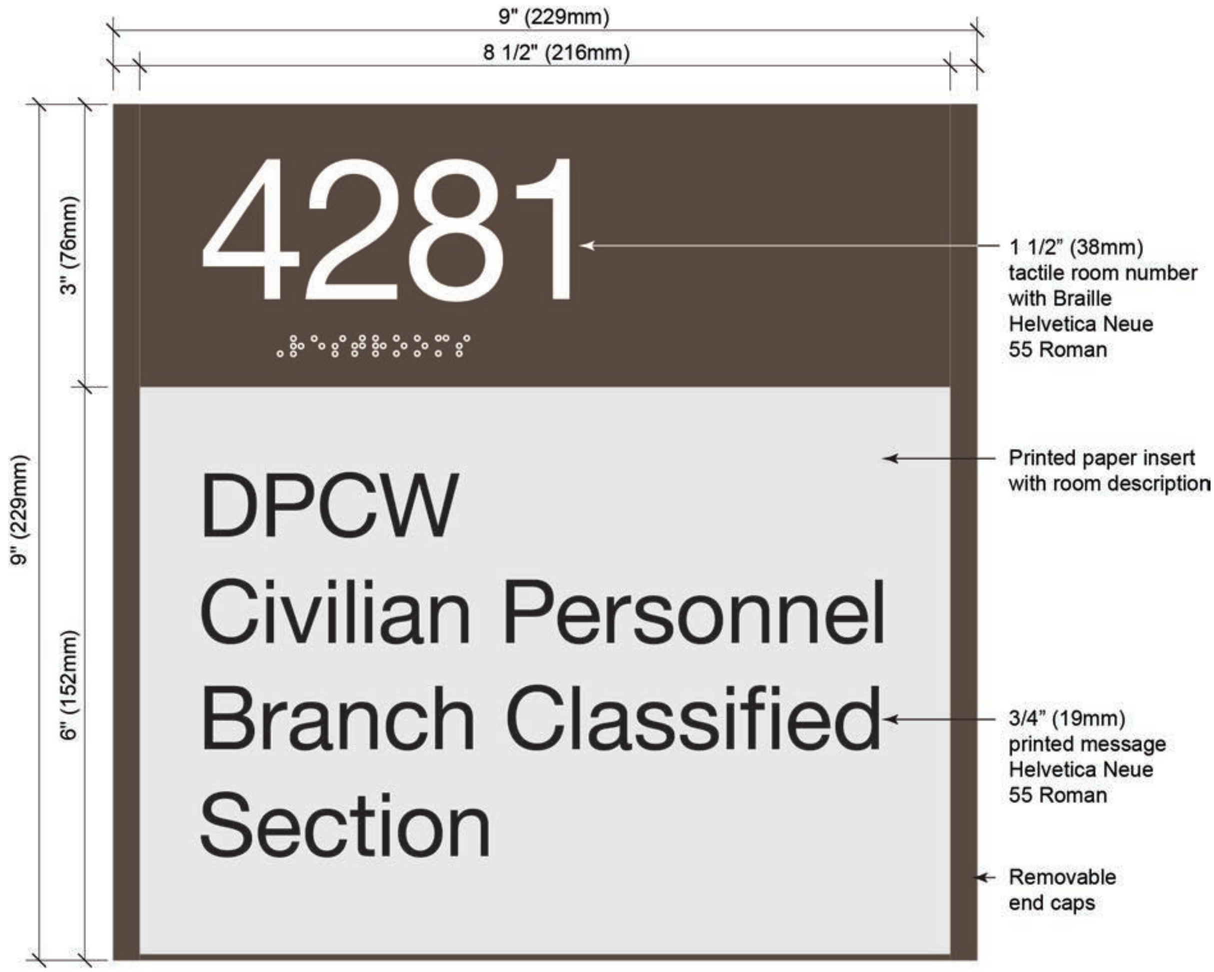
4-2 ROOM, SPACE, AND WORKSTATION IDENTIFICATION SIGNS.

Room identification signs must be included for most facility types. Provide room identification signs as required by ABAAS and other applicable code requirements. Include workstation identification and other signs needed for the core functionality of the building.

4-2.1 Room Identification Signs.

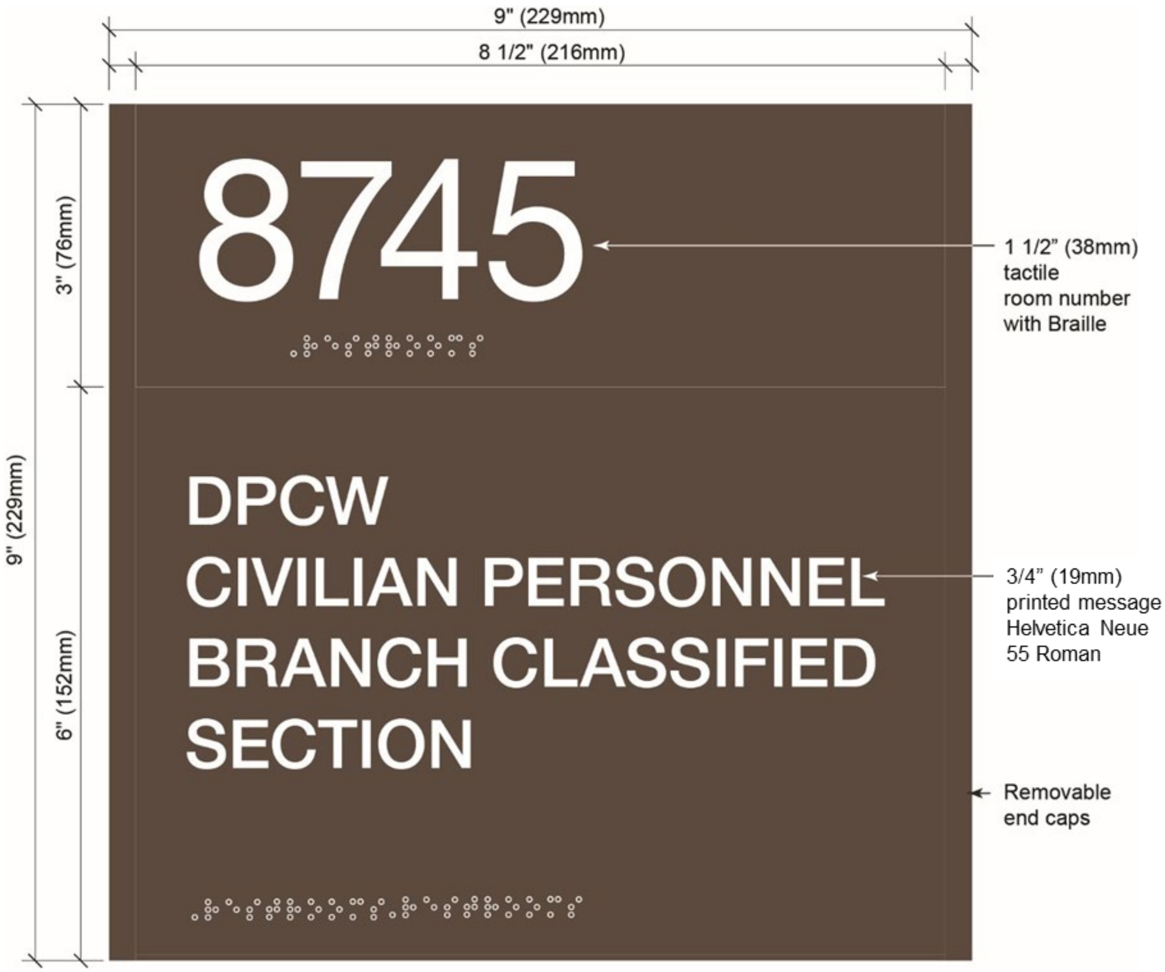
Provide room identification signs for all rooms that have an entrance door and for some entrances to spaces without a door. ABAAS requires that all permanent rooms be identified with signs that use tactile characters raised 0.03125 inch (0.8 mm) from the surface and Grade 2 Braille. Since the architectural room number is the most permanent component of the room description, it is most effective to use it as the tactile character and Braille portion of the sign. The room description, unless it is a permanent space such as a mechanical room, may be provided by a printed paper insert behind clear acrylic that can be easily and inexpensively replaced as the room function and/or occupants change (see Figures 4-1 and 4-2).

\2\ Figure 4-1 Room Identification Signs. /2/



Room Identification Sign with Paper Insert

\3\ Figure 4-2 Permanent Room Identification Signs. /3/

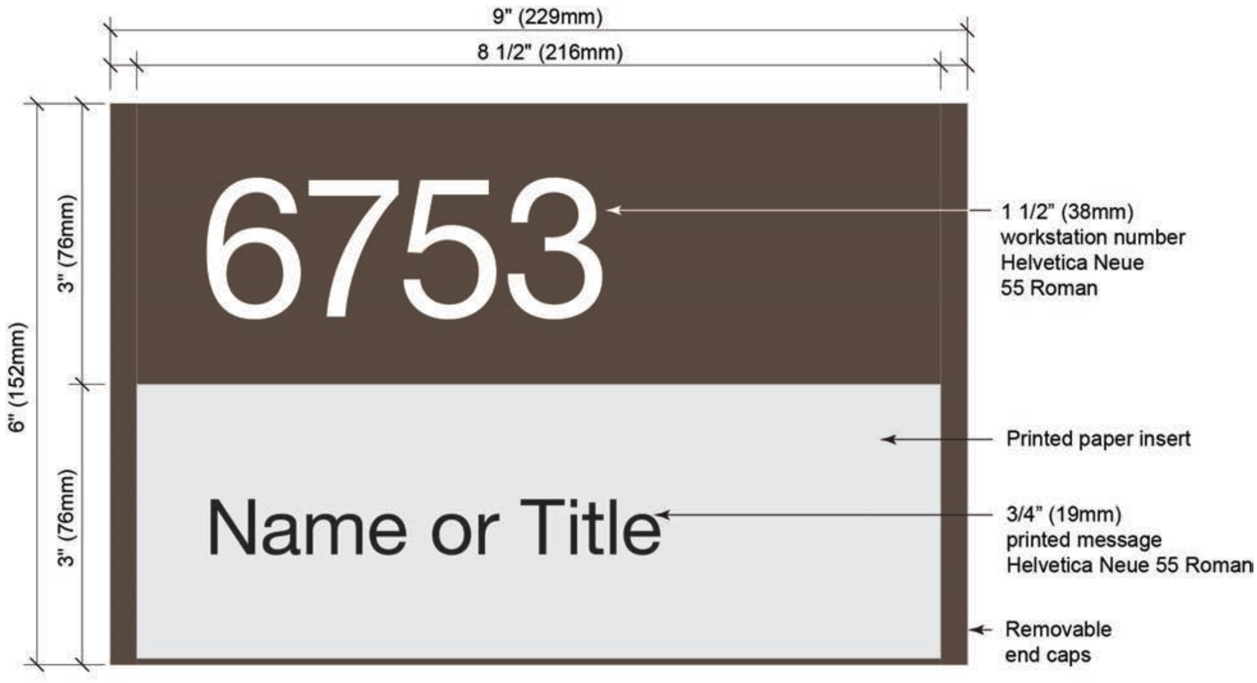


Permanent Room Identification Sign

4-2.2 Workstation Identification Signs.

Most office environments on military installations use workstations or cubical workspaces that are not considered permanent because they can be easily reconfigured (see Figure 4-3). Signs used to identify these spaces are not required to use tactile and Braille information; however, the space or identification number is still a very important component of these signs for wayfinding and facilities management. These numbers impact a wide variety of building systems, such as data connections, and should be clearly identified to assist facility management. Workstation signs are also used for occupant identification. Provide occupant message inserts that can be printed on paper or cardstock and easily replaced behind clear acrylic or plastic.

\1\ Figure 4-3 Workstation Identification Signs. /1/



Typical Workstation Sign with Number

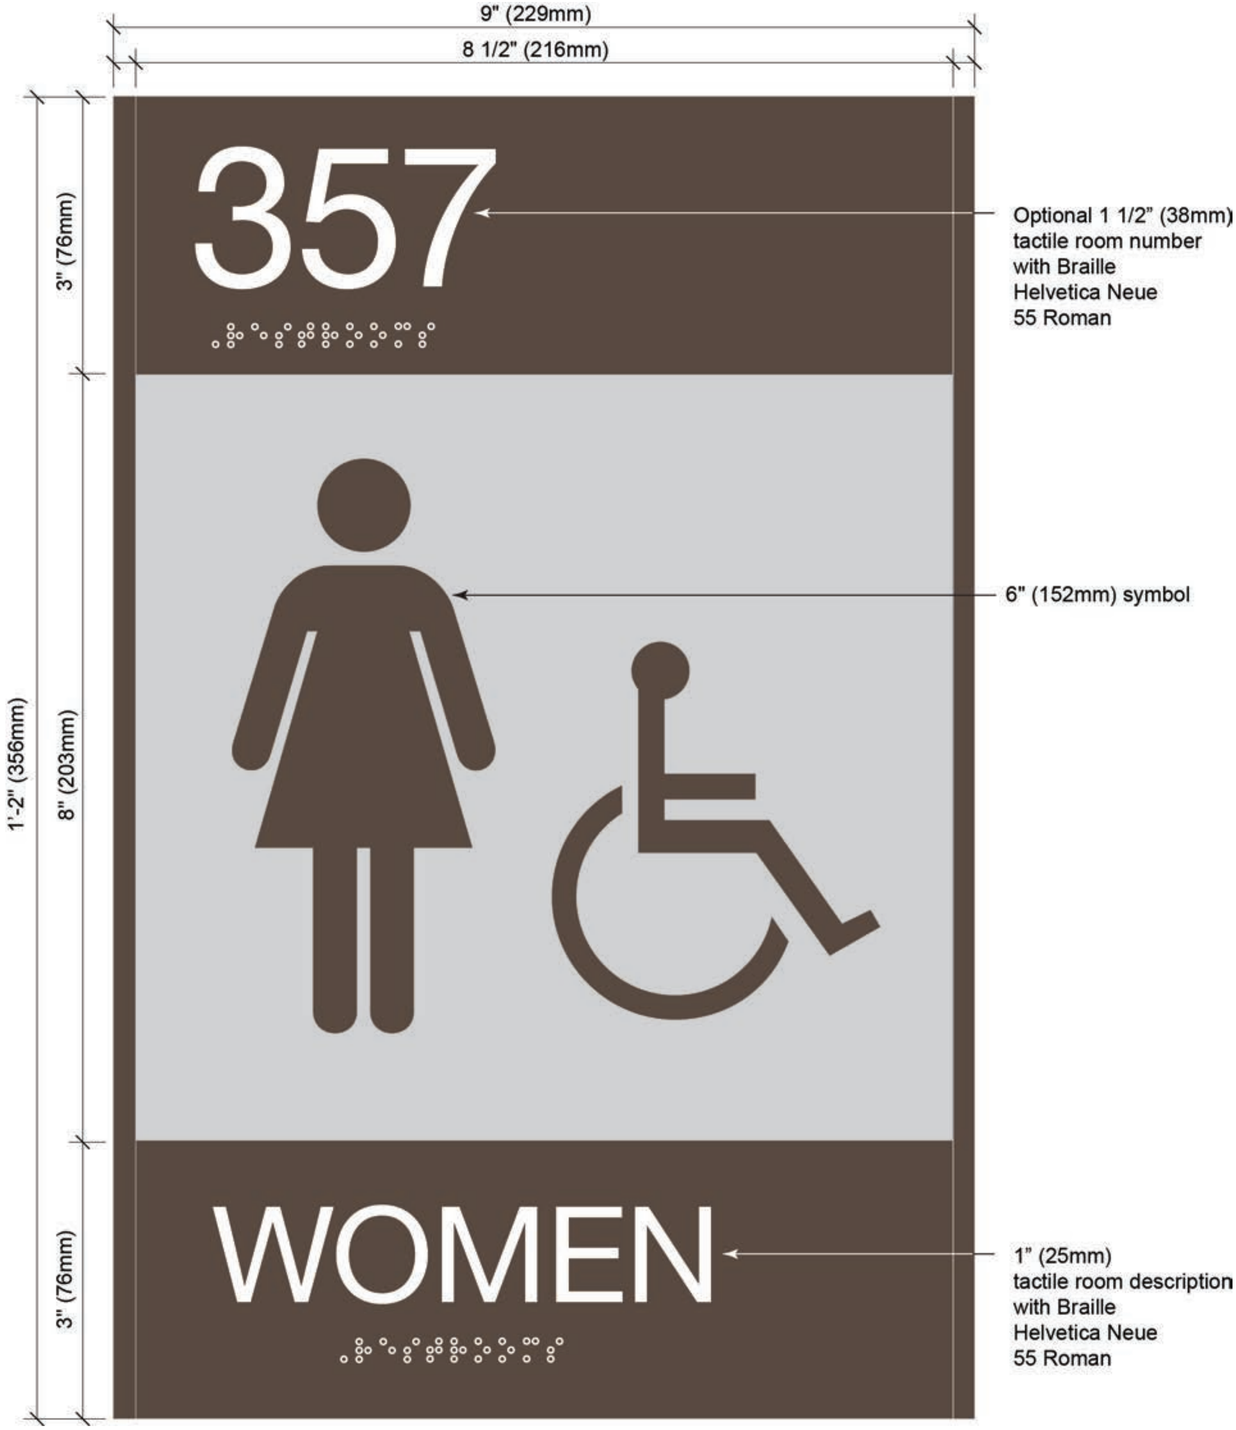
4-2.2.1 Workstation Sign Installation.

Workstation occupant identification signs should be mounted with over-the-panel hangers, mounting brackets, hook and loop (Velcro), or other similar methods, depending on the workstation furniture selected by the owner (see Figure 4-3). Mount signs on glass panels using double-faced foam tape and vinyl.

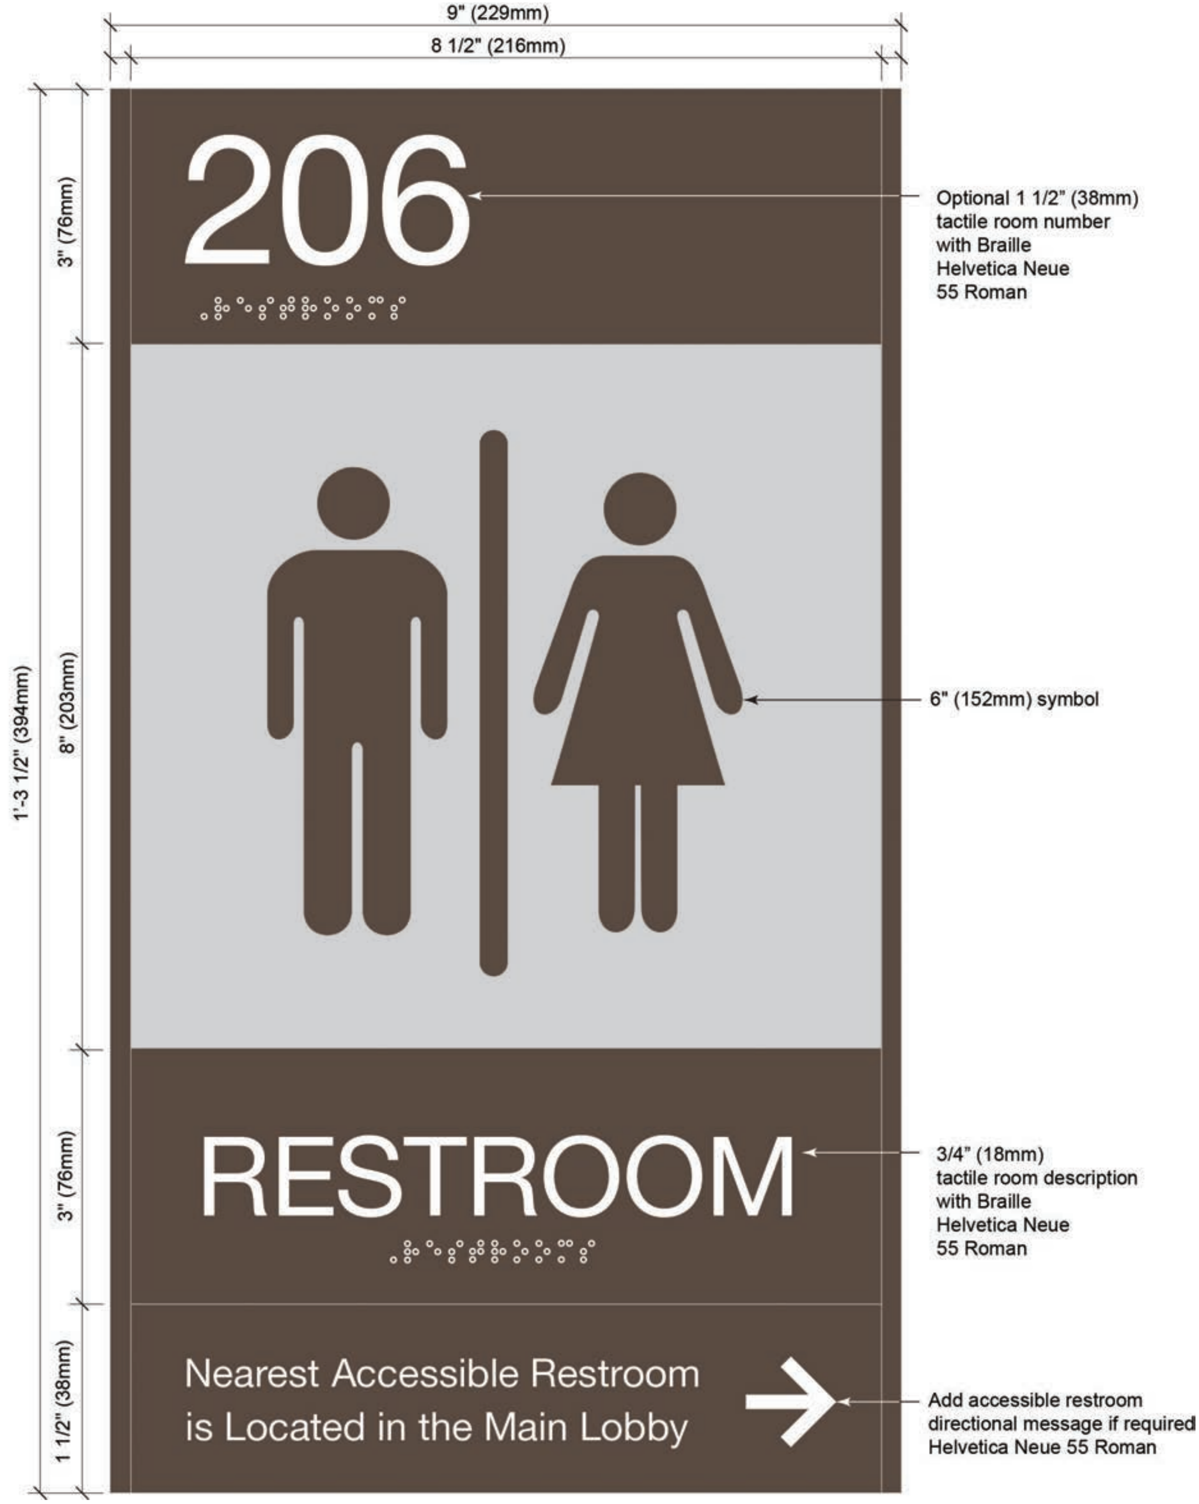
4-2.3 Restroom Identification Signs.

Refer to all current ABAAS requirements regarding restroom sign identification, use of pictograms, symbols of accessibility, finish, and contrast. See Figures 4-4 and 4-5.

\1\ Figure 4-4 Accessible Restroom Identification Signs. /1/



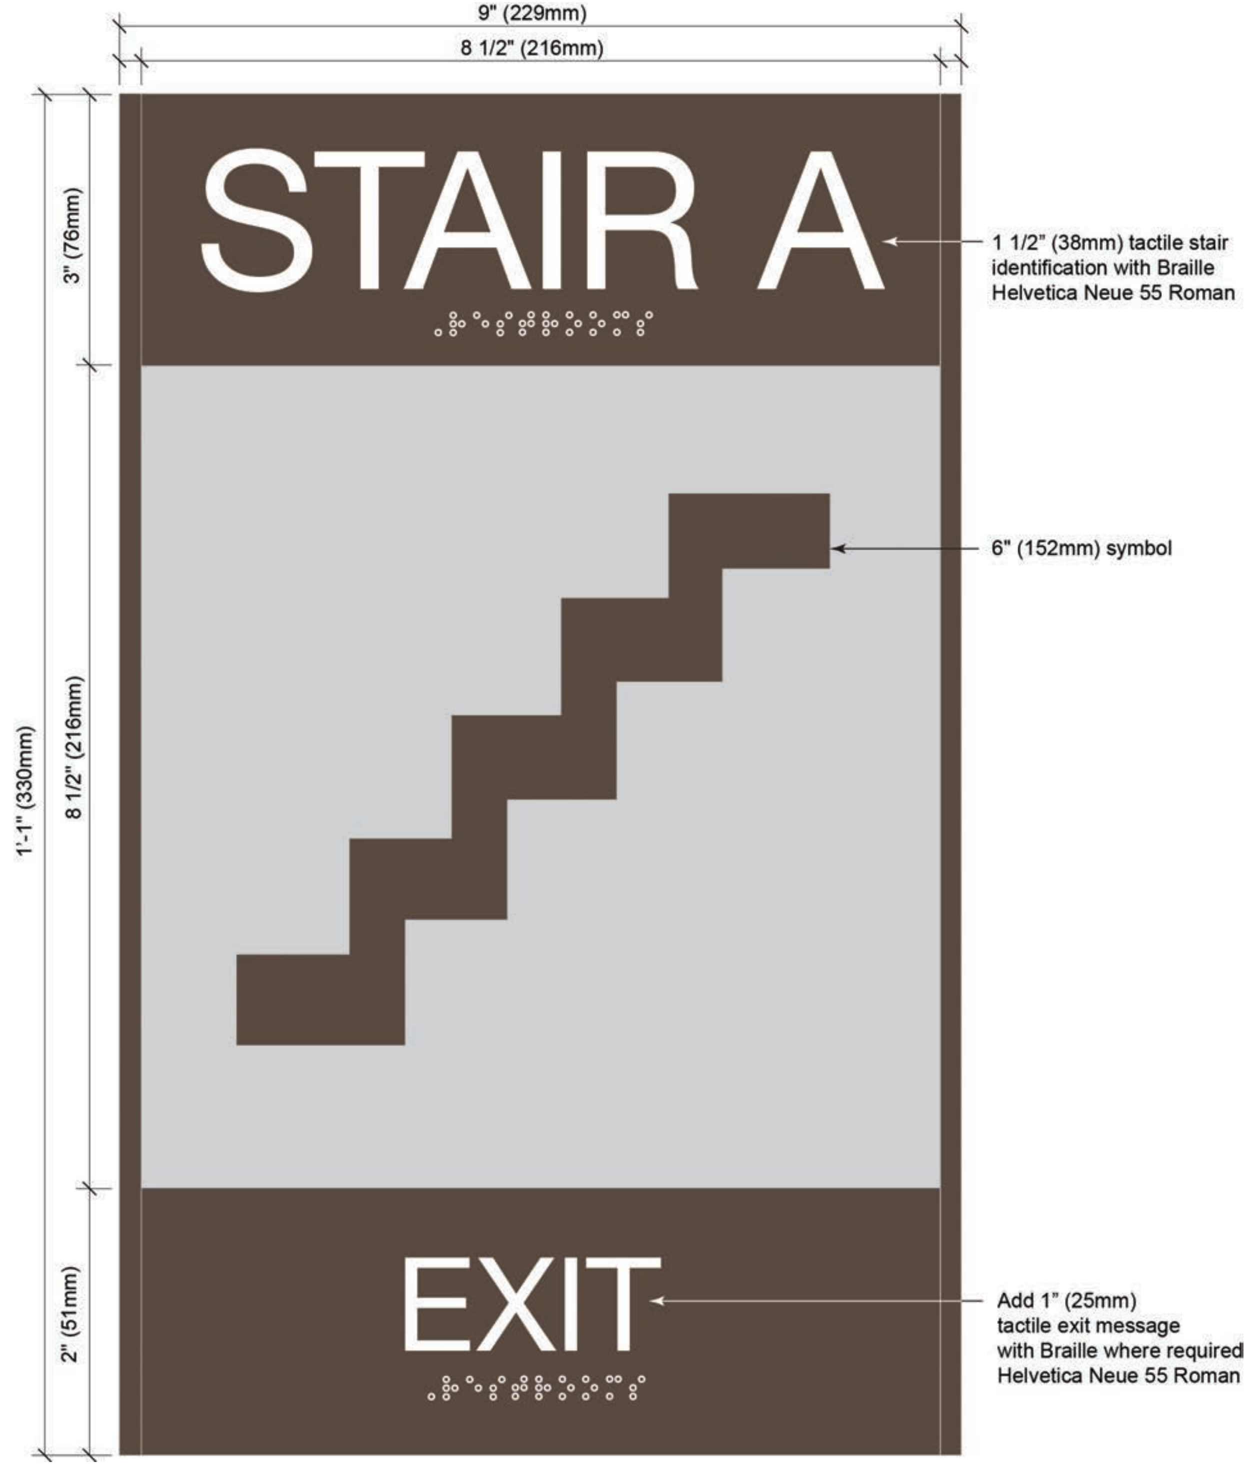
\1\ Figure 4-5 Non-Accessible Restroom Identification Signs. /1/



4-2.4 Stair Identification Signs.

Stair identification signs on the occupancy side of the entrance door are required on the wall next to the strike side of the door. Use tactile characters and Grade 2 Braille to identify each stairway entrance; also consider the need for including the architectural room number if this is beneficial for facilities management. Refer to current ABAAS requirements regarding stair sign identification, use of pictograms, symbols of accessibility, finish, and contrast. Pictograms are not required but may be used if desired for consistency with the overall sign program. The IBC requires that egress stairways be identified with a tactile sign stating “EXIT” in compliance with ICC/ANSI A117.1. Include exit information on stair identification signs to reduce visual clutter. Refer to Figure 4-6.

\1\ Figure 4-6 Stair Identification Signs. /1/



4-2.5 Typical Room and Space Identification Sign Installations.

Most room identification signs required by ABAAS must be installed adjacent to the strike side of the door. This requirement should be coordinated with the architectural and interior design team during the design development of the project. Mounting options will vary with each sign system. Refer to current ABAAS requirements regarding sign mounting height, use of pictograms, finish, and contrast. Since the signage system detailed in this UFC has built-in flexibility for modifying message inserts, most interior signs can be easily installed using a combination of clear silicone adhesive and double-sided foam tape. Another acceptable mounting method is concealed mechanical fasteners. Provide white vinyl backing of the same shape as the sign on the glass to conceal mounting tape whenever signs are installed on glass. Refer to Figures 4-7 and 4-8.

Figure 4-7 Typical Interior Sign Installations.

Typical Wall Sign Installation

Typical Door Mounted Installation

Figure 4-8 Typical Sign Installations on Glass.

Typical Glass Sign Installation

Typical Glass Installation Detail

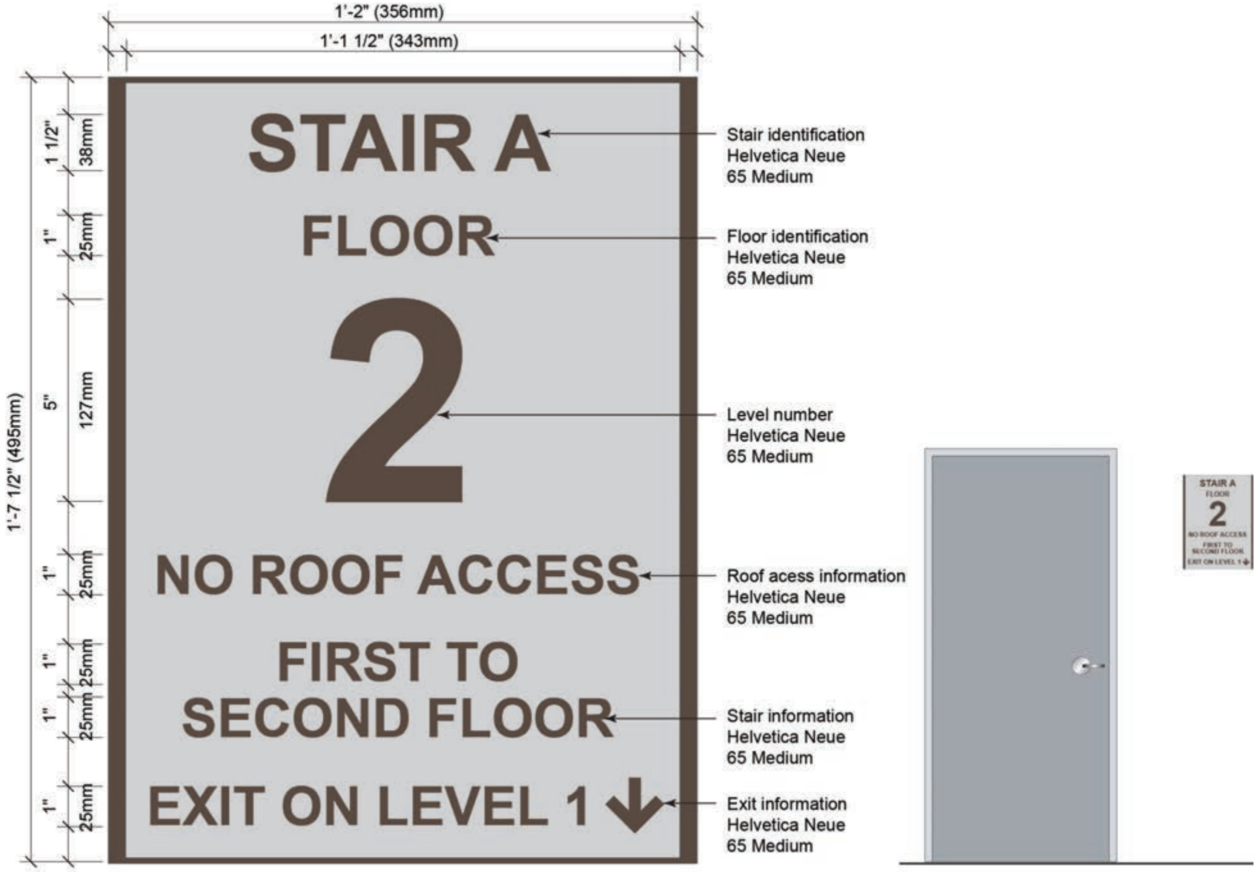
4-3 LIFE SAFETY SIGNS.

Life safety signs are required for building occupancy for every facility type. Provide life safety signs required by NFPA 101, such as exit identification, egress information, elevator information, fire extinguisher identification, and types of signs as required by the applicable life safety code requirements for each project.

4-3.1 Stairway Life Safety Signs.

Stairway life safety signs are required at each stairway landing for new enclosed stairs serving three or more stories and existing enclosed stairs serving five or more stories. Provide the required stairway identification and information at each stairway landing as required by NFPA 101. These sign messages require detailed information about building egress and also provide vital information for the fire department and other first responders. Ensure that these sign messages accurately reflect the current building conditions, such as level information, re-entry restrictions, roof access, and exiting information. Refer to Figure 4-9.

Figure 4-9 Stairway Life Safety Information.



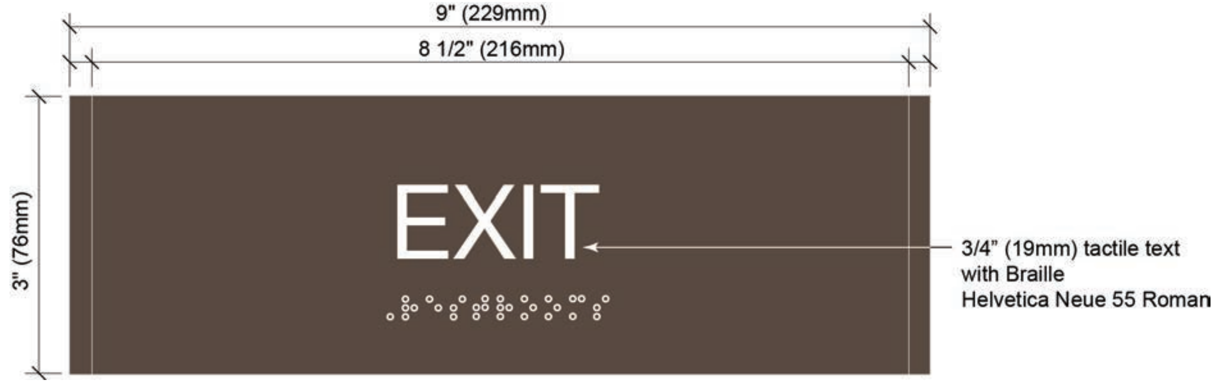
NFPA 101 Sign Message Example

NFPA 101 Sign Placement Example

4-3.2 Tactile Exit Signs.

Tactile exit signs must comply with ICC/ANSI A117.1 according to the current edition of the IBC. Provide signs at each exit door requiring an exit sign, including doors to areas of refuge. Consider including this required exit information on all stair identification signs that are egress stairways to minimize the number of signs required and also include other small exit signs where required. Refer to Figure 4-10.

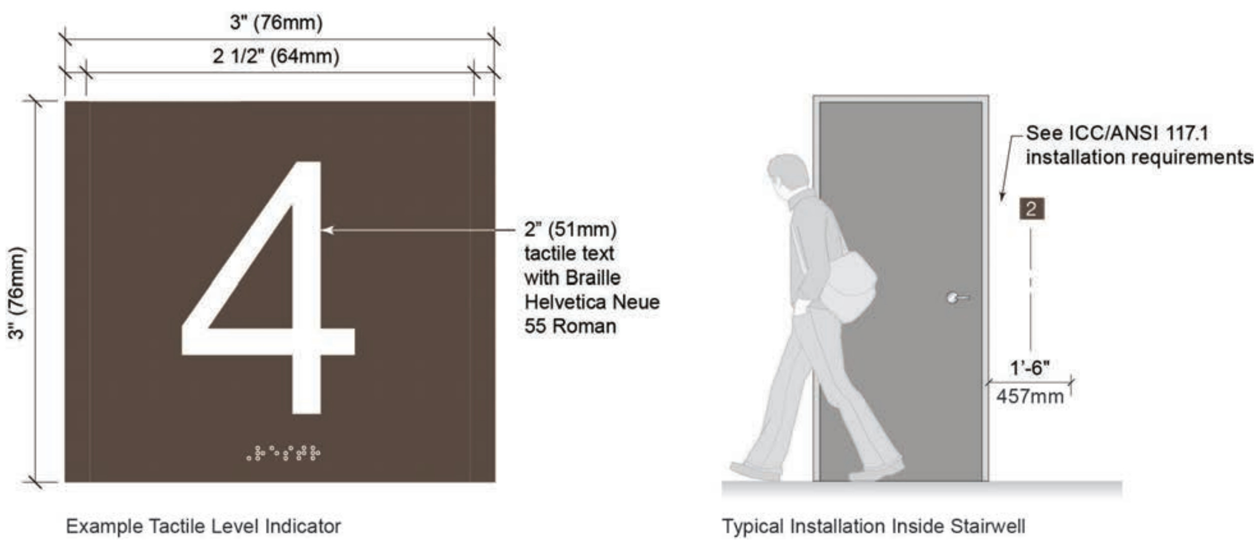
\1\ Figure 4-10 Tactile Exit Signs. /1/



4-3.3 Tactile Stairway Level Indicator Signs.

Provide small tactile level indicator signs adjacent to the door inside each stairway landing on the strike side as required by NFPA 101 (see Figure 4-11). Provide these signs at all stairway landings that do not require tactile exit signs.

\1\ Figure 4-11 Tactile Stairway Level Indicators. /1/



4-3.4 Life Safety Door-Mounted Signs.

The current edition of NFPA 101 requires a variety of door-mounted informational signs, depending upon the egress plans for each building and the door hardware. Provide signs as required to reflect information, such as key-operated locks, delayed-egress locking systems, access-controlled egress door assemblies, powered door leaf operation, and other NFPA and IBC sign requirements. Refer to Figure 4-12.

Figure 4-12 Life Safety Door Signs.

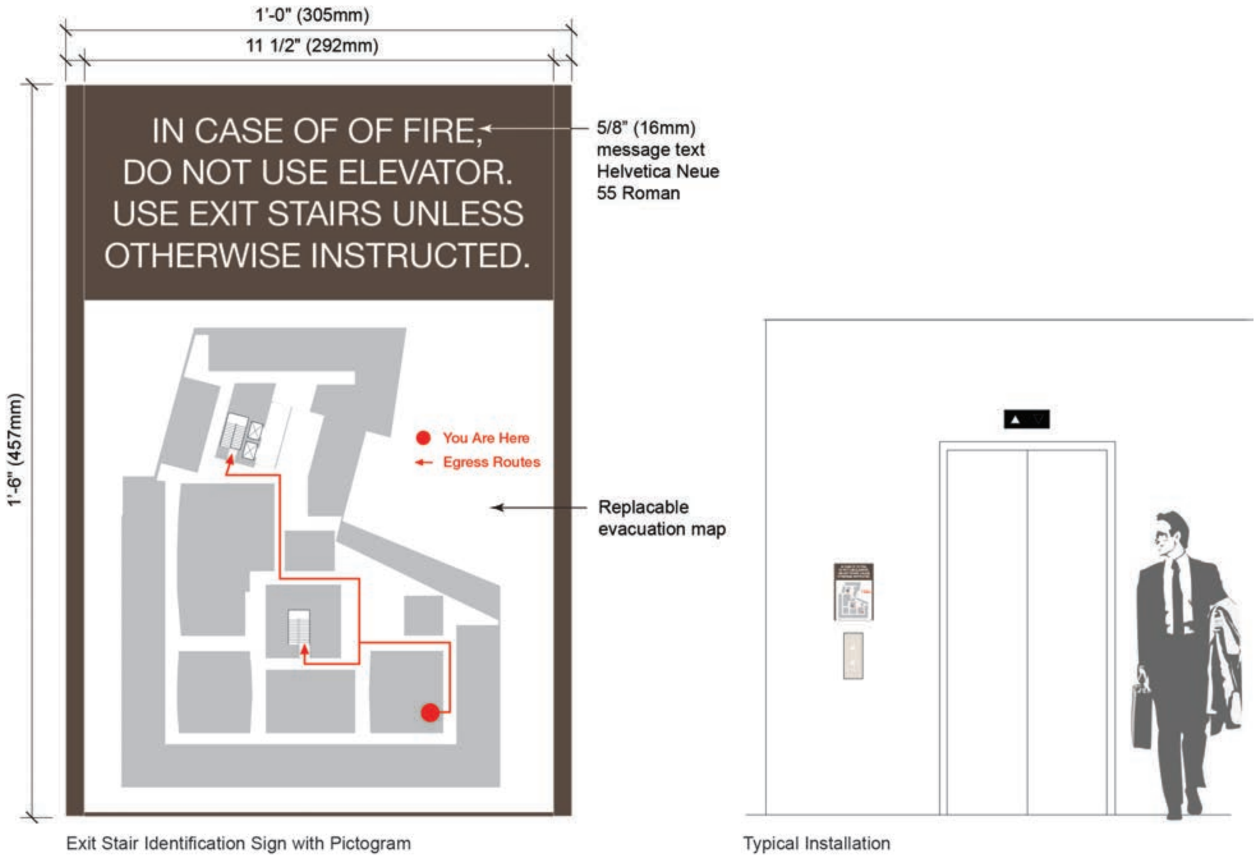
Example NFPA Life Safety Door Informational Signs

Typical Door Mounted Installation

4-3.5 Elevator Egress Signs.

Both NFPA 101 and the IBC have specific signage requirements for elevators. Elevator egress maps and artwork must be provided as part of the overall signage package. Consider the need for using replaceable map artwork that can be modified if there are future changes in the floor plan layout that may impact the provided egress information. Refer to Figure 4-13.

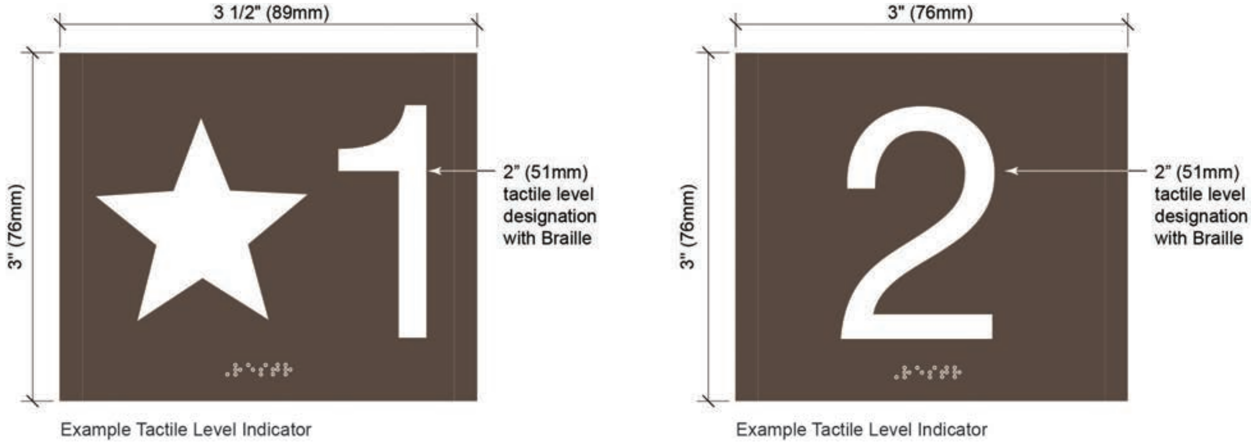
\1\ Figure 4-13 Elevator Egress Signs. /1/



4-3.6 Tactile Elevator Hoist Way Level Indicator Signs.

Tactile elevator hoist way level indicator signs are required on both elevator door jambs in compliance with the IBC (see Figure 4-14). Most tactile and Braille level indicator requirements are typically provided by the elevator contractor. Ensure that these requirements have been addressed or have them included in any new construction signage package.

\1\ Figure 4-14 Elevator Hoist Way Level Indicators. /1/



4-3.7 Additional Life Safety Signs.

There are a variety of other life safety signage requirements regarding NFPA 101 and the IBC that may also be required, such as maximum occupancy signs, two-way communication signs, area of refuge identification, and fire extinguisher identification. Some of the signs, such as fire extinguisher identification signs, are typically provided by the manufacturer of the equipment. Ensure the sign layouts, fonts, colors, and materials are consistent with the rest of the interior signage program.

4-4 INTERIOR DIRECTIONAL SIGNS.

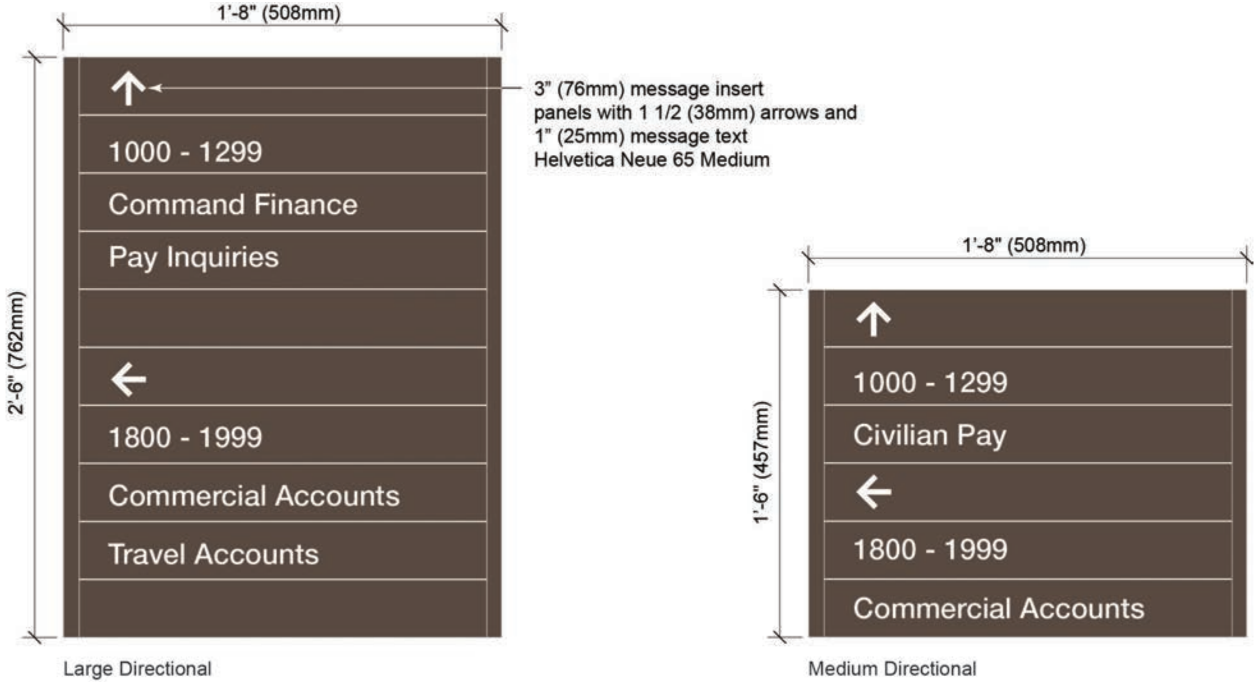
Provide directional signage that contains wayfinding information, identifies rooms or other destinations, and meets additional needs like code requirements. Coordinate the signage package with the architectural design to direct people to their destination and support facilities management activities. Implement signage standards that are designed as part of a wayfinding system integrated with other building systems and the overall project design.

Room or area identification, terminology guidelines, and room numbering strategies are also critical to the effective implementation of a signage program that facilitates wayfinding. This UFC provides guidelines for interior signs that address code requirements, size, appearance, messages, and graphic layouts. Provide strategic implementation of wayfinding signs that are integrated into the interior architecture. Implement an overall wayfinding philosophy that minimizes sign clutter by utilizing concise messages where they are needed most. Use signs of minimal size to communicate the required messages. Overloading the environment with excessive signage reduces their effectiveness. Directional signs should be located at each decision point in the path of travel, e.g., opposite elevators or stairwells.

4-4.1 Wall-Mounted Directional Signs.

Provide wall-mounted, eye-level directional signs at decision-making intersections or as required (see Figure 4-15). Wall-mounted signs are the most effective way to communicate multiple messages. Implement wall-mounted directional signs in a consistent and orderly manner to establish areas where people can look for information.

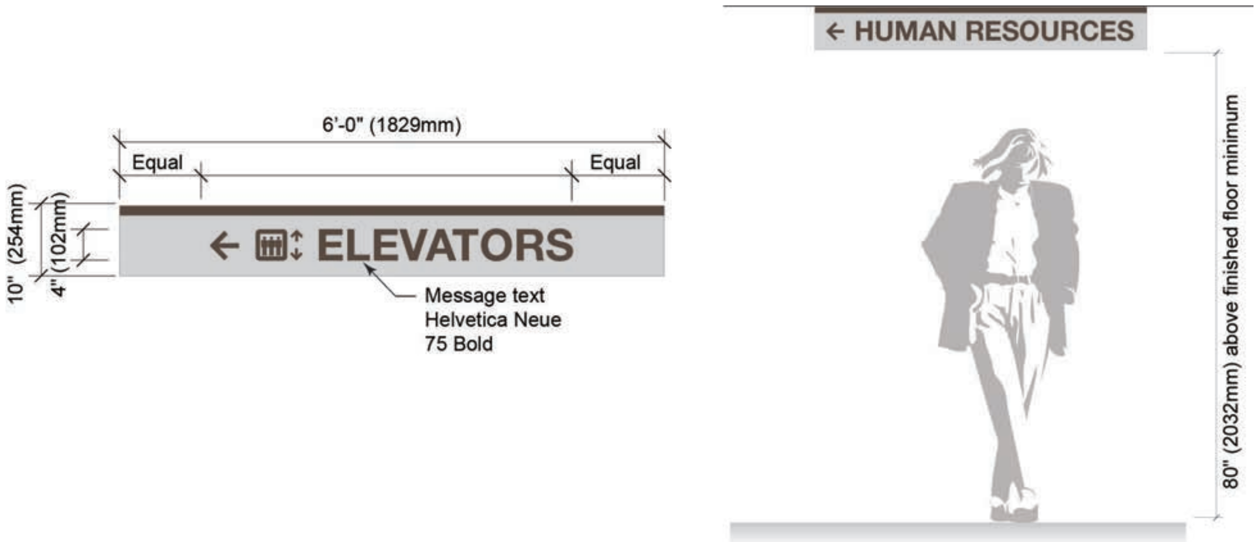
\1\ Figure 4-15 Interior Wall-Mounted Directional Signs. /1/



4-4.2 Ceiling-Mounted Directional Signs.

Ceiling-mounted directional signs may also be used where appropriate, but their use should be selective due to limitations on the quantity of sign messages and potential conflicts with the building infrastructure, e.g., lights, sprinklers, and video cameras. Refer to Figure 4-16. Ceiling-mounted directional signs may also be useful to designate the entrances to major departments or areas. These overhead signs also serve as good wayfinding aids by providing visual cues that visitors can see as they travel down long corridors.

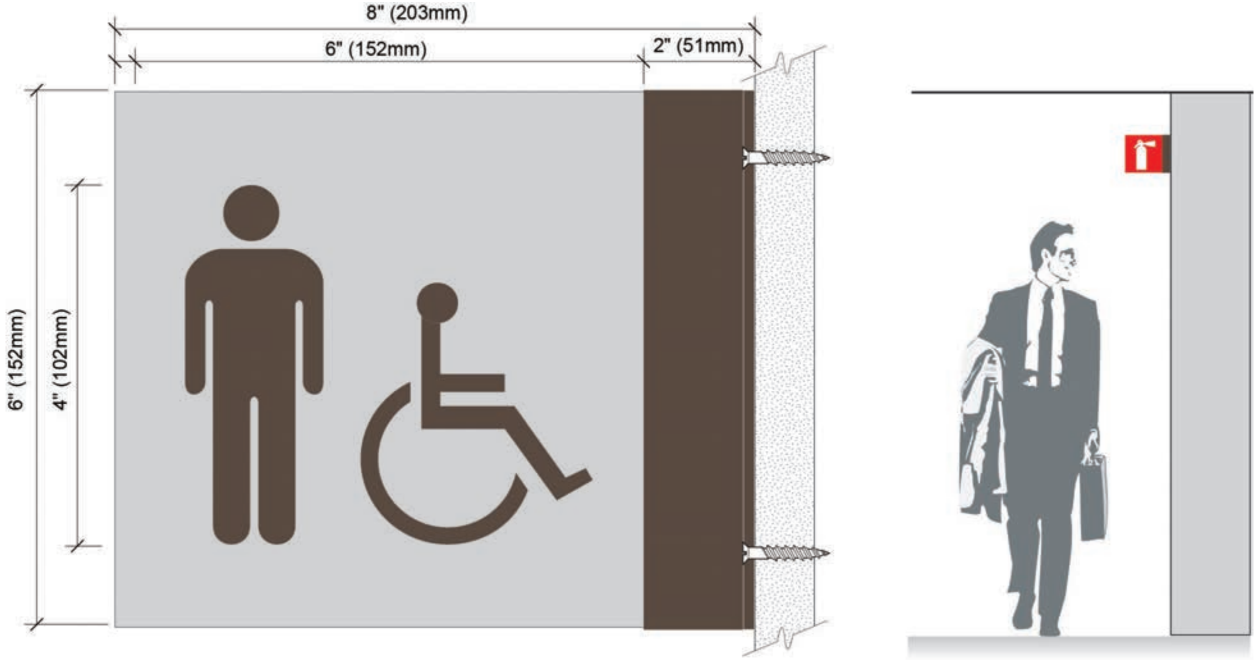
Figure 4-16 Ceiling-Mounted Directional Signs.



4-4.3 Flag-Mounted Signs.

The utilization of flag-mounted identification signs can help facilitate wayfinding by providing additional visual cues for users, especially down long corridors. These signs can help identify high-traffic rooms or amenities like conference rooms, restrooms, coffee/break rooms, and copy or print rooms. These signs are also useful to identify critical life safety items like fire extinguishers and automated external defibrillators. See Figure 4-17.

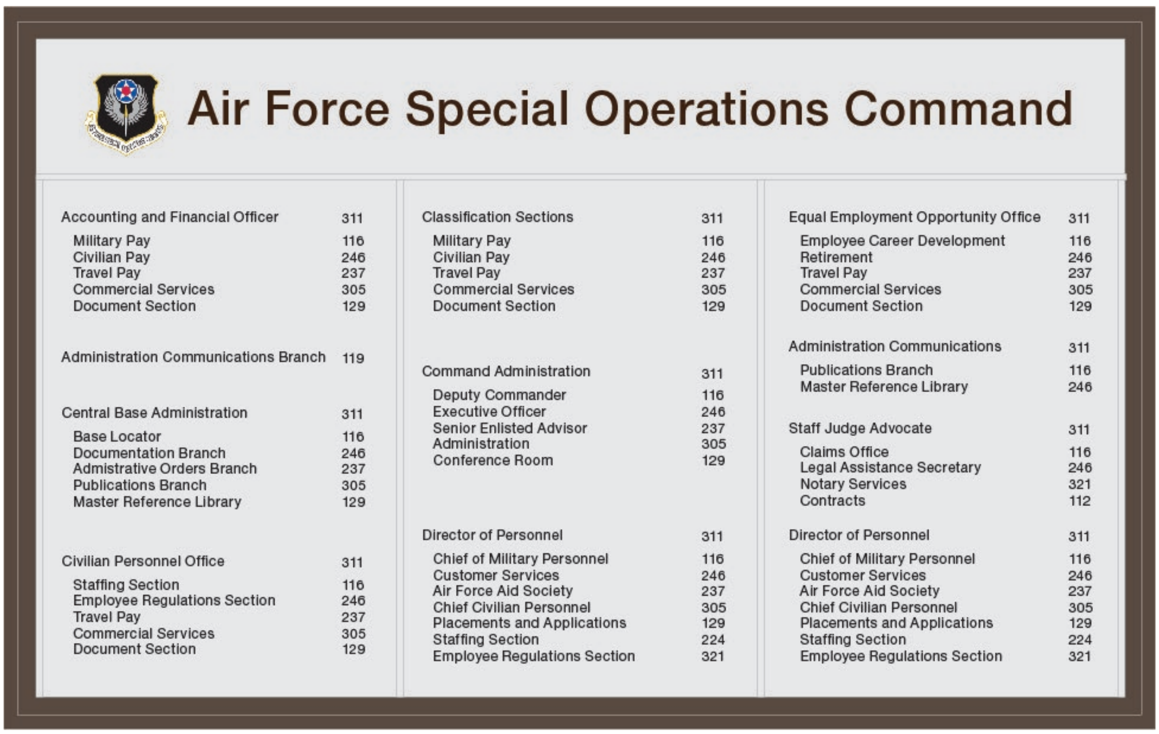
Figure 4-17 Flag-Mounted Signs.



4-5 BUILDING DIRECTORIES.

Provide building directories in major buildings to identify departments, offices, or other required information. Locate directories in the main entrance lobby where they are clearly visible to visitors as they enter the building. Most building directories have two components. The permanent header panel provides the name of the building or the major tenant organization name and/or emblem. The directory message content provides detailed information about destinations located in the building, such as the name of each tenant in the building, room numbers, and department names. Standard commercially available directories may be obtained from a wide variety of sign manufacturers. Coordinate the frame material with the architectural finishes. See Figure 4-18.

Figure 4-18 Building Directory.



4-5.1 Electronic Directories and Wayfinding Systems.

Use electronic or touch screen directories with orientation maps at strategic locations for large, high-profile facilities.

4-6 INTERIOR MANDATORY AND PROHIBITORY SIGNS.

There are many mandatory and prohibitory signs required inside military buildings. These signs may communicate messages that restrict, warn, and advise visitors and military personnel in matters of security and safety (see Figure 4-19). These signs should be designed to be flexible by using printed inserts that can be easily and inexpensively replaced as the room function or occupants change. Where needed, reinforce the meaning of the symbol with a word message for clarity. Sign messages and colors may vary but sign sizes should be consistent within a building.

Figure 4-19 Mandatory and Prohibitory Signs.

4-7 INTERIOR INFORMATIONAL AND MOTIVATIONAL SIGNS.

There may be a need to display informational and motivational signs on military facilities. Provide graphic information that educates visitors about the facility and the various services provided, where required. This may include orientation maps and directories. See Figure 4-20. These signs should be designed to be flexible by using printed inserts that can be easily and inexpensively replaced as the room function or occupants change. Using signs that accept standard paper sizes is most cost effective and efficient. Consider the need for both portrait and landscape versions of these signs. Provide required exterior- and interior-grade signs, depending upon the conditions where each sign will be installed.

Figure 4-20 Informational and Motivational Signs.

4-8 UNIT IDENTIFICATION AND MORALE SIGNS.

Unit identification and morale signs display organization emblems, mottoes, and awards. Refer to Figure 4-21. These signs should be placed at the principal arrival point for visitors and should be designed to easily accommodate changes in the message content as different units are deployed at each installation. If an organizational emblem is used on a unit identification sign or a building entry sign, it should not be repeated on a morale sign placed in the same area.

Figure 4-21 Unit Identification and Morale Sign.

Record of Changes (changes are indicated by **1**\\ ... /**1**/)

Change No.	Date	Location
1	20 Apr 2021	1. Updated CAD standard information in paragraph 4-4. 2. Added reference to USACE Nomenclature document in paragraph 4-4.6. 3. Added bulleted item c, link to USACE Nomenclature document, to paragraph 5-3.1.2. 4. Added reference/link to USACE Nomenclature document in Appendix A.
2	15 Jun 2021	1. Added paragraph prohibiting the use of brand names and proprietary information; added bulleted item c; and deleted last subparagraph in paragraph 4-5.1. 2. Added reference to Pantone Color System in paragraph 4-5.1.1. 3. Deleted paragraph 4-5.1.2. 4. Deleted bulleted items d and p, requirements for manufacturer's contact information and dealer/vendor quotes in paragraph 5-4.7. 5. Deleted paragraph 5-4.9 Manufacturers Source List.
3	22 May 2025	1. Updated the language in the paragraph 1-2 to be in accordance with UFC 1-200-01. 2. Added cordless shades reference to paragraph 1-5.1. 3. Revised paragraph 3-4.1. 4. Added Paragraph 3-5 and Table 3-1 Design Stage Equivalency and removed percentages within the Design Stage paragraphs.

		5. Added references to UFC 3-520-01 and UFC 3-580-01 to paragraph 3-5.3. 6. Added cordless shades reference to paragraph 4-2.5. 7. Added reference to other Defense Agencies to section 5-1. 8. Added paragraph 5-2.3. 9. Updated Army Project references in paragraph 5-3.1.2. 10. Added paragraph 5-3.1.4. 11. Revised paragraph 5-4.6. 12. Removed first sentence of paragraph 5-4.9.1. 13. Updated Department of the Army and WBDG references in Appendix A.

This UFC is a revision to UFC 3-120-10 dated 15 June 2006 including Change 1, July 2007.

FOREWORD

The Unified Facilities Criteria (UFC) system is prescribed by MIL-STD 3007 and provides planning, design, construction, sustainment, restoration, and modernization criteria, and applies to the Military Departments, the Defense Agencies, and the DoD Field Activities in accordance with USD (AT&L) Memorandum dated 29 May 2002. UFC will be used for all DoD projects and work for other customers where appropriate. All construction outside of the United States is also governed by Status of Forces Agreements (SOFA), Host Nation Funded Construction Agreements (HNFA), and in some instances, Bilateral Infrastructure Agreements (BIA). Therefore, the acquisition team must ensure compliance with the most stringent of the UFC, the SOFA, the HNFA, and the BIA, as applicable.

UFC are living documents and will be periodically reviewed, updated, and made available to users as part of the Services' responsibility for providing technical criteria for military construction. Headquarters, U.S. Army Corps of Engineers (HQUSACE), Naval Facilities Engineering Command (NAVFAC), and Air Force Civil Engineer Center (AFCEC) are responsible for administration of the UFC system. Defense agencies should contact the preparing service for document interpretation and improvements. Technical content of UFC is the responsibility of the cognizant DoD working group. Recommended changes with supporting rationale should be sent to the respective service proponent office by the following electronic form: Criteria Change Request (CCR). The form is also accessible from the Internet sites listed below.

UFC are effective upon issuance and are distributed only in electronic media from the following source:

- Whole Building Design Guide web site https://wbdg.org/dod.

Hard copies of UFC printed from electronic media should be checked against the current electronic version prior to use to ensure that they are current.

UNIFIED FACILITIES CRITERIA (UFC)
REVISION SUMMARY SHEET

Document: UFC 3-120-10, *Interior Design*

Superseding:

- UFC 3-120-10, *Interior Design,* dated 15 June 2006, including Change 1, July 2007

Description: This UFC is a coordinated compilation of interior design requirements, and references non-government standards to the greatest extent practicable. It provides a succinct reference for interior designers to ensure that all requirements are met.

Reasons for Document:

- Defines the requirements for interior design work on military construction and renovation projects.
- Relies on a list of industry and government standards, codes and references; and
- Provides DoD sources for standards and guidance not otherwise addressed.

Impact: Cost impacts are negligible; however, design delays should decrease as all requirements for all services are now in a single, consolidated document that has been coordinated with other elements of construction and renovation projects.

Unification Issues

- Each agency has its own procurement process for Furniture, Fixture & Equipment, as directed by the Departments of the Air Force, Army and Navy; refer to Part 5.
- Army and Navy have specific Data Sheet Templates that are required for FF&E procurement; refer to Appendix D.

TABLE OF CONTENTS

TABLES

This Page Intentionally Left Blank

CHAPTER 1 INTRODUCTION

1-1 PURPOSE AND SCOPE.

This UFC provides general guidance and outlines technical requirements that apply to both building-related and furniture-related interior design projects, new construction and renovation projects. The information provided in this UFC will be used by interior designers and architects that meet the interior designer qualifications and serves as the minimum interior design requirements. This UFC covers requirements for schematic design, design development and construction documents including drawings and specifications, procurement documentation and project presentations for Design-Bid-Build (DBB) and Design-Build (DB) projects.

Excellence in design is the primary goal for all projects. Reaching this goal requires a commitment by the Government and designers to a level of quality that includes the coordinated relationship of interior design with the building design, as well as the details of design that affect the users of the facilities. Quality interior design is value added to a project as it vitally improves facility operating efficiency, attractiveness, livability, functionality, life-cycle economics, and the productivity of the users. Project conditions may dictate the need for design that exceeds these minimum requirements.

1-2 APPLICABILITY.

\3 This UFC follows the same applicability as UFC 1-200-01, paragraph 1-3, with no exceptions. **/3/**

1-2.1 Funding.

1-2.1.1 Design.

Design funds are associated with the type of funding for construction. When construction is funded under the Military Construction (MILCON) program, MILCON funds are used for the SID and typically the FF&E designs. Funding of the SID and FF&E design is dependent on the project execution method (DBB or DB) and could be funded with MILCON Planning and Design (P&D) funds for DBB or MILCON construction funds for DB. Typically when a using agency identifies the requirement for furniture on DD Form 1391, this service will be provided from MILCON funds. When furniture is not listed on DD Form 1391, the FF&E design and review effort will be provided by the user with other funds. The design of FF&E for Facilities Sustainment, Restoration and Modernization (FSRM) projects is funded with Operations and Maintenance (O&M) funds. Non-Appropriated Funds (NAF) are used for the design of NAF projects. For projects whose construction is not associated with MILCON, either NAF or O&M funding could be used for the design of the FF&E package.

1-2.1.2 Construction.

Funding for the construction or renovation of a building may come from a broad range of sources. The most common sources in military programs are MILCON, NAF and O&M funds, but other funds may be used.

1-2.1.3 Furniture, Fixtures and Equipment Purchase and Installation.

FF&E is defined as movable personal property. In addition to the furniture funding, the user typically provides O&M or NAF funds to support the procurement, tracking, shipping, warehousing, installation, inspection, and other associated services.

1-3 GENERAL BUILDING REQUIREMENTS.

Comply with UFC 1-200-01 which provides applicability of model building codes and government unique criteria for typical design disciplines and building systems, as well as for accessibility, antiterrorism, security, high performance and sustainability requirements, and safety. Use this UFC in addition to UFC 1-200-01 and other UFCs and government criteria referenced therein.

1-4 REFERENCES.

Appendix A contains a list of references used in this document. The publication date of the code or standard is not included in this document. In general, the latest available issuance of the reference is used.

1-5 OVERVIEW OF MILITARY INTERIOR DESIGN.

Provide a Comprehensive Interior Design (CID) unless otherwise directed. A CID includes the SID and the FF&E design.

1-5.1 Structural Interior Design (SID).

The SID includes building-related design elements and components generally part of the building itself, such as walls, ceilings, floor coverings, primary window treatments (blinds, **\3** shades, drapery hardware, and cordless shades as a safety element **/3/**), signage and built-in casework. The interior designer must be involved with the programming and space planning to help achieve the user’s goals for space utilization and develop a furniture floor plan based on the project program. In addition, the interior designer must determine the desired interior finish materials based on the respective aesthetic, durability and maintenance qualities, and characteristics applicable to each space within the facility. The SID will be designed by a qualified interior designer in accordance with Chapter 2 paragraph “Interior Designer Qualifications.” See Chapter 4 for more detailed requirements for the SID.

1-5.2 Furniture, Fixtures and Equipment (FF&E) Design.

The design of the FF&E includes the layout, selection, specification and documentation of furniture, such as workstations, seating, tables, storage, filing, accessories, and artwork. The documentation facilitates furniture procurement and installation. The FF&E design is based on the furniture floor plan developed in the SID portion of the interior design. Items such as markerboards, bulletin boards and some primary window treatments may be specified in either the SID or the FF&E design. Secondary window treatments such as drapery, sheers and top treatments are typically included in the FF&E design. The FF&E will be designed by a qualified interior designer in accordance with Chapter 2 paragraph “Interior Designer Qualifications.” See Chapter 5 for more information on FF&E interior design requirements.

1-6 GLOSSARY.

Appendix E contains acronyms, abbreviations, and terms.

This Page Intentionally Left Blank

CHAPTER 2 TECHNICAL REQUIREMENTS

2-1 DESIGN REQUIREMENTS.

The interior designer must satisfy the following for each project:

a. Provide a design in accordance with agency standards.

b. Provide a design that is fully coordinated with architectural features, interior finish materials, furnishings, and building systems such as electrical (power, data, voice, audio visual and lighting), mechanical (Heating, Ventilation, & Air Conditioning (HVAC), fire protection and thermostats) and structural. Coordinate design with building maintenance and operations practices to include adequate space allowances for maintaining equipment. Comply with UFC 3-101-01.

c. Provide a flexible interior design that accommodates changing functional requirements. DoD may own or lease a building from its time of construction until the end of its useful life and its functional requirements may change.

d. Incorporate appropriate ergonomic principles in the facility and furniture design.

e. Comply with agency requirements for advanced modeling, to include 3D visualization, Building Information Modeling (BIM), facility data, quantity take-off, geospatial, etc.

   - For Army requirements, refer to USACE Minimum Model Matrix (M3) and Project Execution Plan (PxP) which outline required model uses. Refer to CAD BIM Technology Center (Contract Requirements) for more information on M3 and PxP.

   - For Navy requirements, refer to NAVFAC Building Information Management and Modeling (BIM).

   - For Air Force requirements, follow the Army standards. Refer to USACE Minimum Model Matrix (M3) and Project Execution Plan (PxP) which outline required model uses. Refer to CAD BIM Technology Center (Contract Requirements) for more information on M3 and PxP.

f. Provide a fully coordinated Comprehensive Interior Design (CID), unless otherwise directed, which includes:

   - Structural Interior Design (SID) and

   - Furniture, Fixtures and Equipment (FF&E) design.

2-2 INTERIOR DESIGNER QUALIFICATIONS.

Design and review must be performed by professional interior designers or architects with significant interior design experience. Qualification of designers is based on education, experience and examination. Interior designers or architects must have completed a program accredited by the Council for Interior Design Accreditation (CIDA) or equal accreditation program of academic training in interior design.

For contracted interior design services, the interior designer or architect must also have attained National Council for Interior Design Qualification (NCIDQ) certification or state licensure, certification or registration and must not be affiliated with a furniture dealership, vendor or manufacturer.

2-3 DESIGN CONSIDERATIONS.

Designers must consider interior design compatibility with the local environment, functional requirements, economy of construction, energy conservation, interior details, sustainable design and life cycle costs. Additionally, the interior design must be designed in harmony with the architectural character of existing facilities that are to remain, especially those that are considered historically or architecturally significant and must comply with the installation aesthetic. Design excellence must not add substantial project costs but balance the functionality, aesthetics, quality, sustainability and maintainability of facilities.

2-3.1 Cost Engineering.

Cost Engineering (CE) is an integral part of the design process. Comply with UFC 3-740-05.

2-3.2 Life-Cycle Costs.

Provide interior designs that achieve optimum life-cycle savings. Base design decisions on life-cycle cost considerations to determine an economical design for facilities. Take into account not only the initial construction costs but also the operating and maintenance costs of buildings, the associated impacts on productivity and the missions performed within the facility over their anticipated life. Conduct comparisons as needed to determine the most life-cycle cost effective materials, finishes, construction methods, furnishings and maintenance.

2-3.3 Health and Safety Criteria.

Design floor plans and specify building materials, furnishings and equipment with health and safety in mind. Designers must comply with the latest version of the International Building Code as modified by UFC 1-200-01, NFPA 101, and Occupational Safety and Health Administration (OSHA) Guidelines.

2-3.4 Interior Environmental Quality.

Designers must design an environment that is comfortable, welcoming and conducive to work or other prescribed activity. Contributing factors include proper HVAC, lighting, acoustics and furnishings. Acoustic design issues include speech privacy, sound isolation and sound masking; comply with UFC 3-450-01. Lighting, both artificial and daylight, is an important tool in shaping the ambiance of the environment; comply with UFC 3-530-01.

2-3.5 Wayfinding.

Provide methods of wayfinding throughout the facility, to include an interior signage package, and incorporating graphics, color and patterns as applicable. These design components must form a well-organized, comprehensive interior environment that guides users and visitors through the building to their destinations. Ensure that room numbering strategies used on the architectural and interior design plans align with wayfinding objectives. Comply with UFC 3-120-01.

2-3.6 Sustainable Design.

Sustainable design must comply with UFC 1-200-02. Refer to Appendix C-2.2 Best Practices for additional considerations and preferences. Interior design involves many sustainable requirements. Verify inclusion of all applicable requirements as early as possible in the design process.

2-3.7 Overseas Projects.

Overseas projects may have special interior design requirements based on availability of products and interior finish materials. Finish materials may need to be selected from products available within a certain geographical region. The RAL Colour Standard is an international color-matching system that can serve as a reference for painted and pre-finished interior finish materials. The AMS-STD-595 Colors Used in Government Procurement can also be used for this same purpose. It is recommended that special SID and FF&E requirements be identified early in the design process.

This Page Intentionally Left Blank

CHAPTER 3 INTERIOR DESIGN PROCESS

3-1 GENERAL.

A CID which includes both SID and FF&E design services, will be developed and coordinated with the building design in accordance with applicable design guides, the project delivery process, user requirements and project scope of work. A stand-alone SID or FF&E design may be required depending on project requirements. The following information outlines the interior design process using industry standard design stages and does not reflect the specific submittal phases in terms of percentages and terminology for each agency and type of project. Verify actual submittal phases required on a project-by-project basis as each agency will have its own specific requirements. The project scope of work must reflect project specific requirements.

3-2 PLANNING AND PROGRAMMING.

An interior designer should be involved during the initial programming and DD Form 1391 development and preparation, including information gathering or planning charrettes at the beginning of a project. The designer contributions during the planning and programming stage ensure that all applicable interior design issues are considered and evaluated as part of defining the project scope.

3-2.1 DD Form 1391.

The interior designer should be involved with the development of the DD Form 1391 which provides an estimated cost for furniture based on the FF&E Cost Estimating Guide or other historical project data. When furniture is required as part of a project, it must be specifically identified on the DD Form 1391. Furniture is included on the DD Form 1391 as “Equipment from other Appropriations (Non-Add)”. List the equipment as an O&M funded item, the Fiscal Year (FY) the funds are requested, and the line item cost. The FF&E budget must be verified by the O&M funding source. Any equipment included on the DD Form 1391 must be estimated separately from the furniture and added to the FF&E budget with applicable funding information.

3-3 PROJECT DELIVERY PROCESS.

The two main project delivery processes are Design-Bid-Build and Design-Build; other project delivery methods are possible.

3-3.1 Design-Bid-Build (DBB).

When the DBB project delivery process is used, the SID and FF&E design is typically developed by a single interior design source. The SID and FF&E portions of the interior design should be developed concurrently with the building design to ensure coordination with all building systems and construction documents. Provide a furniture plan for space planning and coordination with building systems when a FF&E design is not required. Coordinate the completion of the FF&E design, procurement and installation with the user’s Beneficial Occupancy Date (BOD). In some situations, a government interior designer or the contractor's interior designer performs the FF&E design instead of the Architect/Engineer (AE) interior designer who designed the SID portion of the project.

Refer to Appendix B for Table B3-1 Design-Bid-Build Project Delivery Process. The table outlines the stages the interior designer is involved during the DBB project delivery process, to include planning and programming, and design.

3-3.2 Design-Build (DB).

3-3.2.1 DB Pre-Award Development.

During the Request for Proposal (RFP) development, the interior designer will participate in the pre-design conference or design charrette to establish project requirements including interior material and finish requirements, space utilization, personnel requirements, SID and FF&E design requirements and FF&E acquisition strategy. The interior designer will develop the performance specifications for the SID and minimum furniture requirements for the FF&E design.

Refer to Appendix B for Table B3-2 Design-Build Pre-Award Project Delivery Process. The table outlines the interior design process and at what stage the designer is involved during the planning and programming efforts and DB RFP development.

3-3.2.2 DB Post Award.

The contractor's interior designer will meet with the government interior designer and user to review the DB RFP SID and FF&E design requirements and then complete the interior design.

Refer to Appendix B for Table B3-3 Design-Build Post Award Project Delivery Process. The table outlines the interior design process for DB after the construction contract has been awarded.

3-4 FURNITURE, FIXTURES AND EQUIPMENT (FF&E) ACQUISITION STRATEGY.

Verify the FF&E procurement methodology in coordination with the Government, facility design criteria and the project delivery process. Confirm what type of funds will be used to procure the FF&E package, for example, O&M or NAF funds. Coordinate the procurement method, format and schedule with the applicable contracting office for their specific requirements. Other items to consider are:

a. Include applicable purchasing fees or other known additional costs.

b. When Best Value Determinations (BVD) are performed, manufacturer's price quotes for backup and product mock-ups may be required, which may increase design fees and extend the design schedule.

c. Confirm if expiring funds can be obligated prior to the completion of the FF&E package; project coordination will be impacted.

d. Identify the project FF&E package funding source(s).

e. Confirm the project procurement office's interpretation of procurement regulations and what type of documentation is required.

3-4.1 Contractor Furnished Contractor Installed (CFCI) FF&E Package.

The contractor may procure and install the FF&E package, known as CFCI. Project coordination is minimized since the user has only one point of contact for a turnkey project. The FF&E design is prepared by the AE interior designer, the interior designer on the contractor's team, or by a government interior designer. The Government will provide separate funding for the actual purchase of the FF&E package including shipping and installation. **\3** Navy and USMC projects require BVDs as an integral part of the design and require the contractor to purchase the final approved FF&E package. /**3**/ The government interior designer must review the interior design deliverables to ensure the government procurement regulations and requirements are met.

Navy projects typically require the contractor to purchase the final approved FF&E package.

3-4.2 Government Furnished Government Installed (GFGI) FF&E Package.

The Government may procure and install the FF&E package independently of the building construction or renovation, known as GFGI. The FF&E design is prepared by an AE interior designer or by a government interior designer. The FF&E package is procured through DoD agencies or non-DoD Agencies, such as the General Services Administration (GSA), Fleet Logistics Command (FLC) and U.S. Army Engineering and Support Center Huntsville (HNC). In this case, the project delivery team must plan for extensive coordination between the building design, the FF&E design, changing construction schedules, and furniture delivery schedules. Other issues to consider in this acquisition strategy are:

a. The procurement agency may not have the technical expertise to purchase large projects or understand the need to purchase FF&E packages without deviating from the design intent. Technical evaluations may need to be performed by the AE interior designer, the contractor's interior designer, or the appropriate government interior designer.

b. Non-DoD procurement agencies may require an Interagency Agreement to procure the FF&E package.

3-4.3 Government Furnished Contractor Installed (GFCI) FF&E Package.

The Government may have the contractor install government furnished new or existing furniture as part of its scope of work, known as GFCI. This may be accomplished with either the Design-Build or Design-Bid-Build acquisition strategies. A FF&E design may be required for reconfiguration of existing furniture and for additional furniture to match existing furniture. Consider costs required for furniture inventory, storage, relocation, planning, phasing and temporary office space when planning to re-use existing furniture. The design team must research the availability of any new furniture required to match existing, and coordinate the construction schedule and new furniture delivery schedules.

3-5 DESIGN STAGES.

\3 Design stage names, percent completion, and submittal requirements vary by service. Confirm the actual submittal requirements with the appropriate service submission criteria. Based upon the scope of a specific project, submittals may be omitted or combined at the discretion of the project design team. The following table and paragraphs are intended to give a general framework for interior design development throughout the design stages. Refer to Appendix B for tables correlating interior design processes/involvement during all design stages for various acquisition strategies.

Table 3-1: Design Stage Equivalency

Design Stage	Tri-Service Submittal Equivalency		
	Air Force	Army	Navy & Marine Corps
Pre-design/ Parametric design	Schematic/Concept Design (10-15%)	Parametric Design (5-15%)	Preliminary Design (0-10%)
Schematic Design	Design Submittal (35%)	Concept Design (35%)	Schematic Design (10-15%)
Design Development	Prefinal Design Submittal (65%)	Interim Design (65%)	Design Development (35-50%)
Construction Documents	Design Submittal (95%)	Final Design (95%)	Pre-Final (100%)
Design complete	Final Design Submittal (100%)	Corrected Final (100%)	Final

/3/

3-5.1 Pre-design/Parametric Design.

During the **\3** pre-design/parametric design phase, the interior designer will participate in the pre-design conference/planning charrette to meet with representatives of the user and the buildings design team to assist with space planning, room-by-room program development, and identification of furniture, fixtures and equipment (FF&E) items. Documentation is typically provided in the form of a parametric design report, planning charrette report or design analysis. A cost estimate for planning purposes may be required. **/3/**

3-5.2 Schematic Design.

During the schematic design stage **\3\ /3/** the interior designer will meet with representatives of the user and the building design team to determine the design concept. The schematic design must be described in the design analysis as required in the project delivery process. The schematic design must meet the user's functional, physical, and aesthetic needs. **\3**

3-5.2.1 DB RFP Development

During the DB RFP project delivery process the interior designer will participate in the pre-design conference or design charrette to establish the RFP SID and FF&E design requirements. During the DB Post Award project delivery process the interior designer will participate in the pre-design conference or design charrette to verify the RFP requirements before proceeding with design development. **/3/**

3-5.3 Design Development.

Upon approval of the schematic design, the interior designer will further develop the design. The designer will participate in the floor plan development and contribute to the interior architectural detailing. The designer will select the appropriate interior finish materials, develop furniture layout and specifications. **\3** The interior designer will develop documents including adjacencies, space utilization, space planning, personnel requirements, furniture plan and FF&E item list. A cost estimate for planning purposes may be required. **/3/** Ensure architectural and engineering disciplines are coordinated with the interior design during design development through construction documents. Locations of equipment, casework, lighting, power and communication, electrical and fire protection panels, and sprinklers must be considered. \3\ /3/

3-5.4 Construction Documents.

During the pre/final stages of a project **\3\ /3/** the interior designer will complete the SID and FF&E design in sufficient detail to ensure successful execution. Coordinate specifications with the final drawings, schedules and details as well as furniture types and layouts with other disciplines. Coordinate placement of equipment such as motorized projection screens and computerized directory systems with electrical systems. **\3** Furniture that requires coordination with electrical or telecommunications systems or both including, but not limited to, systems furniture, powered high-density filing, powered conference and training tables, refer to UFC 3-520-01 Interior Electrical Systems and UFC 3-580-01 Telecommunications Interior Infrastructure Planning And Design for additional requirements. **/3/** Confirm furniture coordination with building elements such as power and communication sources, ceiling heights, column placement, lighting, wall switches, thermostats, alarm panels, and window placement. **3**\ /**3**/

3-5.5 Project Review.

When the design is performed by an AE, direct communication with the government reviewers (project manager, users, and interior designer) is required. This will avoid unnecessary submittal of plans and specifications due to misunderstandings. The reviewer's name, phone number and email address can be found on the comment sheets. The government reviewer(s) will provide comments regarding corrections or clarifications to be incorporated into contract documents at each design submittal. The interior designer will ensure that comments are incorporated into the subsequent submittal, or the reason for not incorporating the comment must be thoroughly documented in the AE's response to the comment. The Army and the Navy use a web-based government review management system called DrChecks, which will be used if indicated in the contract.

This same review process applies to projects designed by government interior designers.

3-6 CONSTRUCTION AND FF&E PACKAGE PROCUREMENT PHASES.

The interior designer or government construction representative will verify that equipment, architectural features, mechanical components and electrical devices are coordinated with the furniture plans and installed properly during building construction.

FF&E delivery and installation will be coordinated with the Government so it will be completed by the user's BOD. Note that a Construction Completion Date (CCD) may occur significantly before the user's BOD, depending on the procurement method selected. FF&E activities during this phase include procurement, tracking of orders, warehousing, delivery, assembly and installation, and verification that the FF&E received match the procurement documents, shop drawings and specifications. When FF&E design services are provided, the interior designer may be required to provide additional services in accordance with the project scope of work to include:

a. Consultation during procurement, delivery and installation of FF&E;

b. Evaluation of the FF&E submittal and assistance in reviewing deviations from the specified FF&E package to avoid installation of inferior or inappropriate FF&E items; and

c. Quality Assurance of furniture and furniture installation to include walk through and punch list.

3-7 POST OCCUPANCY.

When required by the Government, conduct a Post Occupancy Evaluation (POE) of the project approximately one year after construction completion or as directed. POE is required to determine the effectiveness of the design. This evaluation involves inspection of the completed facility by a team composed of members of the project delivery team, the facility management office, and the user. The POE is also used by the project delivery team to improve the project delivery and design process.

This Page Intentionally Left Blank

CHAPTER 4 STRUCTURAL INTERIOR DESIGN

4-1 GENERAL.

The Structural Interior Design (SID) involves the design, selection and specification of applied finishes and building interior features including, but not limited to, walls, floors, ceilings, trims, doors, windows, window treatments, built-in items and installed equipment, lighting, and signage. The SID package includes furniture floor plans, finish schedules, color boards and any supporting interior elevations, details or plans necessary to communicate the building finish design and build out. The SID provides basic space planning for anticipated FF&E design requirements in conjunction with the functional layout of the building and design issues such as life safety, privacy, acoustics, lighting, ventilation, and accessibility.

4-2 SPECIFIC MATERIAL CONSIDERATIONS.

The following paragraphs address special considerations and issues for selecting and specifying materials and finishes, however, these do not cover all finishes normally incorporated into design projects.

For Air Force projects, refer to the individual base Installation Facility Standards (IFS) for additional guidance.

4-2.1 Gypsum Board.

Select gypsum board product appropriate for application in specific situations. Considerations for fire-resistance, high traffic areas, exposure to moisture, water resistance, and radio frequency shielding must be taken into account and coordinated with the overall function of the facility. Identify areas such as backsplashes in breakrooms and tiled walls at water fountains. Refer to UFC 3-101-01 and Unified Facility Guide Specifications (UFGS) 09 29 00 for additional information concerning product selection.

4-2.2 Paint.

Paint selection and specification will be based on the UFGS 09 90 00 Paints and Coatings. Each coating category is identified in the Master Painter's Institute (MPI) "Approved Products List" as either having been performance tested or categorized for intended use. Select paints and coatings from MPI's "Detailed Performance Standards" which are paints and coatings that have been tested to specific performance standards. Do not use MPI's "Intended Use" standards, as they have not been tested against the performance standards. Refer to the Master Painters Institute (MPI) "Architectural Painting Specification Manual" for more information.

4-2.3 Carpet.

Where carpet is required, each project has specific carpet requirements in regards to performance, aesthetics, functional use and maintenance. Refer to the UFGS 09 68 00

Carpeting for guidance on selections and discussion on standards and performance. The use of a multi-colored or patterned carpet is recommended due to superior soil hiding capabilities.

4-2.4 Wallcovering.

Breathable wall coverings are required where used on the interior face of exterior walls in environments with high humidity where mold frequently occurs. Refer to Indoor Air Quality and Mold Prevention of the Building Envelope on the WBDG web page for more information. Also refer to UFGS 09 72 00 Wallcoverings.

4-2.5 Window Treatments.

Maintain uniformity of window treatments and color for primary window treatments such as blinds and roller shades which are viewed from the outside of the building. Primary window treatments may be included in the SID and the construction documents. Secondary window treatments such as drapery, sheers and top treatments are specified as required on a project-by-project basis and are usually included in the FF&E package. **\3** Consider the use of cordless shades as a safety element. **/3/**

4-2.6 Interior Signage.

Ensure that interior signage schedules and details are incorporated into the contract documents. If room names are subject to frequent change, an interchangeable message strip will be used to facilitate removal and replacement. Signage typical drawings and schedules must be coordinated with UFGS 10 14 00.20 Interior Signage. Comply with UFC 3-120-01.

4-3 DESIGN ANALYSIS.

Provide a design analysis that describes the basis of design, building-related finishes and furniture floor plan development and features as it relates to the user's requirements and building design. Include topics that relate to installation standards, life safety, aesthetics and durability

4-4 INTERIOR DESIGN DRAWINGS.

Interior design building-related drawings must indicate the placement and extents of SID materials, finishes and colors and must be sufficiently detailed to define all interior work. Refer to the A/E/C CAD Standard for information such as **\1** level/layer assignments, electronic file naming, and standard symbology **/1/**. Minimum required drawings may include, but are not limited to, the following list and those listed in UFC 3-101-01:

a. Room Finish Schedule

b. Finish Schedule and Finish Legend

c. Interior Finish Plans

d. Reflected Ceiling Plans

e. Interior Building Elevations, Sections and Details

f. Furniture Floor Plans

g. Interior Signage

4-4.1 Room Finish Schedule.

The interior designer is responsible for selection, coordination and specification of interior finish materials. Provide a detailed Room Finish Schedule keyed to the Finish Schedule and Finish Legend, to include finish materials and colors for floors, walls, and ceilings, with special features noted on a per room basis. Obtain input from the user and the government architectural and interior design representatives. The interior design drawings must be fully coordinated with UFGS.

4-4.2 Finish Schedule and Finish Legend.

Provide a Finish Schedule or Finish Legend, or a Finish Schedule and Finish Legend on the drawings, or use UFGS 09 06 00 Schedule for Finishes. Refer to paragraph 4-5.1 for additional requirements.

4-4.3 Interior Finish Plans.

Provide Interior Finish Plans that indicate floor patterns, finish and color placement, material transitions and extents of interior finishes.

4-4.4 Reflected Ceiling Plans.

Provide Reflected Ceiling Plans that show the ceiling tile layout where applicable and all light fixtures, air diffusers, grilles, registers, and other ceiling mounted items.

4-4.5 Interior Building Elevations, Sections and Details

Provide Interior Building Elevations, Sections and Details that indicate material, color and finish placement, and wall patterns. Include casework sections and details, transition details, and critical dimensions.

4-4.6 Furniture Floor Plans.

Incorporate FF&E design requirements throughout the design process. The interior designer will work directly with the user to assess their needs and develop furniture requirements for each space within the facility. Develop the Furniture Floor Plans to show that the furniture necessary for the user's functional requirements can be accommodated within the spaces and satisfy applicable life safety codes. The Furniture Floor Plans will show the appropriate size and type of furniture and include critical and required clearances. Code furniture on Furniture Floor Plans to furniture legends. **\1** For Army projects, refer to USACE Furniture Item Description for Standard FF&E

Nomenclature document. **/1/** The Furniture Floor Plans and documented user requirements serve as the basis for a fully integrated building design as well as the basis for the FF&E design. Coordinate equipment items to be included in the FF&E design with the Government.

The interior designer may not be responsible for specifying equipment, but in coordination with the architect and engineers is responsible for identifying the requirements for equipment items regarding space allocation and coordination with building systems. When the design of the FF&E package is included in the building design scope of work, the Furniture Floor Plans will be fully developed, along with the FF&E package. If the FF&E package is not included as part of the building design, ensure that the Furniture Floor Plans are clearly noted “Not in Contract.” Furniture Floor Plans must be included throughout the design delivery process. Furniture must be coordinated with locations of items such as equipment and casework, lighting, power and communication, electrical and fire protection panels, and sprinklers.

4-4.7 Interior Signage Drawings.

Provide typical sign drawings, plans and details which indicate size, type, location and signage schedule for all signs. The sign symbol on the drawings must be keyed to the signage schedule, which includes the locations, messages, symbols, and other related information. Indicate the location of every sign and directory in the facility. Incorporate building or floor directories and directional signage for larger facilities based on project requirements. The typical sign drawings and schedule, including sign locations, may be included in the specification or as an attachment to the specifications instead of on the drawings.

4-5 SPECIFICATIONS.

Design-Bid-Build and Design-Build projects have differing specification requirements. In either case, the specifications must be as concise as possible, definitive, and free of ambiguities and omissions that may result in controversy and contractor claims for additional compensation. Unified Facilities Guide Specifications provide important information on government quality standards and submittal requirements and should be used as the basis for project specifications. These specifications are available on the WBDG web page Unified Facilities Guide Specifications. UFC 1-300-02 provides guidance on the preparation of specifications.

4-5.1 Finish Schedule and Finish Legend.

\2 Per 2017 NDAA – Section 888, the use of brand names or brand-name or equivalent descriptions, or proprietary specifications or standards is prohibited in Department of Defense solicitations unless a justification for such specification is provided and approved in accordance with section 2304(f) of title 10, United States Code. **/2/**

The interior designer must provide all finish and color selections including finish code, **\2** materials, textures, patterns, and general color **/2/** for all interior finishes and specialties which will be exposed to view in the finished construction. The Government will direct which of the following methods to use.

a. The UFGS 09 06 00 Schedules for Finishes guide specification may be used to document finish and color selections. This specification has been fully integrated as a reference in all UFGSs that require a **\2\ /2/** material, color and finish reference.

b. If the UFGS 09 06 00 is not used, provide a Finish Schedule or Finish Legend, or a Finish Schedule and Finish Legend on the drawings associated with the Room Finish Schedule as per 4-4.2. **\2**

c. When proprietary information cannot be included on the drawings, additional requirements shall be set forth for the contractor to submit complete color boards for the entire project, prior to the submittal and approval of individual finish submittals. This shall be reviewed and approved by the DOR to verify overall building coordination and aesthetic. **/2/**

\2\ /2/

4-5.1.1 Federal Standard Colors.

The current AMS-STD-595 Colors Used in Government Procurement **\2** or the Pantone Color System **/2/** is to be used when required by installation specific criteria. The use of this standardized method of defining colors and finishes varies on a project-by-project basis.

\2\ /2/

4-6 SID BINDER.

SID binder or binders must display actual interior finish color samples proposed for the project. Color boards are required at various submittal phases as noted in the project scope of work. Submit SID information and samples in three ring binder with pockets on the inside of the covers. When samples are numerous or thick, use more than one binder. Each binder must have a table of contents and be labeled on the outside spine and front cover with the following information: Structural Interior Design (SID), design stage, date, design firm, project title and number, location and volume number. Include a copy of the Room Finish Schedule, UFGS 09 06 00 Schedules for Finishes or the Finish Schedule and Finish Legend, and Interior Finish Plans. Provide 8 ½ inch x 11 inch or 11 inch x 17 inch binders; large format color boards and color boards with fold outs can also be used. Coordinate the SID binder format and any specific requirements with the project scope of work. The SID binder may be electronic except for the finish boards with actual finishes. Also provide an electronic copy of the SID binder to include the finish boards to keep on file with the drawings and specifications.

4-6.1 Finish Color Boards for SID Binder.

Finish color boards must be sturdy enough to support samples. When required, use page protectors that are strong enough to keep pages from tearing out. Anchor large or heavy samples with mechanical fasteners, Velcro, or double-faced foam tape rather than rubber cement or glue. Label finish samples with the finish codes used in the contract documents. Samples that are difficult to attach, or large samples, such as ceiling tiles or flooring samples can be provided separately from the color board in a loose sleeve. Samples must be labeled with the finish code so they can be identified independently if removed from the binder. Manufacturer name and number may be included.

Provide actual samples of finishes that indicate true color, pattern and texture. Finish samples must be large enough to show a complete pattern or design where practical. Also provide a color illustration of materials or fabrics when necessary to show large overall patterns. For example, if the specified carpet has a large pattern, provide a color photocopy showing the overall pattern in addition to the carpet sample with representative colors.

4-7 LARGE SCALE PRESENTATION BOARDS.

In addition to the SID binder, large-scale finish color boards may be required for presentations. Boards must be sufficiently rigid to support heavy samples. Finish materials must be labeled to fully coordinate with the contract documents. Finish samples must represent true color, pattern, and texture. Samples must be large enough to indicate any pattern repeats where practical. Provide a label or title block identifying the design stage, project title and location, design firm, construction contract numbers, and date. Separate boards must be submitted for interior finishes. A copy of the Room Finish Schedule and Finish Schedule and Finish Legend must be attached to the back of the board or provided in a separate binder that is labeled the same as the SID binder.

4-8 PERSPECTIVE SKETCHES, VIEWS AND RENDERINGS.

Provide perspective sketches, views and renderings when required by the project scope of work.

4-9 SID DESIGN SUBMITTAL REQUIREMENTS MATRIX.

See Appendix B for Table B4-1 SID Design Submittal Requirements Matrix. The table indicates what components are typically included in each submittal. The submittal phases are representative and will vary due to the project delivery process. The project scope of work will define the SID requirements, submittals, and number of submittals on a project-by-project basis. SID submittals should run concurrent with architectural submittals.

Resubmittal of the SID binder is not required if there are no changes from the previous design submittal. Provide updated cover and spine for insertion into the previously submitted SID binder. If only minor changes are required, resubmit applicable coded samples (tape ready for application), updated binder cover and spine, corrected Room Finish Schedule, UFGS 09 06 00 Schedules for Finishes or Finish Schedule and Finish Legend, Interior Finish Plans, and Design Analysis. If major changes to the color boards are required, resubmit with color samples of all proposed interior finishes, updated binder cover and spine, corrected Room Finish Schedule, UFGS 09 06 00 Schedules for Finishes or Finish Schedule and Finish Legend, Interior Finish Plans, and Design Analysis.

This Page Intentionally Left Blank

CHAPTER 5 FURNITURE, FIXTURES AND EQUIPMENT INTERIOR DESIGN

5-1 GENERAL.

The Furniture, Fixtures and Equipment (FF&E) design includes the selection, specification, color coordination and procurement documentation of the required items necessary to meet the functional, operational, sustainability, and aesthetic needs of the facility. The FF&E package includes information required for purchasing and installing the furniture such as drawings, specifications, finishes and cost estimates. The interior designer will select and specify colors, fabrics, and furniture finishes to coordinate with the SID interior finish materials. The selection of furniture style, function and configuration will be coordinated with the user's requirements. Examples of FF&E items are workstations, seating, tables, storage, filing, accessories, and artwork. Items such as markerboards, tackboards, and presentation screens are typically included in the SID but can also be included in the FF&E design if necessary. Secondary window treatments such as draperies, sheers and top treatments are specified as required on a project-by-project basis and are included as part of the FF&E design. Criteria for furniture selection will include functional and ergonomic considerations, maintenance, durability, sustainability, comfort and cost. Also, the designer may have to consider reuse of and coordination with existing furniture.

The FF&E budget, the user's program requirements and the furniture plans will be the basis for the FF&E design. The designer will work directly with the user to assess their needs and develop a list of furniture required for each space within the facility. The FF&E package will be developed and coordinated with the building design as required by the project delivery process and the acquisition strategy. The designer will coordinate product lead times with the construction completion dates. Refer to Chapter 3 Interior Design Process.

Equipment not included in MILCON construction may or may not be included in the FF&E package, depending on the funding used. The user may provide specifications for specialized equipment. The Army and Air Force do not include equipment in their FF&E package. The Navy typically includes equipment in their FF&E packages where appropriate. **\3** For other Defense Agencies, refer to their FF&E requirements. **/3/**

For Navy projects refer to NAVFAC Collateral Equipment (FF&E) Criteria & Templates for additional information.

5-2 SOURCES OF SUPPLY FOR FF&E DESIGN.

Federal Acquisition Regulations (FAR) Part 8 directly affects the interior design process by outlining the required sources of supplies and services and their use. Of particular importance to the process of developing and procuring FF&E design is paragraph 8.002, Priorities for Use of Mandatory Government Sources.

FF&E items are typically specified through government sources of supply such as GSA Schedules, Federal Prison Industries, Inc. (UNICOR), GSA Global Supply Catalog, Ability One, or Air Force and Navy Blanket Purchase Agreements (BPA)s when applicable. Additional sources include GSA Advantage, or Air Force Non-Appropriated Funds Purchasing Office (AFNAFPO). These government sources of supply may not be available for overseas facilities; coordinate with the government project delivery team and the project scope of work.

If open market procurement of an item is necessary, the interior designer is required to prepare adequate written justification, giving reasons why the item(s) must be procured through the open market. Coordinate requirement with the appropriate purchasing office or contracting officer.

5-2.1 Air Force BPAs and Contracts.

For information on the Air Force's Systems Furniture and Modular Furniture mandatory contracts, contact the Air Force Furnishings Commodity Council at AF.FCC.Systems.Furni@us.af.mil.

Additionally, the AF mandatory BPA's for Executive case goods, seating and files are located on GSA Advantage.

5-2.2 Navy BPAs.

Consult with Navy interior designer for current NAVSUP BPA vendor list. See NAVFAC Collateral Equipment (FF&E) Criteria & Templates.**\3**

5-2.3 Other Defense Agencies.

Refer to agency specific guidance. **/3/**

5-3 FF&E DESIGN SUBMITTAL REQUIREMENTS.

The FF&E package is used for purchasing furniture for new or renovated facilities. It can also become the record and resource document for facilities management personnel to reference for repairing or replacing furniture and reordering additional items.

Information and samples are to be submitted in 8 1/2 inch x 11 inch (216 mm x 279 mm) format using three ring binders with pockets on the inside of the covers. When there are numerous pages with thick samples, use more than one binder. Fold out items must have a maximum spread of 25 1/2 inches (635 mm). Each binder must have a table of contents and be labeled on the outside spine and front cover with the following information: Furniture, Fixtures and Equipment (FF&E), design stage, date, design firm, project title and number, location and volume number. All pages in the binder will include the project name and location, project number, and design submittal phase. Binder information may be electronic except for the finish board with actual finishes. Also include an electronic copy of the binder information to include the finish board.

The requirements of the FF&E package must be coordinated with the government interior designer as well as with the contracting specialists or designated contracting official. The project scope of work must reflect project specific requirements. Comply with the following requirements unless otherwise directed.

5-3.1 Agency Specific Requirements.

5-3.1.1 Navy Projects.

Coordinate the procurement documents with the government interior designer and Collateral Equipment Manager. See NAVFAC Collateral Equipment (FF&E) Criteria & Templates for Navy information.

5-3.1.2 Army Projects.

Provide non-proprietary, project specific salient characteristics for the items specified.

a. **\3** Utilize the USACE Standard FF&E Nomenclature document. See USACE Standard FF&E Nomenclature for Army information.

b. Refer to UFGS 01 33 16.00 10 Design Data (Design After Award) for Design-Build Interior Design specific requirements.

c. HNC Purchased Furniture - All Army MILCON, Sustainment Restoration and Modernization (SRM), Initial Issue and Replacement Unaccompanied Housing (UH) FF&E procurements are centrally administered through HNC, per IMCOM (Installation Management Command) Narrative Funding Guidance.

    i. For a list of approved items for procurement through HNC, refer to HNC Centralized Furnishings Program – Ancillary Items Authorized for Procurement Matrix.

    ii. HNC Furnishings Program supports all DoD Components. Refer to the HNC Furnishings Program MRSI Website for furniture construction standards, additional information, and contacts.

d. Contractor Furnished Contractor Installed (CFCI) Furniture - Include specification UFGS 12 50 00.13 10 Furniture and Furniture Installation or a comparable specification in the contract documents. Specification to include non-proprietary, project specific, salient characteristics for furniture items. A FF&E package is required as an attachment to UFGS 12 50 00.13 10 but may not be required for other comparable specifications. When including a FF&E attachment, omit unit, extended or shipping costs on data sheets. Cost estimate should only be provided for review purposes and not included with the solicitation documents. **/3/**

5-3.1.3 Air Force Projects.

For CFCI furniture follow project CFCI requirements and provide non-proprietary, project specific salient characteristics for the items specified. **\3**

5-3.1.4 Other Defense Agencies.

Refer to agency specific guidance. **/3/**

5-4 FF&E PACKAGE COMPONENTS.

Provide the following components:

5-4.1 Design Analysis.

Provide a design analysis that describes the design objectives as they relate to the selection of furniture, finishes and colors and the furniture plan development and features and how project specific requirements are met. Include design decisions made to fully coordinate the SID and the FF&E design, including function, safety and ergonomic considerations, durability, sustainability and aesthetics.

5-4.2 Point of Contact List.

Provide a comprehensive list of Points of Contacts (POCs). This includes appropriate project team members, user contacts, interior design representatives, contractors and installers involved in the project. In addition to name, address, phone number and email, include each contact's job description.

5-4.3 Itemized Furniture Cost Estimate.

Provide an itemized cost estimate of furniture keyed to the plans and the data sheets. Organize by and include furniture item code and item name so the estimate can also be used as the item code legend. Base the estimate on applicable pricing to include GSA, Navy BPAs, and Air Force BPAs and contracts. The estimate must include percentage allowances for general contingency, shipping, inflation and installation costs, listed as separate line items. Consult with the government interior designer for any additional costs to be included. Installation and freight quotes from vendors should be used in lieu of a percentage allowance when available.

5-4.4 Item Code Legend.

Provide a consolidated list of all FF&E items in the package with the item code and name of each item. Organize item codes by product category such as workstations, seating and tables.

5-4.5 Item Installation List.

The Item Code Legend may be expanded to be used as an Item Installation List. Indicate quantity per room, model number and manufacturer of each furniture item. This provides a quick reference for managing larger furniture installations.

5-4.6 Best Value Determination (BVD).

The purpose of the BVD is to provide a contracting officer with the proper documentation to assist in determining that the FF&E package meets the FAR. A complete and well-written BVD is the first step in ensuring the FF&E package will be purchased as designed. Coordinate with the contracting officer and government interior designer on the procurement source of supply and associated BVD requirements to be incorporated into the FF&E package. Provide BVDs for orders over the current Micro-Purchase Threshold. Typically, furniture must be evaluated through market research and price comparisons. The documentation will list the types of furniture, the three or more required vendors considered for the item, the price of the three or more considered, and a brief statement why the selected furniture items are the "best value" to the Government. **\3** Typically, Army and Air Force projects do not require BVDs. For Navy projects also see NAVFAC Collateral Equipment (FF&E) Criteria & Templates for additional information. For other Defense Agencies, refer to agency specific guidance. **/3/**

5-4.7 Data Sheets.

One data sheet will be prepared for each item specified in the design. This form identifies all information required to order each individual item. The data sheet typically includes:

a. Item Code and Name

b. General Services Administration (GSA) Schedule Information:

- Federal Supply Category (FSC) Group and Part number and Special Item Number (SIN)
- GSA contract number and expiration date
- GSA contractor name, ordering address, phone number, and email or website

c. Provide BPA and contract information for applicable Air Force and Navy projects:

- BPA and contract number, and expiration date
- BPA and contractor name, address (ordering and payment), phone number, and email or website

\2\ /2/

d. Federal Stock information (if applicable)

e. Product specification information, manufacturer's item name, series, model number, dimensions and description to include minimum quality standards, construction materials and methods, configuration, features, options, warranty and any critical dimensions

f. Finish and fabric information coded to the finish color boards

g. Illustration must be close to the actual item specified or it must be noted that it is representative or similar

h. Quantity by room number and name

i. Total quantity of items

j. Unit cost

k. Total cost

l. Shipping costs

m. Special Instructions for ordering such as packaging information, mounting height information, and installation coordination notes (can be included in description)

n. Interior Design Source contact – whether it be the AE interior designer, or the government interior designer

\2\ /2/

The goal is to provide this information on one page, however, if necessary, a second page may be used for additional detailed specifications. Open market justifications and any other critical procurement information must be indicated. The Data Sheets are to be organized by product category in the binder and keyed to the Item Code Legend. Refer to Appendix D for examples of agency specific data sheets.

5-4.8 Furniture Material Boards.

The finish and fabric samples on the boards must be labeled and keyed to the item codes and names used on the Data Sheets and the Furniture Plans.

5-4.8.1 Finish Color Boards.

Provide Finish Color Boards with actual finishes and fabric samples. Color boards must be in 8 1/2 inch x 11 inch (216 mm x 279 mm) format and must be sturdy enough to support the samples. When needed, use page protectors that are strong enough to keep pages from tearing out. Large samples in protective sleeves must be labeled with the item code so they can be identified independently if removed from the binder. Samples must indicate true color, pattern, and texture. Use photographs or color photocopies of materials or fabrics to show large overall patterns in conjunction with samples to show the true colors. Samples must be large enough to show a complete pattern or design where practical. Provide a label or header identifying the design stage, project title and location, design firm, construction contract numbers, and date on each board.

5-4.8.2 Furniture Presentation Boards.

Large-scale Furniture Presentation Boards may also be required for presentations to illustrate typical products proposed for the project and their associated finishes and fabrics samples. Boards must be sufficiently rigid to support heavy samples. Samples must represent true color, pattern, and texture and must be large enough to indicate any pattern repeats where practical. Color photocopies of artwork and plants are acceptable. Provide a label or title block identifying the design stage, project title and location, design firm, construction contract numbers, and date on each board.

\2\ /2/

5-4.9 Furniture Plans.

Provide furniture plans to indicate locations of all furniture, equipment and accessories. Also provide furniture power, voice and data plans, panel plans and legends. Furniture plans must include composite and area plans; area plans must have key plans. Identify these items with an item code that is keyed to the Data Sheets and the finish color boards. Each drawing sheet shall include a legend listing all furniture item codes and names. Provide to scale as required by scope of work. Typically, furniture plans will be the same scale as the architectural drawings. Some projects may require furniture plans for individual rooms or areas to show furniture in sufficient detail for installation. Examples of this include enlarged plans for systems furniture or individual room drawings where typical room configurations are repeated throughout a project. Refer to the A/E/C CAD Standard for drawing requirements. The furniture plans will be included in both the SID drawings and in the FF&E package.

5-4.9.1 Systems Furniture.

\3\ /3/ Provide large scaled plans and elevations/isometrics (minimum 1/2 inch = 1 foot – 0 inches) (.5 mm = 305 mm showing workstation typical configurations which clearly identify major workstation components to include but not be limited to panels, storage, worksurfaces, accessories (such as monitor arms and keyboard trays), and task lighting. Include location of all power, voice and data outlets and indicate height on panels by note or symbol. Refer to UFGS 12 59 00 Systems Furniture for specifications or NAVFAC Collateral Equipment (FF&E) Criteria & Templates for Navy Performance Criteria Documents.

5-4.9.2 Artwork Placement Plans.

If the artwork locations and item codes cannot be clearly shown on the furniture plans, provide separate artwork placement plans. Ensure that mounting heights and special installation instructions are indicated on the plans and on the Data Sheets.

5-5 FF&E DESIGN SUBMITTAL REQUIREMENTS MATRIX.

Refer to Appendix B for Table B5-1 FF&E Design Submittal Requirements Matrix. The table indicates what components are typically included in each submittal. The submittal phases are representative and will vary due to the project delivery process. The project scope of work will define the FF&E package requirements, submittals, and number of submittals on a project-by-project basis.

Resubmittal of the FF&E binder is not required if there are no changes from the previous design submittal. Provide updated cover and spine for insertion into the previously submitted FF&E binder. If only minor changes are required, resubmit applicable coded samples (tape ready for application), updated binder cover and spine, and corrected FF&E components. If major changes to the color boards are required, resubmit with color samples of all proposed finishes, updated binder cover and spine, and corrected FF&E components.

APPENDIX C BEST PRACTICES

C-1 INTRODUCTION.

This appendix identifies background information, good interior design practices, and DoD preferences. The interior designer is expected to review and interpret this guidance and apply the information according to the needs of the project.

C-2 BEST PRACTICES.

C-2.1 Whole Building Design Guide.

The WBDG provides up-to-date information on integrated design of facilities. It is a valuable resource for information on sustainable design, accessibility, aesthetics, cost effective design, functional requirements, historical preservation, productivity and security. The WBDG provides access to all **\3** federal facility **/3/** criteria, standards and codes for the DoD Military Departments, National Aeronautics and Space Administration (NASA), and others. These include UFC, UFGS, Performance Technical Specifications (PTS), design manuals, and specifications. For approved government employees, it also provides access to non-government standards. Additionally, it contains information on and links to "Building Types" such as armories, aviation facilities, educational facilities, healthcare facilities, libraries, office buildings, parking facilities, and warehouses.

C-2.2 Sustainability.

Many sustainable elements are required in a project, and each project is different. Interior designers must take the initiative to influence nearly every sustainable goal of a project. The following list illustrates a few examples of how interior design is critical to good sustainable design, and complying with required criteria:

a. Integrated Design (participate early to ensure compliance with all applicable sustainable requirements)

b. Commissioning (verify the systems to be commissioned, and if they affect systems furniture or other interior elements such as lighting, under-floor HVAC (energy, ventilation, thermal comfort), and fenestrations (affects color and texture of finishes and shading))

c. Energy (Energy Star or FEMP labeled equipment, such as task lighting)

d. Interior Environmental Quality

- Ventilation/thermal comfort (see Commissioning above)

- Daylighting (location of offices/furniture, reflective surfaces, glare control, dimming controls, etc.)

- Indoor Air Quality (material off-gassing specifications, moisture control of exterior wall, entry way systems)
- Occupant Health and Wellness (part of early integrated design discussion)

e. Impact of Materials

- Recycled content (specification of materials)
- Biobased content (specification of materials)
- Storage/collection of recycled materials (layout consideration)

Refer to UFGS 01 33 29 for Third Party Certification (TPC). Verify the appropriate TPC for each individual project.

C-2.3 SID Items to Consider During Design.

1. Limit the number of similar colors for each material. This will assist the facility management office during maintenance and repairs.
2. In building renovation and addition projects, new interior finishes and colors must be compatible with existing where they occur in areas that are adjacent to occupied areas. More flexibility in selections can be exercised in areas not adjacent to existing occupied areas. Where it is necessary that existing materials be matched closely, include both a manufacturer and color reference for the contractor to prepare his bid, and the requirement to match the existing materials for the actual construction process.
3. Uniformity of window covering color and material must be maintained to the maximum extent possible within a building.
4. Solid surface material colors must not be too dark since they show water marks and scratches. Countertops at sinks must be light to medium range in color to help hide water spotting.
5. Color of ceramic and porcelain tile grout must be at a minimum a medium range color to help hide soiling.
6. Finish colors of fire extinguisher cabinets, receptacle bodies and plates, fire alarms/warning lights, emergency lighting, and other miscellaneous items must be coordinated with the building interior design. Color of equipment items on ceilings (such as speakers, smoke detectors, and grills) shall match the ceiling color.
7. Specifications must not be proprietary.
8. Provide finish and color selections that help hide soiling and are easy to maintain.

C-2.4 FF&E Items to Consider During Design.

1. Coordination is required with the contracting office to ensure that the FF&E package is procurable.

2. The interior designer is to provide a FF&E design which includes all services and information necessary for a complete and procurable package. The designer shall ensure that the FF&E design and building-related design schemes are coordinated.

3. Specify furniture from within a manufacturer's family wherever possible while ensuring aesthetic, quality and functionality are not compromised.

4. Provide furniture from manufacturer's standard product line as shown in the most recent published price list or amendment. Custom products are not recommended.

5. Specify seating upholstery that meets the following Wyzenbeek Abrasion Testing unless otherwise noted: 55,000 minimum double rubs for regular use areas and 100,000 minimum double rubs for high use areas. HNC requires the use of seating upholstery that meets 100,000 minimum double rubs.

6. Specify a topical or inherent soil retardant treatment on fabric where appropriate.

7. Furniture specified and furniture layout must allow access to building power and communication where required.

8. Coordinate furniture layout with locations of SIPRNET and NIPRNET, and other secure communications as applicable. Ensure required SIPRNET and NIPRNET separation requirements are met.

9. Furniture must not block windows or negatively impact the perimeter heating and cooling systems.

10. Furniture layout must allow for easy access to HVAC equipment for routine maintenance.

11. Existing furniture must be inventoried for reuse and incorporated into the furniture layout when applicable. Any new furniture required must be compatible with and complementary to the existing furniture.

FOREWORD

The Unified Facilities Criteria (UFC) system is prescribed by MIL-STD 3007, and provides planning, design, construction, sustainment, restoration, and modernization criteria, and applies to the Military Departments, the Defense Agencies, and the DoD Field Activities in accordance with USD (AT&L) Memorandum dated 29 May 2002. UFC will be used for all DoD projects and work for other customers where appropriate. All construction outside of the United States, its territories, and possessions is also governed by Status of Forces Agreements (SOFA), Host Nation Funded Construction Agreements (HNFA), and in some instances, Bilateral Infrastructure Agreements (BIA). Therefore, the acquisition team must ensure compliance with the most stringent of the UFC, the SOFA, the HNFA, and the BIA, as applicable.

UFC are living documents and will be periodically reviewed, updated, and made available to users as part of the Military Department's responsibility for providing technical criteria for military construction. Headquarters, U.S. Army Corps of Engineers (HQUSACE), Naval Facilities Engineering Systems Command (NAVFAC), and Air Force Civil Engineer Center (AFCEC) are responsible for administration of the UFC system. Technical content of UFC is the responsibility of the cognizant DoD working group. Defense Agencies should contact the respective DoD Working Group for document interpretation and improvements. Recommended changes with supporting rationale may be sent to the respective DoD working group by submitting a Criteria Change Request (CCR) via the Internet site listed below.

UFC are effective upon issuance and are distributed only in electronic media from the following source:

- Whole Building Design Guide website http://www.wbdg.org/dod.

Refer to UFC 1-200-01, *DoD Building Code*, for implementation of new issuances on projects.

CHAPTER 1 INTRODUCTION

1-1 BACKGROUND.

The field of Arctic and Subarctic engineering, also known as cold regions engineering, covers a wide range of multidisciplinary topics and principles. Unique issues exist in the planning, design, construction, and operation of infrastructure and facilities in Arctic and Subarctic regions. Among them are permafrost, seasonal ground frost heave and thaw settlement, extreme low temperatures, high wind loads, heavy snow loads, and remote construction sites. Additionally, the implications of the rapidly changing climate in Arctic and Subarctic regions exacerbate these unique challenges.

This Unified Facilities Criteria (UFC) Arctic and Subarctic series includes five volumes that summarize relevant information and the most feasible approaches and solutions for planning, design, construction, and maintenance of infrastructure and facilities in the Arctic and Subarctic areas of the globe.

1-2 NEED FOR SPECIAL APPROACHES.

Cold regions engineering involves design and construction in locations that experience extreme, low-temperature conditions with freezing and thawing periods. In the design, construction, and maintenance of facilities such as buildings, roads, utilities, embankments, and other improvements in the Arctic and Subarctic regions, many problems are encountered that do not exist, or are not present to the same degree, in temperate regions. These problems have several causes:

- The presence of permafrost, with its potential for thaw and subsequent thaw settlement.
- The special properties of frozen soil, frozen rock, and ice
- The effects of frost action, specifically frost heave, in soil, rock, pavement, and other materials subject to intense annual freeze–thaw cycles.
- Drainage, water supply, and sewer disposal problems specific to those regions.
- The effects of solutes and the influence of salinity on frozen-soil properties
- The effects of changing climate, which present new challenges and environmental constraints.
- Other factors, such as the shortness of the above-freezing summer season, as well as the limited amount of daylight in fall and winter; environmental aspects; and difficult conditions for transportation, access, material and equipment supplies, and communications.

1-3 REISSUES AND CANCELS.

This document supersedes and cancels inactivated UFC 3-130-01, dated 16 January 2004.

1-4 PURPOSE AND SCOPE.

The Arctic and Subarctic UFC series provides technical guidance and available technical requirements for planning, design, construction, and maintenance of DoD facilities worldwide for all service elements in Arctic and Subarctic environments. These guidance and technical requirements are based on the International Building Code (IBC) and the requirements in UFC 1-200-01. The UFC 3-130 series covers many aspects of Arctic and Subarctic engineering with the specific exception pavements, which is incorporated into the UFC 3-250 and 3-260 series as discussed in paragraph 1-6.3. In addition to this volume, there are four other series volumes:

- UFC 3-130-02, *Arctic and Subarctic Site Assessment and Selection*. UFC 3-130-02 provides applicability and technical guidance for geotechnical site assessment for the Arctic and Subarctic environment conditions.
- UFC 3-130-03, *Arctic and Subarctic Foundations for Freezing and Thawing Conditions*. UFC 3-130-03 includes horizontal and vertical foundations, considerations affecting foundation design, and construction and monitoring of facilities in the Arctic and Subarctic areas.
- UFC 3-130-04, *Arctic and Subarctic Buildings*. UFC 3-130-04 includes building design in the Arctic and Subarctic areas.
- UFC 3-130-05, *Arctic and Subarctic Utilities*. UFC 3-130-05 provides criteria and guidance for the design of utility systems for military facilities in Arctic and Subarctic regions.

UFC 3-130-01 serves as an introduction to the Arctic and Subarctic UFC series. It includes background information, data, and engineering considerations pertaining to the various elements of Arctic and Subarctic facility planning and design presented elsewhere in the series. Chapter 2 defines Arctic and Subarctic regions. Appendix B defines terms unique to cold regions and cold regions engineering. This volume also introduces risk assessment and resilience in terms of cold regions engineering. These are emerging topics in Arctic and Subarctic infrastructure, whose development is critical to planning sustainable projects. UFC 3-130-01 is not all inclusive. Other resources are cited to provide additional sources of information. The revision of the Arctic and Subarctic UFC series provides state-of-the-practice criteria and guidance for engineers, architects, and planners when planning, designing, and constructing DoD infrastructure in cold regions.[1]

1-5 APPLICABILITY.

This UFC follows the same applicability as UFC 1-200-01, paragraph 1-3, for those geographic locations in Arctic and Subarctic regions worldwide.

[1] *New Construction Criteria for a Changing Arctic and Subarctic: The UFC 3-130 Series Revision Process,* Bjella et al.

1-6 GENERAL BUILDING REQUIREMENTS.

This UFC is an integrated part of the Arctic and Subarctic UFC 3-130 series. Use the other documents of this series in conjunction with this UFC to address construction aspects unique to cold regions. See Chapter 2 for the definitions of Arctic and Subarctic.

Often, conventional construction practices are acceptable in Arctic and Subarctic regions with appropriate modification to account for extreme cold temperatures, frost heaving soils, and permafrost areas. This UFC modifies and supplements the criteria found in the core UFCs. Utility provider's or Installation specific requirements must be considered.

1-6.1 Structural.

Use UFC 3-301-01 for the design and analysis of DoD buildings and other DoD structures. Also, use UFC 3-301-02 for Risk Category V structures.

1-6.2 Geotechnical.

It is essential for engineers to consider the effects of extreme low temperatures, freeze and thaw conditions, variable soil conditions, snow and ice, and drainage on soil properties such as bearing capacity and other geotechnical engineering requirements. Geotechnical investigations must be tailored to the individual projects and sites.

1-6.3 Pavements.

Comply with the UFC 3-250 and UFC 3-260 series. These series provide technical requirements and guidance for roads, pavements, and airfield design, construction, and maintenance. Note that pavements in the Arctic and Subarctic present unique challenges. Unlike the temperate pavements, it is essential for engineers to consider the effects of extreme low temperatures, freeze and thaw conditions, bearing capacity, material behavior, snow and ice, variable soil conditions and material properties, and drainage or the effects of groundwater in the pavement structure. Several cold regions textbooks include detailed information on pavements topics:

- *Cold Regions Pavement Engineering*, by Doré and Zubeck;
- *Introduction to Cold Regions Engineering*, by Freitag and McFadden;
- Permafrost Engineering Design and Construction, by Johnston; and
- *Construction in Cold Regions: A Guide for Planners, Engineers, Contractors, and Managers*, by McFadden and Bennett.

These texts include design methodologies, material selection, approaches for proper calculations of structural design, strategies for constructing new roads, recommendations for rehabilitating old or damaged surfaces, maintenance techniques, as well as case studies of problems and respective solutions.

1-7 CYBERSECURITY.

All facility-related control systems (including systems separate from a utility monitoring and control system) must be planned, designed, acquired, executed, and maintained in accordance with UFC 4-010-06, and as required by individual Service Implementation Policy.

1-8 LEVEL OF CONSTRUCTION.

See UFC 1-200-01, paragraph 1-3.2, for the definitions of permanent construction, temporary construction, and facilities in support of military operations.

1-9 MODULAR OR NONPERMANENT FACILITIES.

Use UFC 1-201-01 for the minimum requirements for life safety and habitability-related design of nonpermanent facilities for use by DoD in support of military operations. This includes portable structures intended for use up to 3 months, 24 months, 60 months (5 years), and semipermanent facilities that can be extended to 25 years. Portable structures require specific foundation considerations for placement on the frozen ground (see UFC 3-130-03). Additionally, the effects of extreme low temperatures in the Arctic and Subarctic environment, including freeze and thaw conditions, snow drifting or snow and ice effects, and material behavior of the structures, must be determined.

1-10 PERSONNEL REQUIREMENTS.

Engineering decisions for the planning, design, construction, and maintenance of infrastructure in Arctic and Subarctic regions are based not only on applicable federal, state, and local codes but also on the expertise of engineers or practitioners with experience dealing with the unique conditions and the extreme weather of these regions. The intent of this UFC, and the Arctic and Subarctic UFC series, is to provide requirements and guidance to prevent significant missteps in the planning, design, and construction of cold regions infrastructure. Consultation with experienced engineers at the Command, District, and Installation level is required to ensure technologies and practices that are unsuitable for this environment, or a specific location, are not proposed. This UFC provides indicators of potential problem areas that may require unique engineering solutions outside the realm of those seen in temperate or standard construction practice.

The Engineer of Record or Designer of Record (DoR) must be a registered design professional, defined as an individual licensed to practice engineering in the project area; knowledgeable in the design and construction of infrastructure in Arctic and Subarctic areas; and experienced with the permafrost, frozen ground, and other geotechnical and climate conditions found in these regions. Some jurisdictions require licensure in the location of the project to obtain permits and approvals.

1-11 PLANNING.

Follow the site planning requirements as described in UFC 3-201-01. This includes environmental requirements, land-use restrictions, building setbacks, flood hazard areas, utility connections, utility offsets, vehicle circulation, buffers from natural and manmade features, and other similar requirements. Use UFC 3-201-01 prior to starting design to determine specific project requirements (such as demolition, site development, water distribution, and wastewater collection). Familiarization with the UFC 3-130 series at the planning stage is advisable to anticipate and prepare for issues of concern for structure and infrastructure development in Arctic and Subarctic areas.

1-12 APPLICABLE POLICIES AND PROGRAMS.

Comply with UFC- 3-201-01 for National Environmental Policy Act (NEPA) actions. NEPA is not unique to climate regions.

Arctic and Subarctic military facilities can either benefit or adversely impact the environment, affecting the air, water, land, local ecology, and socioeconomic environment. Despite low population density and minimal development, the fragile nature of the ecology of the Arctic and Subarctic has attracted the attention of environmental groups. Actions that may meet the criteria for a Categorical Exclusion (CX or CATEX) at other locations may not apply in the Arctic and Subarctic. Areas of particular concern in the Arctic and Subarctic include, but are not limited to, threatened and endangered species and habitat; wetlands; migratory birds; and historic, archaeological, and cultural resources for both Indigenous peoples and early settlers.

1-13 APPROVALS AND PERMITS.

During the planning, design, and construction of the project, the DoR will be responsible for obtaining all necessary permits and approvals and for complying with all applicable laws, codes, and regulations, or overseas equivalent. Regulatory authorities may be at the federal (to include Occupational Safety and Health Administration [OSHA]), state, or local level. In the United States and its territories and possessions, the government will review permits for acceptability. In locations outside the United States and its territories and possessions with Host Nation agreements, follow permit approval procedure as directed in the project scope and by the Government Project Manager. In locations outside the United States and its territories and possessions without Host Nation agreements, the government will review and approve plans for compliance. Consult with the Government Project Manager to determine the appropriate signatories for permit applications.

1-14 SAFETY CONSIDERATIONS.

1-14.1 Facility Safety.

Use UFC 1-200-01, paragraph 1-6.3.4, for facility-safety-related requirements. All DoD facilities must comply with Department of Defense Instruction DoDI 6055.01 and applicable OSHA safety and health standards.

1-14.2 Safety for Geotechnical Investigations.

Comply with UFC 3-220-01, paragraph 2-4.2.

1-14.3 General Safety for Cold Regions Operations.

Awareness of safety aspects relevant to field activities is especially important in the Arctic and Subarctic. Consider safety awareness and planning when conducting site reconnaissance or field assessment for site planning and construction, including but not limited to

- cold weather hazards such as freezing injuries, dehydration, hypothermia, frostbite;
- encountering wildlife;
- visibility;
- slip and fall hazards on snow and ice surfaces and uneven terrain;
- limited daylight during the winter months; and
- site-specific safety and health plan considering support contingencies at remote locations.

1-15 BEST PRACTICES.

Appendix A identifies background information; lessons learned; and proven best practices, methodology and approaches pertinent to engineering planning, design, and construction in Arctic and Subarctic locations. The DoR must review and interpret this guidance as it conforms to criteria and contract requirements and apply the information according to the needs of the project. If a Best Practices document guideline differs from any UFC, the UFC takes precedence. For Best Practices guidelines not discussed in the UFCs, the DoR must submit to the Government Project Manager a list of the guidelines or requirements being used for the project with documentation sufficient for review and approval prior to completing design.

1-16 GLOSSARY.

Appendix B contains acronyms, abbreviations, and a list of terms used in this document and are specific to cold regions engineering, design, and construction.

1-17 SUPPLEMENTAL RESOURCES.

Appendix C provides supplemental resources on subjects related to Arctic and Subarctic engineering, design, and construction. These resources are valuable tools to the engineer for additional information on topics pertinent to and affiliated with cold regions engineering. It also identifies additional background information and resources for accomplishing building design and construction in Arctic and Subarctic regions.

1-18 REFERENCES.

Appendix D contains a list of references used in this document. The publication date of the code or standard is not included in this document. Unless otherwise specified, the most recent edition of the referenced publication applies.

This Page Intentionally Left Blank

CHAPTER 2 ARCTIC AND SUBARCTIC ENVIRONMENT AND CLIMATE

2-1 INTRODUCTION.

This chapter provides background information on the environment, site characteristics, and climate conditions unique to Arctic and Subarctic regions for engineering, design, construction, and maintenance of facilities and other infrastructure. The topics include permafrost and ground ice, permafrost structure and stability, geomorphic features, permafrost structure, climatic conditions (such as air-temperature distribution, design freezing index, ground temperature, snow, wind, and visibility), climate change, vegetation, wildfires, seismic condition, and freeze and thaw of soils.

For the purposes of the UFC 3-130 series, the Arctic is characterized by mean annual temperature ranges between below 32°F (0°C) for the coldest month and below 50°F (10°C) for the warmest month of the year (see Appendix B, paragraph B-3.2).[1] Generally, Arctic conditions are found north of the Arctic Circle (approximate latitude of 66°33' N). The Arctic Circle marks the latitude above which the sun does not set on the summer solstice and does not rise on the winter solstice. The Subarctic is characterized by mean annual temperature ranges between below 32°F (0°C) for the coldest month and above 50°F (10°C) for the warmest month (see Appendix B, paragraph B-3.2). Subarctic conditions are generally south of the Arctic and north of temperate forests, between latitudes 50° N and 70° N. Other cold regions, with similar temperature and ground conditions, exist in the Aleutian Islands and at high altitudes in mountainous areas of the globe and therefore warrant cold regions engineering considerations. Additional discussion of Arctic and Subarctic conditions as they pertain to each specific topic are found in the other documents of the UFC 3-130 series.

2-2 PERMAFROST AND GROUND-ICE DISTRIBUTION.

Permafrost boundaries further define the Arctic and Subarctic regions. Permafrost distribution is divided into classifications, including continuous permafrost, discontinuous permafrost, sporadic permafrost, and isolated patches. Permafrost extent provides general information on ground-ice content (Figures 2-1 and 2-2). See Appendix A, paragraph A-5, for additional information on permafrost extent and distribution under natural, undisturbed ground cover conditions in the area with a mean annual air temperature of 21°F to 30°F (−6.1°C to −1.1°C). Surface temperatures are potentially available from global observational networks or from observation stations. Actual ground-temperature measurement at the specific location provides more-accurate information of the site conditions. The existence of perennially below-freezing ground temperatures is a result of many factors other than air temperatures, including solar radiation, surface cover, snow cover, wind, soil type, soil moisture content, groundwater flow, and presence of stationary or moving surface water. Landscape changes due to

[1] The way the Arctic and its location are defined varies based on the topic of concern. Many of the common definitions are based on scientific, climatic, geologic, biologic, marine, and political considerations. Cold regions engineers define the Arctic and Subarctic regions in terms of permafrost boundaries, ice contents, ground temperatures, air temperature (freezing-degree days), snow and ice distribution, and other factors that influence design and construction.

land developments, forest fires, or stream meandering may alter permafrost conditions over many years.

Figure 2-1 Circum-Arctic Map of Permafrost and Ground-Ice Conditions

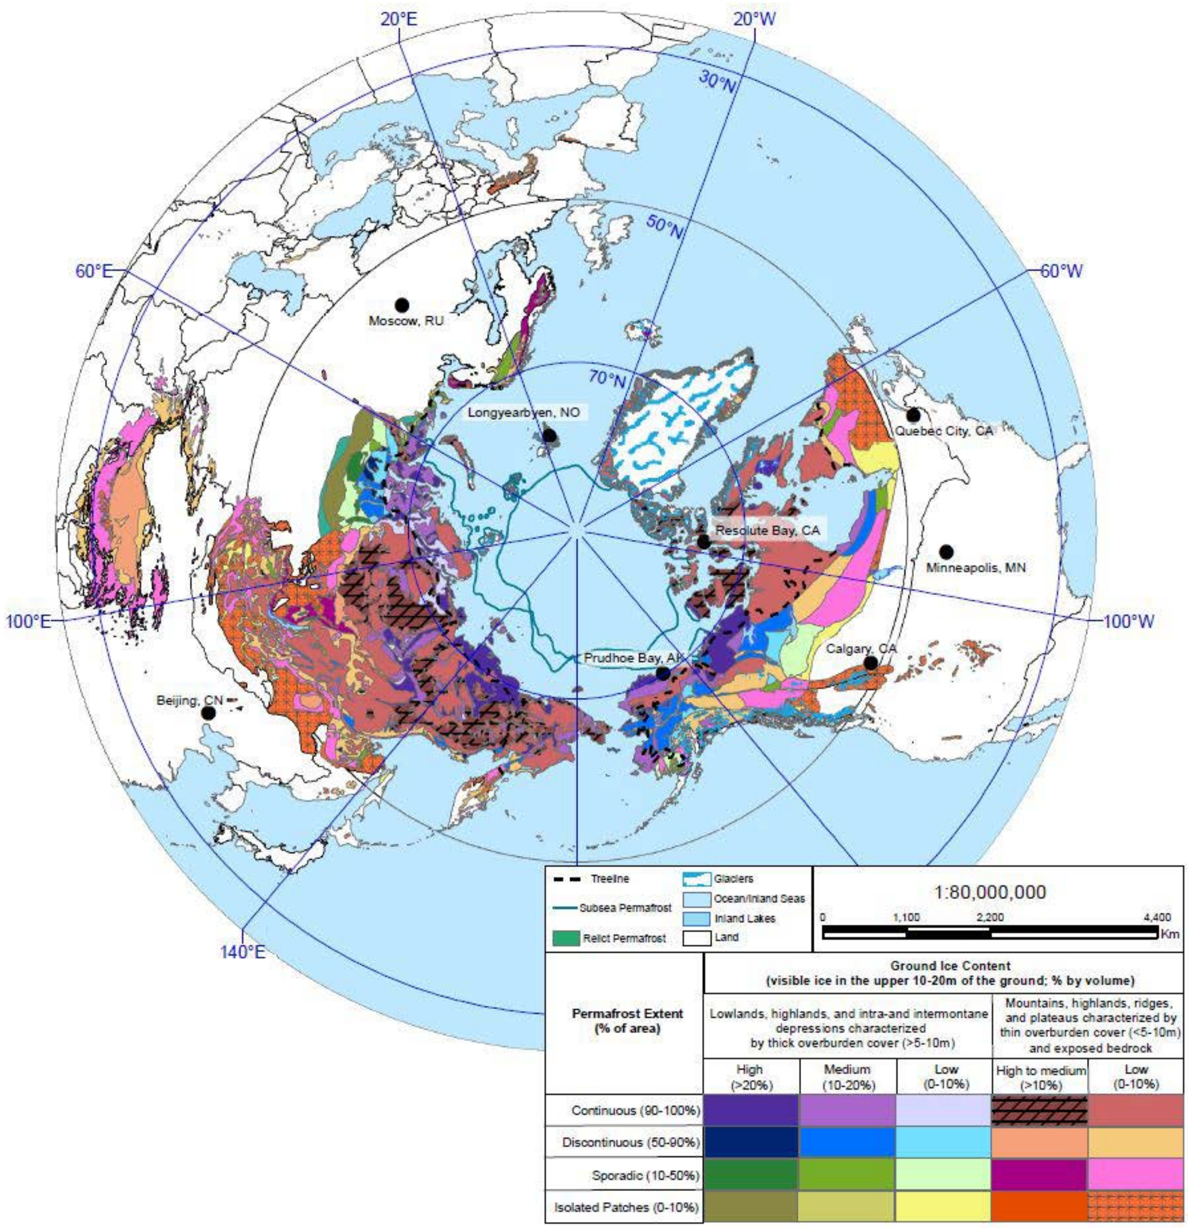

Figure 2-2 Permafrost Conditions in Alaska

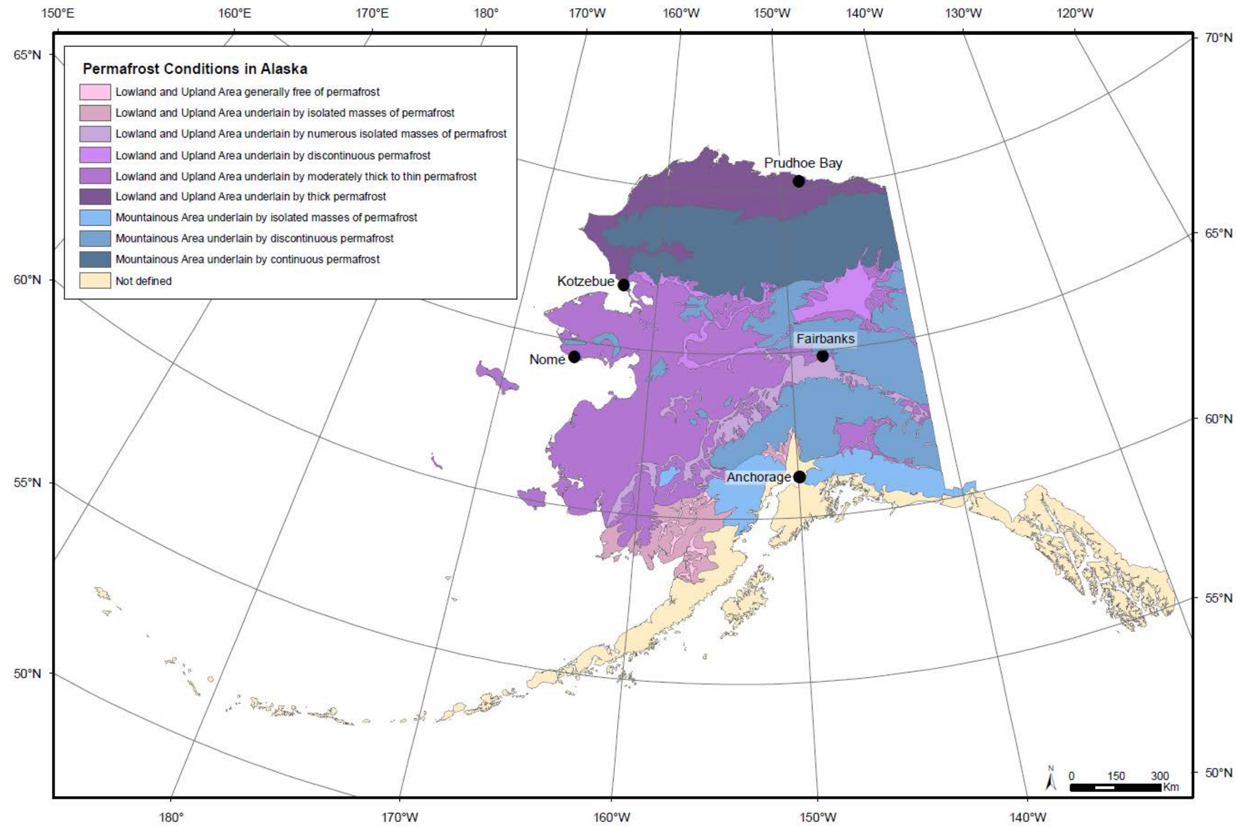


2-3 GEOMORPHOLOGY AND SURFICIAL FEATURES.

Understanding the geomorphic features of the permafrost landforms is important in the design and construction of facilities in the cold regions. Thus, guidance for design and construction in Arctic and Subarctic environments requires thorough consideration of ground characteristics, climatic information, and local thermal conditions, as well as the physical, mechanical, and thermal properties of the permafrost and seasonally frozen ground. See Appendix A, paragraph A-5.1, for additional resources on this topic.

The cold regions landforms are unique geomorphic features produced from frost action, permafrost degradation, mass degenerative and other geologic processes, or cryogenic actions in the active layer and in permanently frozen ground. These features include solifluction markings, pingos, thermokarst depressions, and patterned ground. They can serve as important indicators of ground conditions, such as the likelihood of permafrost and ground ice.

2-3.1 Polygonal Ground.

Areas of intensive frost action, common in Arctic and Subarctic regions, can result in the formation of surface expressions such as polygonal-patterned ground or polygons. Polygons can range in size from several feet to hundreds of feet in diameter and generally have four to eight sides. Ice-wedge polygons are grouped into either high centered or low centered. Low-centered polygons, where water is ponded in the middle of the polygon, indicate climatic conditions conducive to maintain the environment in the frozen condition. High-centered polygons, where water is not ponded in the middle but along the margins of the polygon, indicate the overall thermal regime is creating a thawing permafrost environment. In general, the existence of polygonal features indicates a very high probability that permafrost exists.

2-3.2 Pingo.

Pingos are good indicators of permafrost as they are very rare outside continuous permafrost zones. They are formed as permafrost creates hydraulic pressure on liquid water beneath an overlying, confining layer of soil, focused on a single area, where it forms a massive ice lens and causes the ground surface to heave upward dramatically.

2-3.3 Thermokarst.

While there are several different types of thaw features, they all have similarly identifiable characteristics, as they are all the result of the same process of permafrost degradation. Thermokarst landform features include hummocks, sinkholes, ravines, caverns, tunnels, thaw lakes, and beaded drainages. Hummocks are mounds many feet in diameter and height and are the result of thaw degradation of the very ice-rich margins of the polygonal terrain. Thawing leaves the soil-rich center of the polygon at a much higher elevation, resulting in recurring mounds across the landscape. Thaw lakes are characterized as rounded or scalloped depressions with sharp or shear banks that often extend into the waterline, with impounded water as evidence of active caving along the edges. These often include trees tilted toward the center of the lake or, in the case of treeless terrain, crevices forming parallel to the edges of the bank. Beaded streams are characterized by a series of small, rounded thaw lakes connected to one another by short waterways. Each rounded thaw lake is the result of both mechanical and thermal erosion. Connecting waterways can follow the strait profile of degrading ice wedges, but this is not always the case. Further evidence of thermokarst and permafrost degradation is the occurrence of “drunken forests,” large numbers of trees at an angle to each other and the ground. Trees off axis are indicative of unstable ground, often due to permafrost in Arctic and Subarctic regions.

2-4 PERMAFROST CHARACTERISTICS.

In Arctic and Subarctic regions, the depth of frost and permafrost is related to both the temperature, duration, and intensity of winter for a given location. Cold regions textbooks provide detailed descriptions of permafrost features. The following summary of the characteristics of permafrost are merely introductory.

2-4.1 Structure.

The structure of permafrost varies and depends on the ground characteristics and local thermal conditions. Permafrost may exist as the following:

- A continuous layer with its upper surface at the bottom of the annual frost zone (active layer) (This is common in Arctic regions.)
- A continuous layer with its upper surface separated from the annual frost zone (active layer) by a residual thaw layer (If the permafrost table is progressively lowering, the subsequent effect is degradation of permafrost.)
- Frozen layers separated by layers of unfrozen material.
- Inclusions of remnants of permafrost in unfrozen ground.

2-4.2 Thickness and Depth.

The thickness of the permafrost layer increases with increasing latitude, being greater in Arctic than in Subarctic regions. The depth to the permafrost layer depends primarily on the magnitude of the air thawing index, the amount of solar radiation that reaches the surface, the surface cover conditions from the previous several years, and the water content and dry unit weight of the soil. Methods for estimating depths of freeze and thaw penetration are described in paragraph 3-5 and are thoroughly discussed in *Frozen Ground Engineering,* by Andersland and Ladanyi.

2-4.3 Factors on Permafrost Structure.

Factors and stability aspects of permafrost must be considered and are described in the following sections.

2-4.3.1 Active Layer.

The active layer refers to the portion of the permafrost soil or soil and rock column from the surface downward, which thaws each summer season to some depth. The depth of thaw is determined by the extent of the previous winter freezing, snow depth, groundwater, soil type, vegetation, slope gradient, and slope aspect. However, the complex nature of the soil thermal regime generally yields varying active layer depths of inches to feet on yearly to decadal scales.

Because the bottom of the active layer transitions to impermeable frozen soils and rock, this confining layer prevents adequate draining of the active layer's moisture, often increasing moisture content to values greater than saturation. During the winter freezing process, the top-down movement of the freeze front creates layers of segregation ice, often inches thick. This segregation ice heaves the active layer soils upwards during the winter season, with subsequent settlement in the next summer's full thawing season. With this repetitive freeze–thaw cycle, active layer soils in the natural or undisturbed state are often very loose with poor bearing capacity and drainage capability.

2-4.3.2 Soil Factors.

As a rule, the characteristics of permafrost will depend on the texture, water content, and temperatures of the soil. Relatively clean sands and gravels located in well-drained positions may not present serious engineering construction problems if they do not contain appreciable amounts of excess ice and are termed thaw stable. Conversely, permafrost consisting of fine-textured soils such as silt, silty-sands, and clays often contain excess volumes of ice in the soil matrix, in lenses, layers, wedges, and veins or other shapes and are termed thaw unstable. See paragraph 3-4 for quantifying soil factors. UFC 3-130-03, Chapter 5, presents information on the strength and other properties of frozen soils. Information on the standard system for classification of frozen soils, frost action, and the strength and thermal properties of frozen soils can be found in cold regions textbooks such as *Frozen Ground Engineering*, by Andersland and Ladanyi.

2-4.3.3 Thaw Stable.

Frozen soils are termed thaw stable if the amount of water contained within a soil matrix (as a direct result of the thawing of ice in the soil) can freely drain away without any settlement and maintain the soil strength.

2-4.3.4 Thaw Unstable.

Frozen soils are termed thaw unstable if they, on thawing, would exhibit loss of strength below normal or exhibit long-term significant settlement as a direct result of the thawing of ice in the soil. Soils that contain an excess of thaw water on melt (greater than available pore space in the material) and soils that do not exhibit particle-to-particle contact in a frozen state due to excess ice, in general, will exhibit settling on thawing.

2-4.3.5 Frost Susceptible Soil.

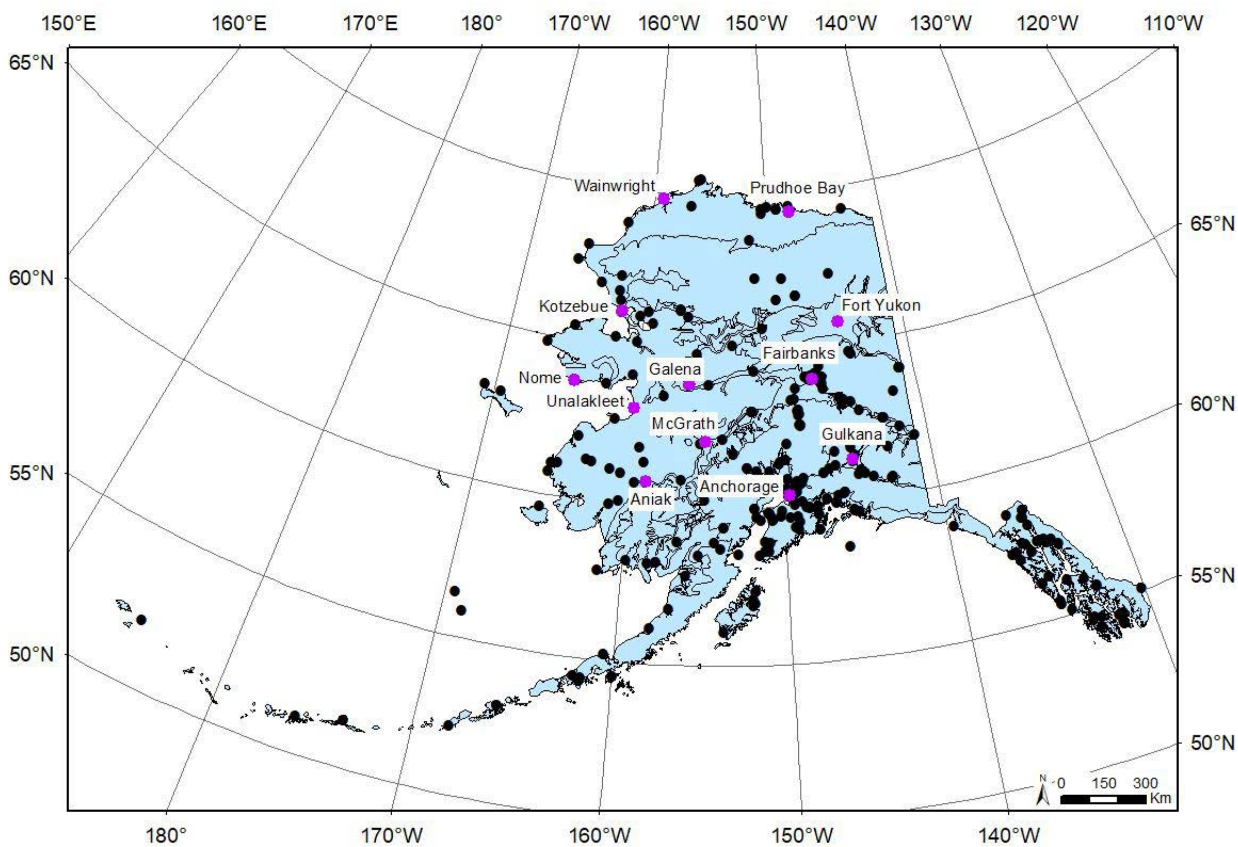
Fine-grained soils such as silty-sands, silts, and clays generally have the ability to wick and retain moisture. Soils located at and near the surface are often inundated with surface and subsurface water flow, so fine-grained soils in the vicinity of these regions will tend to have high moisture levels, with potential to exceed saturation levels. On freezing, the excess amount of soil moisture, when changed to ice, will cause the soil particles to be pushed apart, or disaggregate. The result is the ground surface and any associated structural elements within or on it can be significantly pushed upwards, or heaved. This is most common with pavement materials with poor subsurface drainage but also can occur under foundation elements and floors of structures, causing cracked floors and fractured foundation elements. These soil types are termed frost susceptible.

Structural fill material used for bearing support is considered non–frost susceptible (NFS) when the percentage of the fill material passing the 200 sieve is less than 3% to 5%. Under normal compaction requirements for typical bearing capacity, this low quantity of fines eliminates wicking of moisture and decreases the available pore space volume for water entrainment. Minimizing the entrainment of water also eliminates excess ice development on freezing, preventing disaggregation of the soil particles and frost heaving.

2-5 CLIMATIC CONDITIONS.

Refer to UFC 3-400-02 for an overview of available Engineering Weather Data (EWD) sites and instructions on how to access climate data. A Common Access Card (CAC) is required to access the 14th Weather Squadron's website https://www.climate.af.mil/. For those without a CAC see paragraph 1-6 in UFC 3-400-02 to request EWD. Also, land-based atmospheric observational data, including temperature, dew point, relative humidity, precipitation, and wind speed and direction, are collected and are available online. Ground-based observation records, including those from the Alaska observation stations (Figure 2-3), are available from the National Weather Service (NWS) website; and links to download the data are included in Appendix A, paragraph A-6.

Figure 2-3 Locations of Observation Stations in Alaska



The American National Standards Institute / American Society of Heating, Refrigerating, and Air Conditioning Engineers (ANSI/ASHRAE) Standard 169-2020 covers climate data and climatic zones (based on heating and cooling degree-days) worldwide. For engineering purposes, the general climatic conditions of the Arctic and Subarctic regions are best defined by the prevailing air temperature for the location. The Arctic and Subarctic regions have wide climatic variations; and the climatic conditions differ between the coastal areas and interior locations because of latitude, circulation patterns, and elevation. Atmospheric observations are needed to monitor and examine the climate conditions at a particular location. Definitions based on air temperature are given in Appendix B. See paragraph 2-6 for implications of the changing environments in the Arctic and Subarctic.

2-5.1 Air Temperature.

Air temperatures, which vary significantly from place to place in the Arctic and Subarctic regions, are typically collected by sensors located a few feet above the ground. Distributed air-temperature data sets (minimum, maximum, and mean temperature) for Alaska, and historical 30-year normal data are available online (see Appendix A, paragraph A-6.1, for resources).

2-5.2 Freezing Temperatures.

The patterns of the mean annual temperatures across North American and Eurasian continents are shown in Figures 2-4 and 2-5. On both the North American and Eurasian continents, the lowest mean annual temperature is about 5°F (−15°C). These maps are derived from the WorldIndex database, which is compiled from the Global Surface Summary of Day (GSOD) data. The GSOD data are available at the National Oceanic and Atmospheric Administration (NOAA), National Centers for Environmental Information (NCEI), website https://www.ncei.noaa.gov. The compiled data include the period of record from approximately 1980 to 2017 at various climate stations in North America and in northern Eurasia.[2] See paragraph 2-6 for implications of climate change on air temperatures.

The freezing season, defined as the period when the average daily temperature is below 32°F (0°C), also varies by location. In general, the freezing season begins as early as September in the northern latitudes (Figure 2-6). The freezing season starts when the mean daily temperature stays below freezing for three consecutive days, and it ends when the mean daily temperature begins to remain above freezing for three consecutive days. The average length of the freezing season (in terms of number of days) over the period of record can be more than two hundred days in the northern latitudes (Figures 2-7 and 2-8). Thus, the thawing season can be as late as June (Figure 2-9).

[2] "One-Dimensional Computer Models to Estimate Frost Depth," Barna et al.

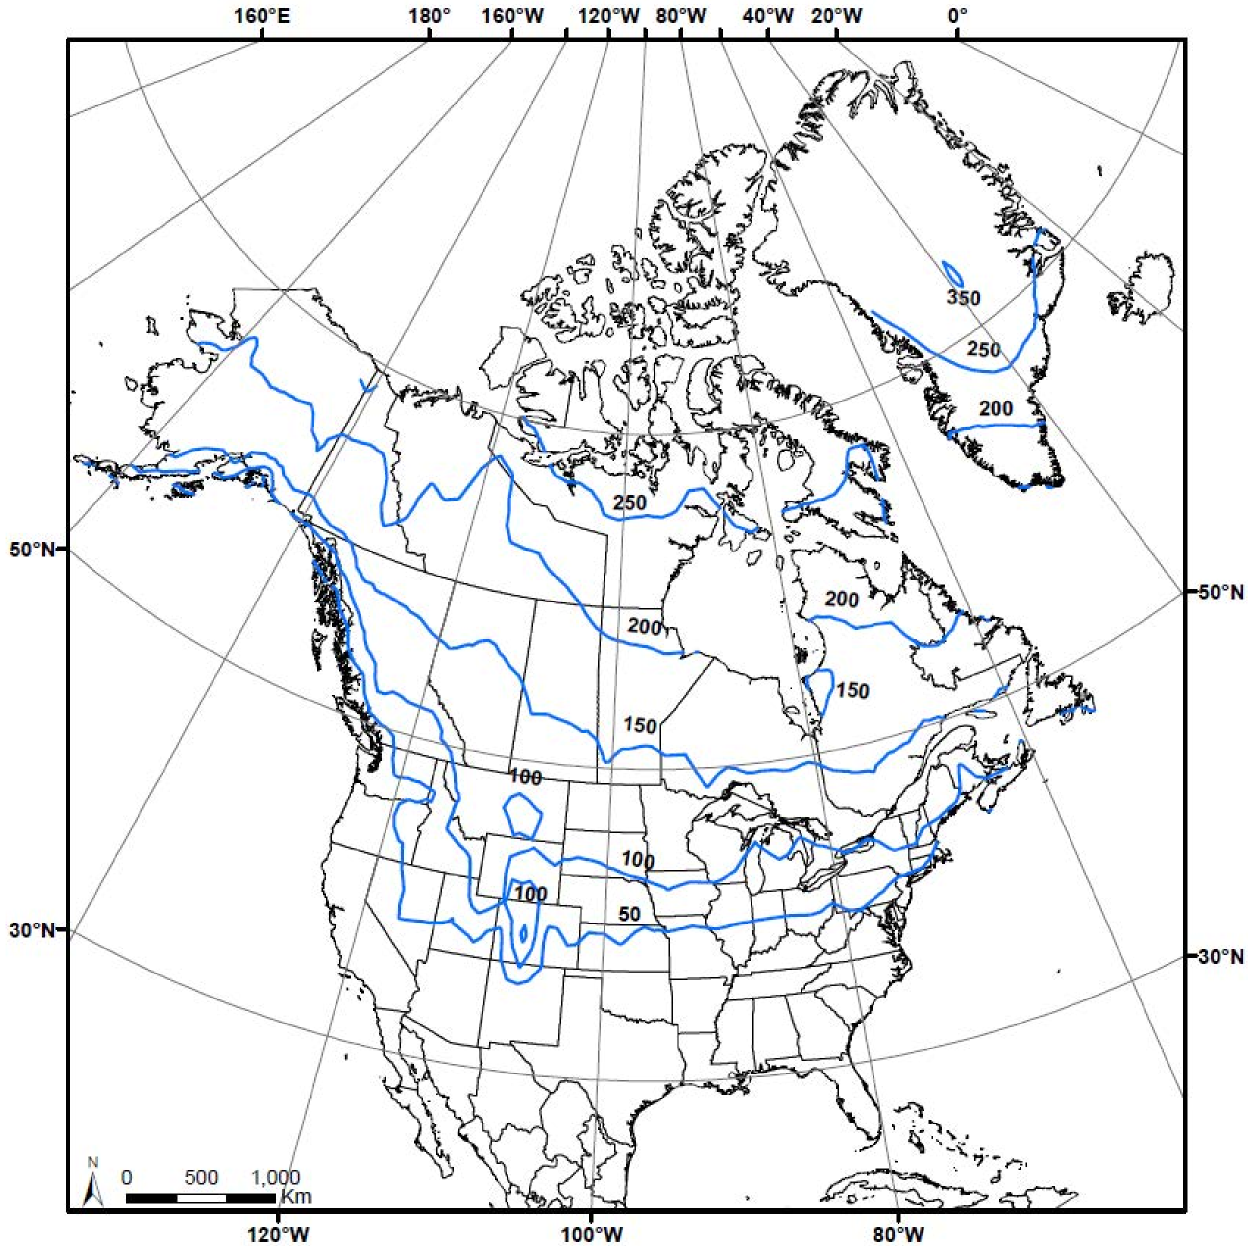

Figure 2-8 Average of the Number of Days in the Freezing Season in Northern Eurasia, Derived over the Period of Record from the WorldIndex Database

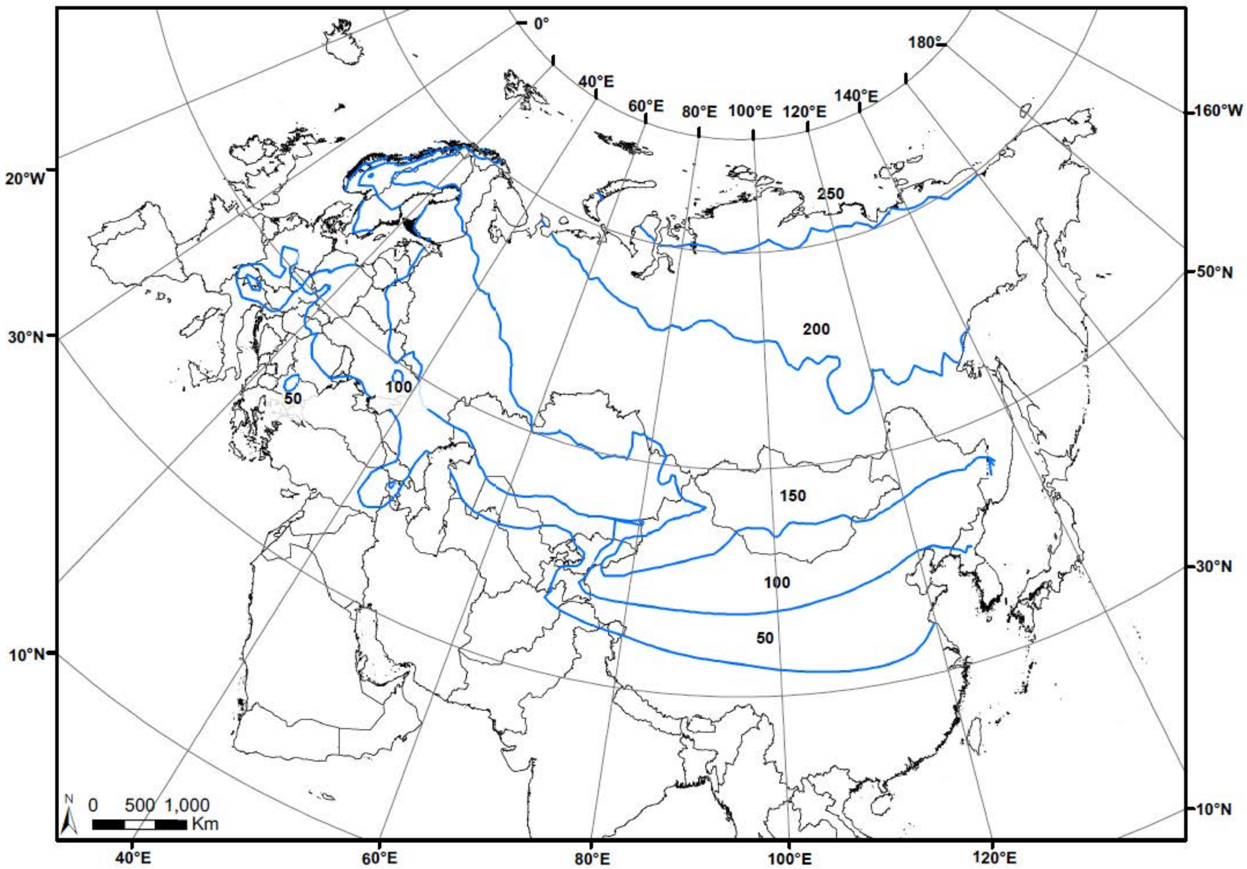

Figure 2-9 Mean Date of the Beginning of the Thawing Season, Derived over the Period of Record from the WorldIndex Database

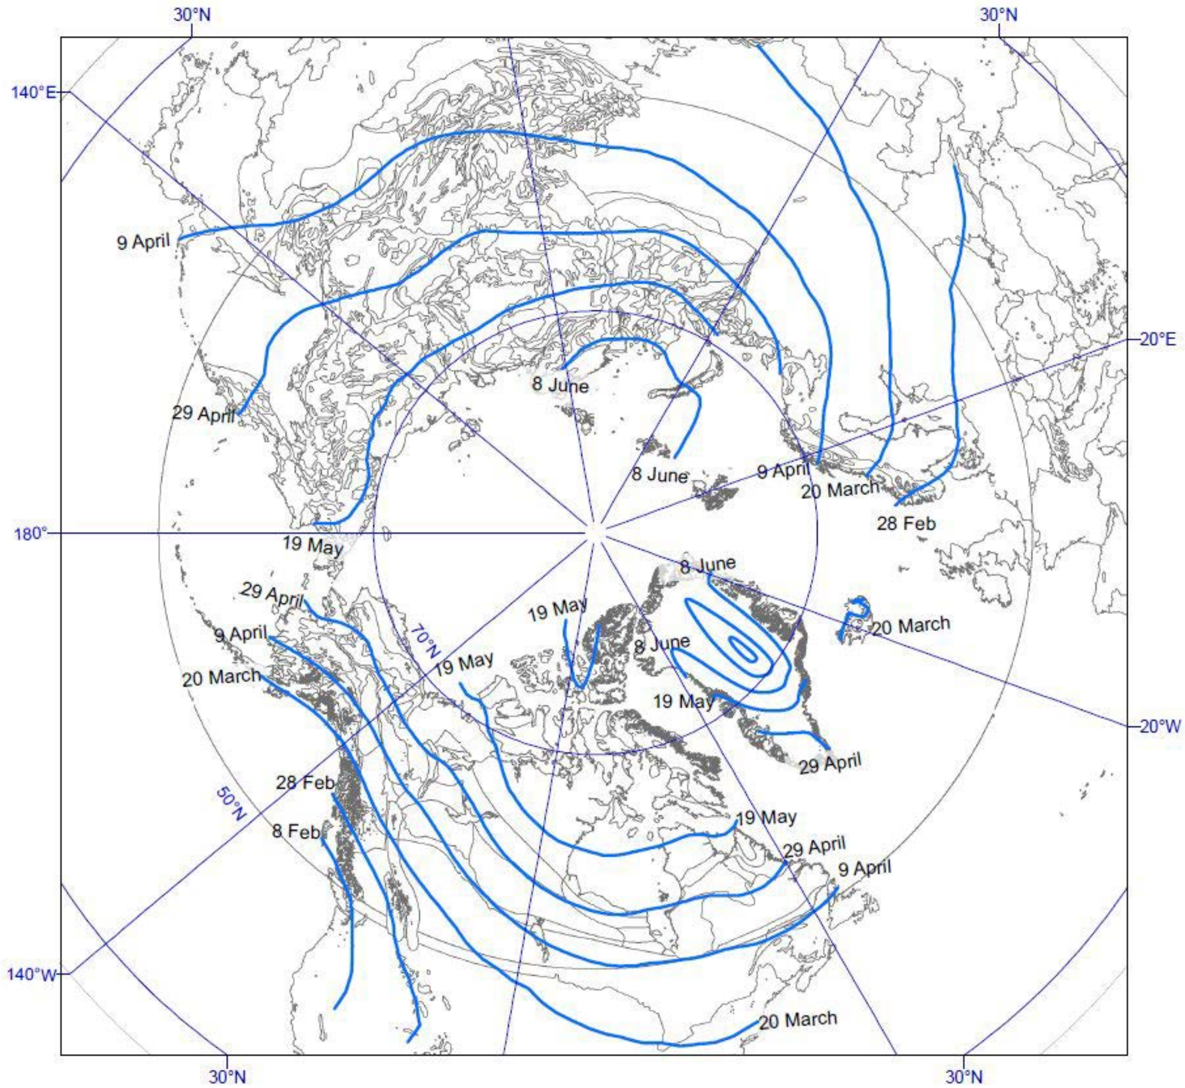

2-5.3 Freezing Index and Design Freezing Index.

Air-temperature records for a given location are also used to quantify the intensity of temperature variation using the degree-day concept. The freezing index is computed as the sum of the number of degrees that the mean daily temperature departs from the freezing point of bulk water (32°F) during the freezing season. See *Frozen Ground Engineering*, by Andersland and Ladanyi, for graphical illustration of cumulative degree-days versus time for determining the freezing index, as well as thawing index. These indices are affected by the changing climate in the Arctic and Subarctic. See paragraph 2-6 for climate change implications.

The design freezing index is an expanded value of the freezing index and is used to account for climatic variations from year to year. The traditional method for calculating the design freezing index is to average the freezing indices of the three coldest winters in the most recent 30 years of weather records. If the weather records are less extensive, the design freezing index is calculated from the coldest winter in ten years. A more modern approach takes advantage of computers to calculate the design freezing index using the mean freezing index plus the product of 1.5 times the standard deviation of the freezing indices for the winters of record.[3] For pavement and foundation designs, comply with this approach for determining design freezing. Figure 2-10 and 2-11 show the estimated design freezing indices using the more modern approach described in "Computer Assisted Calculations of the Depth of Frost Penetration in Pavement-Soil Structures," by Cortez et al., for North America and northern Eurasia.

2-5.4 Ground Temperature.

Ground temperatures vary from one place to another. Ground temperature is a function of many factors other than air temperature. These factors include solar radiation, surface cover, snow cover, wind, soil type, soil moisture content, groundwater flow, and presence of stationary or moving surface water. The periodic fluctuation of ground-surface temperatures produces the diurnal cycle from day to day, season to season, or year to year. Measurements of subsurface temperature profiles are the most suitable to use for design. However, equations for estimating ground-temperature profiles using surface temperature or mean annual temperature data are in cold regions textbooks such as *Frozen Ground Engineering*, by Andersland and Ladanyi.

Data for ground temperatures is not always available for most locations in the Arctic and Subarctic. However, surface temperatures are available for certain locations and are accessible through global observational networks, observation stations, and from models. See Appendix A, paragraph A-6.2 for data resources. See paragraph 2-6 for climate change implications on ground temperatures.

Figure 2-10 Design Freezing Index (°F days) in North America Derived Using the More Modern Approach Described in "Computer Assisted Calculations of the Depth of Frost Penetration in Pavement-Soil Structures," by Cortez et al., over the Period of Record from the WorldIndex Database

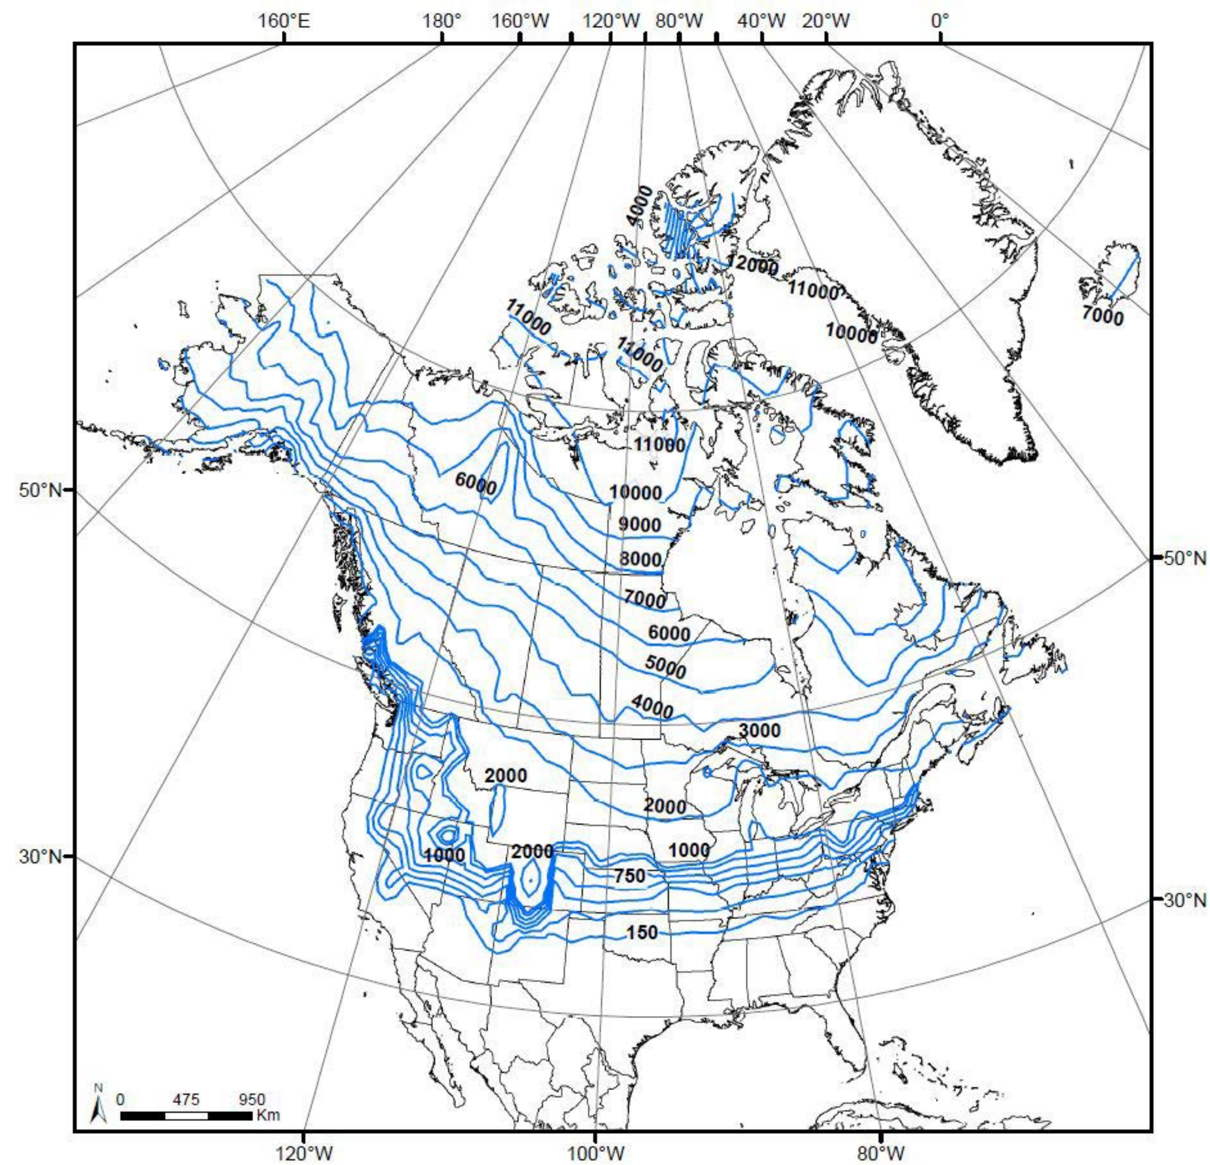

Figure 2-11 Design Freezing Index in Northern Eurasia Derived Using the More Modern Approach Described in "Computer Assisted Calculations of the Depth of Frost Penetration in Pavement-Soil Structures," by Cortez et al., over the Period of Record from the WorldIndex Database

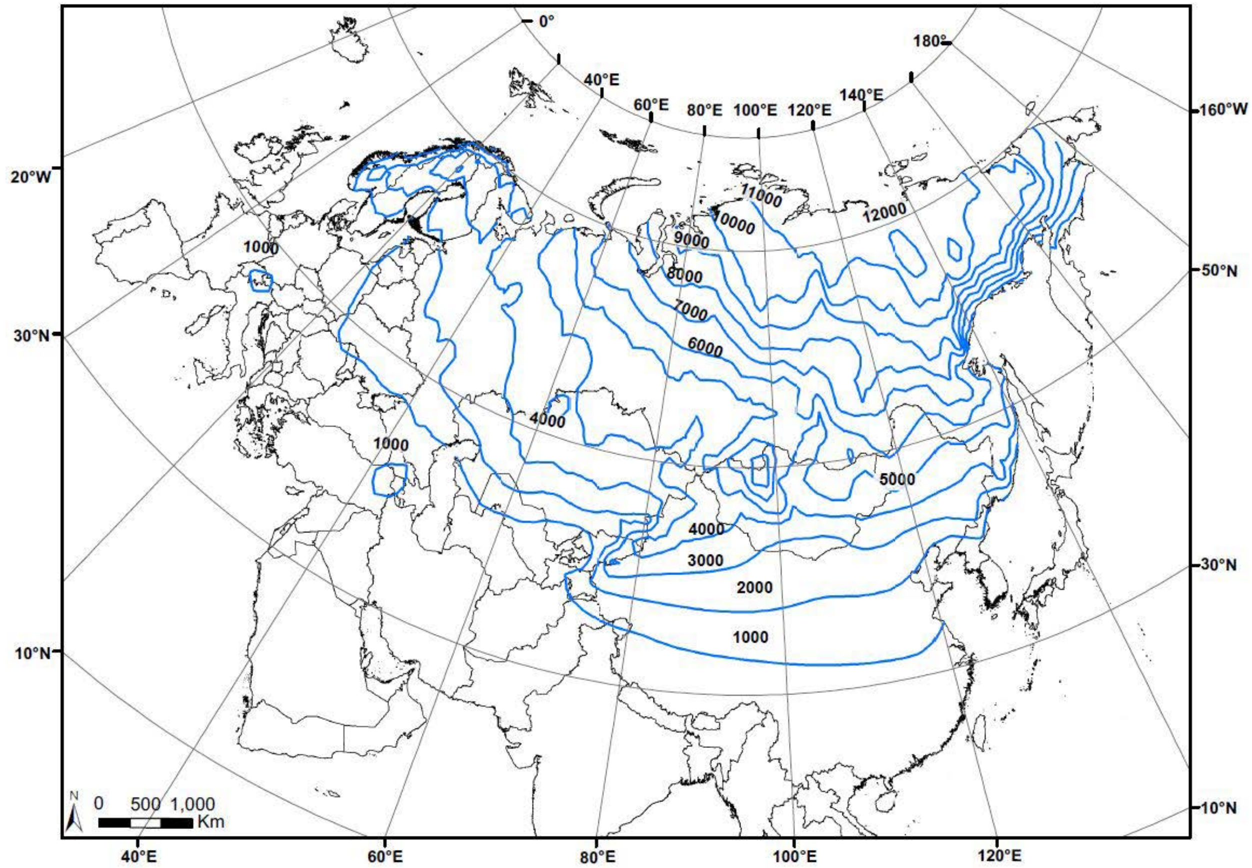

2-5.5 Precipitation and Snow Distribution.

Precipitation and snowfall vary in the Arctic and Subarctic regions due to the complex interactions between the atmosphere, ocean, ice, and snow, as well as global and local processes and environmental changes. Winter has lower rainfall since moisture precipitates as snow. Archives of precipitation observations and other climatic products, like the Operational Climatic Data Summary (OCDS), are available from the U.S. Air Force 14th Weather Squadron for several different stations. Figure 2-12 shows mean monthly and annual precipitation values at selected stations over the observed period of record ending 2020, which are mapped in Figure 2-13. The observed period of record varies by station depending on when the station was established. For Alaska, summaries of climatological conditions such as precipitation, snowfall, and snow depth are also available from NCEI. For additional information, see Appendix A, paragraph A-6.3. Also see paragraph 2-6 for implications of the changing environments on precipitation and snow in the Arctic and Subarctic regions.

Figure 2-12 Mean Monthly and Annual Precipitation in Inches at Selected Stations from the U.S. Air Force 14th Weather Squadron Archived Data

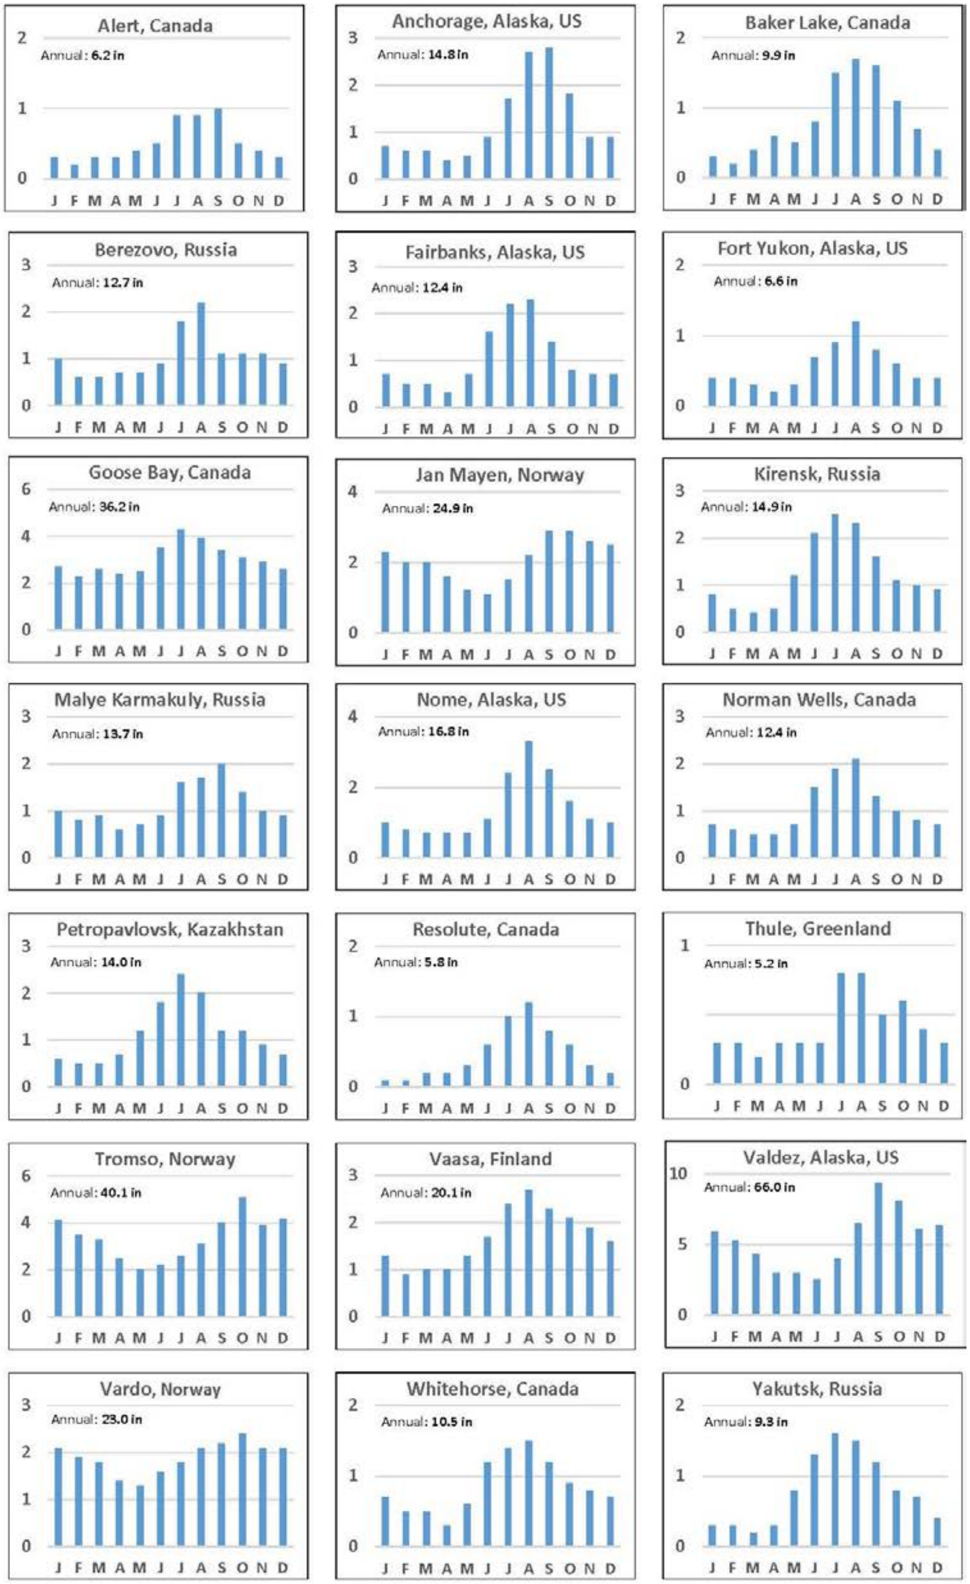

Figure 2-13 Locations of Selected Stations used in Figure 2-12

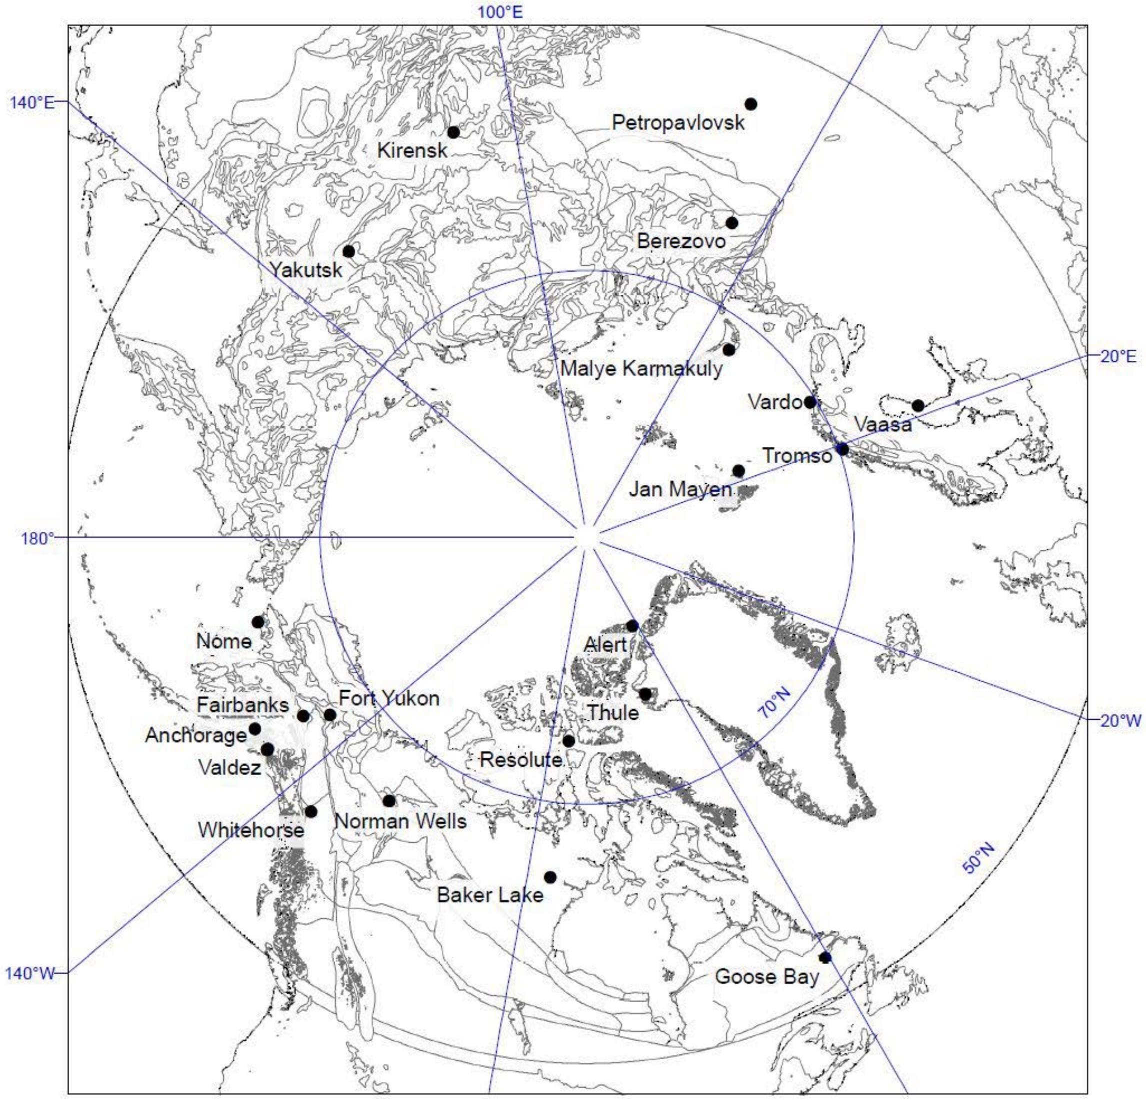


2-5.6 Snow Loads.

Comply with UFC 1-200-01, UFC 3-301-01, and UFC 3-301-02. Base snow load design on American Society of Civil Engineers (ASCE) guidance ASCE 7, *Minimum Design Loads and Associated Criteria for Buildings and Other Structures*. Ground snow load information is available from the following sites:

- The Structural Load Data Tool (SLDT), hosted on the Whole Building Design Guide website https://www.wbdg.org/ar/tools/sldrt
- The ASCE Hazard Tool (https://asce7hazardtool.online/)
- The Structural Engineers Association of Alaska website https://seaak.net/alaska-snow-loads, which provides values in two

formats: 50 year mean recurrence interval values described in ASCE 7 and reliability-targeted values sorted by risk category

- *Site-Specific Case Studies for Determining Ground Snow Loads in the United States,* by Buska et al., which provides additional locations for site-specific case studies in both the Lower-48 states and Alaska.

Note that ground snow loads in ASCE 7 account for rain-on-snow events and include snow water equivalent (SWE) data as needed in the criteria. At locations where the ground snow load is not provided, use the best locally available criteria. With the approval of the Authority Having Jurisdiction (AHJ), completing snow load case studies may clarify and refine snow loads for site-specific conditions.

2-5.7 Snow Drift.

Wind-induced snow movement, or drifting, is a common occurrence that creates a variety of problems for Arctic and Subarctic infrastructure. Considerable drifting snow deposited adjacent to and on structures can create unanticipated extra snow overburden, potentially accelerating the settlement and deformation of these structures, leading to premature failure. The mechanics of the snow-drifting process deal with snow particles lifted by the dynamic forces of the air flow. General engineering guidance to minimize snowdrift problems is described in publications such as *Introduction to Cold Regions Engineering*, by Freitag and McFadden. An updated summary follows:

- Avoid locations in which snowdrifts form, if possible.
- Before deciding on a final site, evaluate or study snow conditions at proposed locations for at least one winter by using aerial and satellite imagery to identify drift features. Analyze historical meteorological data from the site to determine representative wind directions, speeds (and more importantly, dominant snow transport direction and amount as this may differ from prevailing wind directions).[4]
- Identify potential effects of wind-transported snow on the operation of the facility access roads, sidewalks, and parking areas.
- Consider the entire facility when evaluating snow problems.
- Select locations with the least snow transport by considering the fetch distance, winter precipitation, and wind exposure. Where possible, select sites in the snow erosion zone, 490 to 650 ft (150 to 200 m) downwind from a deposition area.
- Chapter 7 in ASCE 7, Minimum Design Loads, contains design guidance for the calculation of different snow loading conditions, including guidance for drifts, sliding, and rain on snow applied to various roofing configurations and scenarios.

[4] "Blowing Snow Transport Analysis for Estimating Drift Orientation and Severity," Haehnel.

Find design guidelines for controlling blowing and drifting snow in *Design Guidelines for the Control of Blowing and Drifting Snow*, by Tabler. Numerical methods are applicable for modeling and evaluating snowdrift conditions. Procedures and methodology from case studies of snow transport and using computational modeling of snowdrifts around a building are listed in Appendix A, paragraph A-13.

2-5.8 Ice Load and Atmospheric Icing.

Comply with UFC 3-301-01 to design ice-sensitive structures that withstand ice loading caused by freezing rain, snow, and in-cloud icing.

Structures are subject to two categories of ice loadings. The first category includes loads caused by the ice formed on lakes and rivers. Structures affected by these loads include dams, locks, bridges, pile-supported structures, wharves, docks, and all structures located immediately on the shoreline. Infrastructure and structures located adjacent to lakes and rivers, such as channel erosion controls and buildings, are also subject to ice loads. These loads tend to occur during ice ride-up events when wind pushes ice onto shore and during wintertime floods, typically caused by river ice jams. See paragraph 2-5.9 for guidance on ice loads from ice formed in lakes and rivers. The second category includes loads caused by freezing rain, snow, and in-cloud icing. This category is referred to as atmospheric icing. Structures that are sensitive to atmospheric icing include, but are not limited to, lattice structures, guyed masts, overhead lines, light suspension and cable-stayed bridges, aerial cable systems (such as for ski lifts and logging operations), open catwalks and platforms, flagpoles, and signs. ASCE 7 describes the requirements to design these types of structures to withstand atmospheric icing. Electric transmission systems and communications towers and masts are also sensitive to atmospheric icing but are not included in ASCE 7 because other national standards exist for these types of structures. See *National Electrical Safety Code* (Institute of Electrical and Electronics Engineers [IEEE C-2]), *Guidelines for Electrical Transmission Line Structural Loading* (ASCE MOP 74), and *Structural Standards for Steel Antenna Towers and Antenna Supporting Structures* (ANSI/EIA/TIA-222).

2-5.9 Ice Cover and Ice on Water Bodies.

The freezing of lakes, rivers, and coastal waters is a major factor controlling scheduling and effectiveness of field activities in the Arctic and Subarctic. Waterways used for boats or float-equipped aircraft are unusable during the freeze period from September through November. Several weeks of freezing temperatures are required before the ice becomes thick enough to support other types of vehicles. During the winter, ice surfaces, or cover, are often extremely valuable as aircraft landing areas and as smooth, obstruction-free surfaces for tractor trains and other forms of surface transportation. See paragraph 3-2 for guidance on ice-engineering-related ice hydraulics and hydrology and paragraph 3-10.3 for ice or snow roads.

2-5.9.1 Ice Thickness and Bearing Capacity.

When a load is placed on an ice cover, the ice cover deflects downwards in response. The amount of deflection is proportional to the magnitude of the load and the flexural rigidity of the ice cover. The ability of the ice cover to support a load is the bearing capacity of the ice cover. The cover deflects until the water pressure on the bottom of the ice cover increases sufficiently to balance the load. The greater the flexural rigidity of an ice cover, the less it deflects and the larger the area over which the ice cover deflects. The two basic parameters that determine flexural rigidity are the ice cover thickness and its elastic modulus (Young's modulus). In practice, elastic modulus of an ice cover is rarely measured in the field due to practical difficulties. In almost all cases, the bearing capacity is estimated based on the ice thickness, an easily measured parameter.

There are some important considerations when estimating the ice thickness needed to achieve a required bearing capacity.

- **Ice Quality.** It is important that the measured ice thickness be competent blue or black ice and that the ice excludes any unfrozen or partially frozen layers. Snow ice, also called white ice, forms when an ice layer covered with snow floods and the saturated surface snow and water layer freezes. Generally, snow ice has less strength than blue or black ice, and its presence downgrades the ice-cover bearing capacity.
- **Creep.** When a load on an ice layer remains at one location, the deflection of the ice increases with time. The additional deflection is known as creep. In effect, creep reduces the bearing capacity of the ice cover with time. For a load close to or at the maximum bearing capacity of the ice cover, creep can lead to an eventual failure and breakthrough. The occurrence of creep requires treating stationary (or long-term) loads placed on ice differently than moving loads.
- **Risk Factor.** The ratio of the load (pounds force) to the square of the ice thickness (square inches) is often referred to by the symbol *A* and is called the risk factor in using the ice cover. The level of risk increases with increasing *A* values. Operational controls are necessary to implement for managing the risk associated on ice cover with an *A* value of higher than 50. For example, closely monitored, one-of-a-kind missions can tolerate relatively high *A* values of 100 or more. On the other hand, heavily trafficked ice covers such as ice roads require *A* values much closer to 50.
- **Minimum Ice Thickness for Lighter Loads**. Generally, a minimum ice thickness of 4 in. (100 mm) is specified for pedestrians (260 lb or 120 kg), 7 in. (175 mm) for snowmobiles with riders (1,100 lb or 50 kg), and 15 in. (380 mm) for 3/4-ton 4×4 vehicles (up to 11,000 lb). When using the risk factor *A* to estimate the required ice thickness for lighter loads, the estimated ice thickness may not be adequate to support the load because

of normally occurring ice thickness variations (see below), unknown spacing between loads, and other considerations.

See Appendix A, paragraph A-12, for additional guidance on estimating bearing capacity, ice thickness with creep, ice risk, and loads.

2-5.9.2 Ice Thickness Variation.

Ice covers on the surface of a body of water increase in thickness due to the formation of new ice on the underside of the ice layer. The thickness of the ice cover and the resulting ice cover bearing capacity are determined by the climatic conditions. The primary parameters controlling ice thickness are the daily average air temperature and the snow-cover depth.

Ice thickness is also affected by Arctic warming trends due to climate change, with warmer-than-average air temperatures, fewer very cold days, river break-up happening earlier, annual precipitation increase, increase in the occurrence of freezing rain, and a shrinking snow season. Milder winters have resulted in later freeze-up dates, earlier break-up dates, or both, for lakes and water bodies.

2-5.10 Wind and Wind Chill.

Comply with UFC 1-200-01, UFC 3-301-01, and UFC 3-301-02. Identify wind loads at all DoD Installations worldwide by using the structural load data tool hosted on the Whole Building Design Guide website https://www.wbdg.org/ar/tools/sldrt. In many parts of the Arctic and Subarctic, where pressure gradients are weak and temperature inversions are common, surface winds are normally low. Where pressure gradients are more marked, however, near seacoasts and mountains, strong winds are quite common; and wind speeds can attain hurricane velocities. Consider the possibility of strong katabatic winds concentrated in valley outlets during site selection. If strong winds are possible, they may especially affect outdoor activities during the colder months. Worker efficiency decreases with lowering air temperatures, and wind significantly increases this effect. See Appendix A, paragraph A-6.4, for data and online resources.

2-5.11 Visibility and Natural Illumination.

Considerations for adverse weather conditions are necessary when conducting site assessment and surveys, particularly in remote locations. Daylight and seasonal variations affect construction. Poor visibility can disrupt operations and increase safety hazards. Visibility problems may arise from ice fog, blowing snow, and whiteout conditions. Localized fog can form over bodies of water. Ice fog is a type of fog consisting of fine ice crystals suspended in the air. Blowing winter snow can cause severe reductions in visibility, compounded by the shortage of natural daylight. Ground blizzards with winds gusting as high as 40 mph (1.6 km/h) create whiteout conditions in blowing snow. Significant drifting of the snow is likely. Whiteout conditions produce a lack of contrast between the sky and the snow surface and are dangerous and disorienting. See Appendix A, paragraph A-6.5, for hazard warnings and advisory resources.

2-6 CLIMATE CHANGE AND PROJECTIONS.

Global climate change trends are expected to accelerate in the Arctic and Subarctic regions and increase challenges for designing, building, and sustaining infrastructure. These changes are expected to affect many of the climatic factors described in paragraph 2-4. Paragraph 2-6 highlights how future projections of these climatic factors are developed and can affect the infrastructure and facilities criteria in the Arctic.

2-6.1 Overall Climate Observations and Projections.

Climate change trends will present an increasing challenge for infrastructure in Arctic and Subarctic environments with observed changes in air temperatures, ice cover, permafrost, coastal erosion, and other factors. However, translating these trends into the future requires considering climate projections developed from climate models under a range of future greenhouse-gas (GHG) emissions scenarios. These are called projections, rather than specific predictions, because they are “what-if” scenarios, where any of the future GHG emissions scenarios are possible, and actual future trends in emissions may not follow any one of them consistently over time. The future GHG emissions scenarios used in climate projections include low-, moderate-, and high-emission rates under Representative Concentration Pathways (RCPs), for example, 4.5, 6.2, and 8.5, to represent the amount of added infrared greenhouse forcing (in watts per square meter). These projections represent the most comprehensive picture of the expected changes on the climatic factors that would affect Arctic and Subarctic infrastructure.

The Scenarios Network for Alaska and Arctic Planning (SNAP) developed climate projections specifically for the Alaskan and Arctic regions that are applicable to infrastructure and building criteria. SNAP uses global climate model results from the Coupled Model Intercomparison Projects (CMIP3 and CMIP5) for twentieth-century conditions and future low-, moderate-, and high-emissions scenarios out to the year 2100. See Appendix A, paragraph A-7, for additional resources and links to the SNAP future climate projections, reports, and related studies documenting the changing Arctic environment, models, and data. The most likely or significant projected climate impacts affecting the design, building, and sustainability of Arctic and Subarctic infrastructure are summarized in the following sections.

2-6.2 Surface Air-Temperature Projections.

Surface air-temperature increases in the Arctic are projected under all GHG emissions scenarios. Even for low-emissions scenarios, models show on average 5.4°F (3°C) warming over much of Eurasia and North America, and more than 7.2°F (4°C) warming over the Arctic in 2081–2100. The high-emissions scenarios show annual increases of 14.4°F to 18°F (8°C to 10°C) in years 2081–2100 across the Arctic.

The local temperature-change projections developed by SNAP for Alaskan regions and locations assess future changes for criteria infrastructure design for each decade from 2040 to 2100. For coastal northwest Alaska, for example, it shows increasing average temperatures by 12°F (6.6°C) in winter and 8°F (4.4°C) in summer by 2050 in the low-emission scenario and 15°F (8.3°C) in winter and 10°F (5.5°C) in summer in the high-emission scenario.

2-6.3 Projections on Permafrost Warming and Thawing.

Increasing air temperatures, both observed and projected, invariably result in warming and thawing permafrost, whose strength and stability are dramatically reduced by warming. The projections of the observed circumpolar degradation of permafrost across North America and Eurasia concluded that nearly 70% of current infrastructure will have damages associated with high thaw potential by 2050.

2-6.4 Precipitation Projections.

Climate projections in all scenarios are highly consistent in showing increasing precipitation in the Arctic and northern latitudes due to higher air temperatures and a northward moisture transport due to a warmer climate. The projected increase for annual precipitation for Alaska is estimated from +10% for low scenarios to +30% for high scenarios. In Fairbanks, for example, the monthly maximum precipitation expected, with a 50-year return period, would increase from 7 in. (175 mm, historical average) to about 10 in. (250 mm) with projected climate change over 2020–2099.

2-6.5 Snow, Rain, and Ice Events.

Future projections of snowfall and snow cover are more variable and uncertain. As greater moisture becomes available for snowfall, and with the increase in mixed precipitation, the SWE would increase. However, increased temperatures also mean a shorter duration of snow cover and an increase in the fraction of rain in storm events, both for “shoulder seasons” (spring and fall) and for winter rain events.

These winter rain events are expected to result in more frequent freezing rain and icing events that impact roadways and damage trees and power lines in regions not previously affected. The increase in SWE and winter rain events may also increase the total weight of snow loads on roofs, compared to historically dry snow. Because ground snow load measurements consider rain-on-snow events, the expected increase in SWE is included in the updated ground snow load criteria.

2-6.6 Sea Ice Cover.

Climate warming dramatically decreases the safety of operating on Arctic Ocean sea ice. The sea ice extent (the area covered by 15% ice concentration) has declined significantly from 1979 to 2021, decreasing by 2.6% per decade for the March maximum extent and decreasing 13.0% per decade for the September minimum extent. In future projections, the Arctic sea ice area steadily decreases significantly by 2050. The Arctic Ocean is likely to be ice-free in summer (less than 0.4 million square miles) at least once before 2050 under all assessed scenarios and consistently ice-free in September by 2050 under the moderate- and high-GHG emissions scenarios.

2-6.7 Coastal Erosion.

The projections of sea level rise, permafrost thawing (paragraph 2-6.3), and sea ice reduction (paragraph 2-6.6) all contribute to an acceleration of coastal erosion rates in the Arctic. The reduction in ice cover along coastlines, specifically during spring and fall, leaves coasts susceptible to greater storm-driven wave activity that can significantly damage coastal infrastructure in addition to eroding the thawing ground.

2-6.8 River Discharge.

The increases in precipitation (paragraph 2-6.4) also appear to be driving an overall increasing trend in river discharge across the Arctic. While there is significant year-to-year variability in the amount of discharge, there are many natural terrestrial effects and water management activities that will affect local river discharge.

2-7 STABILITY AND PERMAFROST DEGRADATION.

Increasing air temperatures and additional frequency of heat waves as discussed in paragraph 2-6 pose risks for irregular thermal thawing of landforms, creating uneven subsidence and thawing of ice-rich permafrost. The degradation processes include inflow of heat energy into the ground, reduction in soil strength or bearing capacity, water migration, and progressive settlement soils containing excess ice. Issues associated with permafrost degradation due to collapse of soil structure include slope instability; coastline and riverbank erosion; and damage to foundations, roads, railways, retaining embankments, and utilities. Consider such potential effects during design. See Appendix A, paragraph A-8, for additional resources.

2-8 VEGETATION AND WILDFIRES.

The three major types of vegetative cover in Arctic and Subarctic areas are tundra, muskeg, and forest. Vegetation types with shallow root systems that occur in wet or poorly drained areas will often occur over shallow depths of permafrost. North American examples of shallow-rooted vegetation commonly overlaying permafrost are black spruce and larch. Ground layers consisting of sphagnum moss (North America) and other thick, spongy insulating ground layers are also high-probability indicators of permafrost. Vegetation types with deeper root systems and requiring better drained soils will occur in areas with deeper occurrences of permafrost, if present. Generally, deciduous tree cover indicates a low probability of shallow permafrost occurrence. Vegetation profiles are useful as indicators of potential permafrost occurrence but should be interpreted in concurrence with other indicators. It is reasonable to assume that areas of homogenous vegetation share similarly homogenous conditions across the same area. UFC 3-130-02 provides further guidance on vegetation for site assessment.

Wildfires or forest fires affect vegetation, promote permafrost thawing, and may alter permafrost conditions over many years. In the Alaskan interior, summer is typically the driest and warmest season and, as such, is prone to wildfires. Appendix A, paragraph

A-9 contains information on fire-weather conditions and fire impact on vegetation and soil in the Arctic.

2-9 WETLANDS.

Wetlands are common in the Arctic and Subarctic environments. Approximately 40% of the State of Alaska is considered wetlands (Alaska Department of Environmental Conservation, Division of Water website https://www.fws.gov/wetlands/Documents/Status-of-Alaska-Wetlands.pdf, and Hall et al. 1994). Some of these wetland types are bottomland forests, bogs, wet meadows, potholes, and wet tundra. In the winter months, these areas are frozen and covered with snow and ice. Executive Order 11990 directs all Federal agencies to avoid wetlands development wherever there is a practicable alternative. Also, see UFC 3-201-01 for basic site development, design, and planning requirements and for specific issues such as wetlands, flood hazards, and tidal zones.

2-10 SEISMIC.

Comply with UFC 1-200-01, UFC 3-301-01, and UFC 3-301-02. Assess location-specific seismic parameters using the structural load data tool hosted on the Whole Building Design Guide (WBDG) website https://www.wbdg.org/ar/tools/sldrt.

2-10.1 Seismic Loading.

Design codes for the dynamic loads imposed by earthquakes are applicable to frozen soil conditions; however, the presence of permafrost can significantly alter the ground-motion characteristics. Stress-wave velocities are much higher and damping is lower in frozen soils. Propagation of stress waves through permafrost is faster and of a higher intensity than for nonfrozen soils. The average response in spectra vary depending on the depth of permafrost, local soil conditions (unfrozen soils above the frozen layer), and the interaction between distributed blocks of isolated frozen soil. See Appendix A, paragraph A-10, for additional literature on how these affect ground motion in Arctic and Subarctic areas. Site exploration must include a seismic survey to quantify spectral values for seismic parameters because the stratigraphy and geotechnical properties of soil profiles affect seismic responses.

2-10.2 Design.

Infrastructure in the Arctic and Subarctic includes seismic design by considering the probability, severity, frequency, and potential damage of seismic ground shaking or tsunamis, in addition to designing for dead, live, snow, and wind structural loads. The U.S. Geological Survey (USGS) Earthquake Hazards Program website posts and archives seismic activities worldwide. The University of Fairbanks (UAF), Alaska Earthquake Center, posts earthquake activities in Alaska. Alaska is a seismically active region with frequent earthquakes. Ground motion can be characterized as moderate to high, depending on location and proximity to faulting. See Appendix A, paragraph A-10, for additional resources.

The National Institute of Building Sciences Building Seismic Safety Council, along with the U.S. Department of Homeland Security, Federal Emergency Management Agency (FEMA), publishes *An Introduction to the NEHRP Recommended Seismic Provisions for New Buildings and Other Structures* (FEMA P-749), highlighting earthquake effects and design requirements. FEMA P-749 also provides a seismic design category map for Alaska.

2-11 GEOSPATIAL DATA.

Geospatial data are valuable for site planning, reconnaissance, and initial site characterization of ground conditions. Geospatial data sets including the digital elevation model (DEM), digital surface model (DSM), soils, and other terrain features in Arctic regions are available. See Appendix A, paragraph A-11, for other resources.

CHAPTER 3 ENGINEERING FACTORS AFFECTING DESIGN AND CONSTRUCTION

3-1 INTRODUCTION.

This chapter introduces specific requirements for planning, design, and construction procedures for Arctic and Subarctic regions and identifies issues associated with the extreme cold region conditions. Full discussions of these topics are found in the other volumes of the UFC 3-130 series.

3-2 ICE ENGINEERING.

Water infrastructure in cold regions, such as piers, bridges, dams, and riprap, are included in the field of ice engineering. Resources for various ice engineering topics to consider in the design and construction of water infrastructure are available in Appendix A, including practical recommendations for modeling ice-jam floods. Additional considerations, such as freezing of lakes and streams, ice and snow in hydrology, and ice and snow in hydraulics, are discussed in *Introduction to Cold Regions Engineering*, by Freitag and McFadden. Climate change may affect river ice, including ice-jam floods.

3-3 HYDROLOGY: SNOW AND SNOWMELT.

In general, hydrology in Arctic and Subarctic environments is highly dynamic, is seasonally and climatically dependent, and varies greatly in extent for both surface and subsurface conditions across the regions. The important characteristics for hydrology in Arctic and Subarctic environments include considerations with surface energy balance, snow process, snow insulation, snowmelt, infiltration, soil temperature, soil moisture, permafrost, active layers, and other aspects. Surface hydrology is influenced by permafrost depth (the active layer) and snow loading as well as the potential retention of winter or late-season rain events. Also, permafrost greatly influences subsurface hydrology (groundwater), causing reduced ground permeability, which in turn affects the distribution and movement of subsurface water.

Snow hydrology and estimating snowmelt runoff produced by a watershed over a specified time are important factors to consider for groundwater flow and drainage design. There are three basic components required to estimate snowmelt runoff. The first is the spatial distribution of the SWE throughout the watershed at the start of the snowmelt period. SWE is the depth of water produced by melting the entire depth of snow over a unit area of the watershed. The second is a snowmelt model that estimates properties of the snowpack (temperature and liquid-water saturation) and the heat transfer into the snowpack from the atmosphere and calculates the amount of the liquid water that reaches the soil surface over the specified time period. The third is a routing model to determine the time for watershed channels to transport surface water to a point of interest, generally the watershed outlet. See Appendix A for more resources and best practices on SWE measurements and snowmelt estimation.

3-3.1 Aufeis.

Aufeis is a phenomenon in which liquid water (stream or ground source) overflows and refreezes on a frozen surface or near-surface confines and atop existing terrain or ice pack. Aufeis is considered an infrastructure geohazard. It affects infrastructure by accumulating on road surfaces; eroding stream channels; contributing to ground uplift; subsidence due to ice accumulation; and thaw and frost sorting ground materials, which leads to unstable soil conditions. Aufeis generally forms in the same areas annually or can form randomly one season and never appear again in the same location. Changes in climatic, geological, or hydrological conditions can cause abrupt variance in occurrence and severity of aufeis formation. In general, the formation is controlled by local or regional surface topography, groundwater, climate, soil conditions, and permafrost presence and distribution. Practical mitigation options include removing the ice buildup by ripping with heavy equipment, installing ice fences, and installing ice storage areas or interceptor systems to divert water flow. See Appendix A for more resources on best practices.

3-3.2 Avalanche.

Mountainous terrain has the potential to pose avalanche hazards. Avalanches are the result of high-altitude structural failure of snowpack and the resulting movement of snow, ice, and debris from higher to lower altitude. Avalanche hazards include the mechanical hazards of large amounts of moving material, as well as air blast and shockwave hazards.

3-4 FROZEN GROUND ENGINEERING.

Frozen ground engineering factors affecting design and construction of facilities in Arctic and Subarctic environments are briefly introduced below. Comply with the more-detailed requirements in UFC 3-130-03 and UFC 3-130-05. Discussions of fundamental concepts and advances in the field of frozen ground engineering are available in various textbooks such as *Frozen Ground Engineering*, by Andersland and Ladanyi, and *Introduction to Cold Regions Engineering*, by Freitag and McFadden.

3-4.1 Physical Properties and Soil Factors.

As a rule, the engineering characteristics of permafrost depend on the texture, water content, salinity, and temperature of the soil. Clean sands and gravels located in well-drained areas may not present serious engineering construction problems if they do not contain appreciable amounts of excess ice. Conversely, permafrost consisting of fine-textured soils, such as silt, often contains large formations of ice lenses, wedges, veins, or other shapes. Cold regions textbooks such as *Frozen Ground Engineering*, by Andersland and Ladanyi, contain information on the standard system for classification of frozen soils, frost action, and the strength and thermal properties of frozen soils. Investigate and evaluate frozen soil index properties (for example, soil type, moisture content, ice content, and density) in accordance with accepted engineering practices, including the following:

- ASTM D4083, *Standard Practice for Description of Frozen Soils (Visual-Manual Procedure)*
- ASTM D2216, *Standard Test Methods for Laboratory Determination of Water (Moisture) Content of Soils and Rock by Mass*
- ASTM D2487, *Standard Practice for Classification of Soils for Engineering Purposes*
- ASTM D7015/D7015M, *Standard Practice for Obtaining Intact Block (Cubical and Cylindrical) Samples of Soils*
- ASTM D7099, *Standard Terminology Relating to Frozen Soil and Rock*

ASTM publishes symposia and technical papers on the latest information on frozen soil properties and measurements of soil indices. Since frozen saline soils are widely distributed, particularly along the Arctic coast, consider the special engineering properties of these soils. See Appendix A for an additional list of information.

3-4.2 Heat Flow at the Ground Surface.

Permafrost remains stable if its natural cover of trees and other vegetation remain intact or undisturbed and if the mean annual temperature of that location is maintained. However, one of the most important things to consider in any civil engineering work in the Arctic and Subarctic is the effect of a change in surface condition on the thermal regime in the ground. Transfer of heat at the air–ground interface depends on such time-varying factors as the thermal properties of the soil, the albedo (reflectivity) and insulating properties of the ground cover at the surface, the amount of solar radiation reaching the surface, the wind structure and velocity above the surface and the surface roughness, the air temperature and humidity as a function of height above the surface, precipitation, snow cover, and evapotranspiration from vegetation. Heat flow toward the ground surface from the soil below is also a factor. Alteration by stripping away, compressing, or otherwise changing the existing vegetative ground cover, erecting structures, or constructing pavements, pipelines, or other features alters the thermal balance in the ground, changing the depth of annual freeze and thaw and, in permafrost areas, alters the depth of the permafrost table. Cold regions textbooks discuss permafrost degradation or aggradation due to ground-surface alteration in more detail, specifically *Frozen Ground Engineering*, by Anderson and Ladanyi (see Appendix D).

3-4.3 Mechanical Properties.

The mechanical properties of frozen soils are influenced by soil temperature, water content, density, applied load, and specimen orientation. See Appendix A for additional resources on mechanical properties. While certain data sets of soil mechanical properties are available, experienced field geotechnical engineers and technicians must identify and conduct the required tests for site-specific soil and loading conditions.

3-4.3.1 ASTM Standards.

Use the following ASTM standards that are specific to frozen soil material properties:

- ASTM D5520, *Standard Test Method for Laboratory Determination of Creep Properties of Frozen Soil Samples by Uniaxial Compression*
- ASTM D5780, *Standard Test Method for Individual Piles in Permafrost Under Static Axial Compressive Load*
- ASTM D5918, *Standard Test Method for Frost Heave and Thaw Weaking Susceptibility of Soils*
- ASTM D6035, *Standard Test Method for Determining the Effect of Freeze–Thaw on Hydraulic Conductivity of Compacted or Intact Soil Specimens Using a Flexible Wall Permeameter*
- ASTM D7300, *Standard Test Method for Laboratory Determination of Strength Properties of Frozen Soil at a Constant Rate of Strain*

3-4.3.2 Other Standards.

Aside from ASTM standards, the following are other commonly used, nonstandardized frozen soil test methods:

- Thaw-consolidation test
- Compressibility of thawing soils
- Shear stress test
- Triaxial compression test
- Pile pullout test for field measurement

See Appendix A for additional resources and sources of experimental data for soil properties for ice-soils.

3-5 CALCULATION OF DEPTH OF FREEZE AND THAW IN SOIL.

It is essential to understand the thermal properties that influence soil heating and cooling in cold region design and construction. The parameters include thermal conductivity, heat capacity, latent heat, thermal diffusivity, and thermal expansion and contraction as described in detail in cold regions engineering textbooks (see list in Appendix A). Heat transfer and the depths to which soils freeze and thaw are particularly important when designing structures, utilities, and pavements in areas of seasonal frost and permafrost. Methods for calculating such depths are based on heat-transfer principles and are presented in cold regions textbooks such as *Frozen Ground Engineering*, by Andersland and Ladanyi, and *Cold Region Structural Engineering*, by Erranti and Lee. The methods include one-dimensional linear, multiple-plane, and two-dimensional radial heat flow. Use UFC 3-130-03, Chapter 6, for numerical modeling of ground thermal response.

3-5.1 One-Dimensional Linear Heat Flow.

The modified Berggren equation is a mathematical construction over Fourier's Law for one-dimensional heat conduction through a homogeneous soil. The solution to the modified Berggren equation requires numerical methods. Use the modified Berggren equation for (1) calculating the depth of frost penetration in Subarctic and seasonal frost regions where the ground freezes during winter and thaws during spring and (2) for calculating the depth of seasonal thaw penetration (active layer thickness) in permafrost areas.[1] See Appendix A, paragraph A-16, for a list of one-dimensional models used in cold regions.

3-5.2 Multiple-Plane and Two-Dimensional Radial Heat Flow

Thermal problems dealing with multiple planes and radial heat flow are common for foundation and utilities design. Comply with UFC-3-130-03 for foundation design, including pile foundations, in permafrost and UFC-3-130-05 to design and construct utility supply lines including water and sewage transport in permafrost and seasonal frost areas.

See *Frozen Ground Engineering*, by Andersland and Ladanyi, and *Cold Region Structural Engineering,* by Erranti and Lee, for steady-state heat-flow equations to quantify thermal resistance and temperature conditions for multiple layers and cylindrical or spherical heat flow. The steady-state solutions include heat flow

- through several layers of different thicknesses and material conductivity, such as floor systems or a concrete pad over soil, soil layers with insulation, pavements, buried insulated utilities, and other scenarios;
- for effective thickness with a cylindrical cross section;
- of two infinite areas, with one heated and one cooled, for estimating the radial geothermal gradient between them such as temperature gradients near shores, beneath rivers, and around heated or cooled structures.

Note that these solutions can over- or underestimate results due to the variability of surface temperature or surface cover, the effects of phase change, moisture (in the frozen and thawed soil), and salinity.

3-6 SITE SELECTION AND GEOTECHNICAL INVESTIGATIONS.

Comply with UFC 3-201-01, Chapter 2, for planning and conducting geotechnical investigations during the various stages of development for civil and military projects.

Geotechnical investigations must be tailored to the individual projects. Comply with UFC 3-130-02 for site selection and development procedures specific to cold regions. The requirements and information for site selection and geotechnical assessment described in UFC 3-130-02 are unique to the Arctic and Subarctic regions. Moreover, all designs

[1] *Frozen Ground Engineering*, Andersland and Ladanyi.

for construction in Arctic and Subarctic regions are preceded by thorough site or route investigations to obtain any existing information on the proposed location and to identify new field data requirements on surface and subsurface features, drainage, permafrost, and other conditions. The importance of thorough site investigations before construction cannot be overemphasized. Sites with non-frost-susceptible subsurface conditions or foundations are much easier to develop for than those having frost-susceptible materials or permafrost. Soil investigations (sampling, testing, and evaluation) must be in accordance with UFC 3-220-01, UFC 3-250-01, and UFC 3-260-02 as discussed in UFC 3-201-01, paragraph 2-4.1. Comply with UFC 3-130-02 for site selection and geotechnical investigations, specifically on frozen and permafrost soils. Also see Appendix A, paragraph A-17, for other guidance and other standard practices.

3-6.1 Site Selection.

Arctic and Subarctic site selection and development is much more complex than in temperate regions because of the remoteness of the locations, the large distances sometimes involved, the limited support facilities, and the seasonal and environmental constraints on field activities. Over large areas of the Arctic and Subarctic, specific terrain or local climatic information is limited. The use of existing geospatial and remote-sensing data sets is beneficial. Access to proposed site or route locations is difficult and expensive, may require careful seasonal scheduling, and may involve severe restraints on sizes and weights of survey equipment that can be brought in. Field working conditions are difficult, considering that very low temperatures persist for several months of the year. Costs of site selection and development studies are high, but do not allow these costs to justify inadequate investigations.

3-6.2 Soil Sampling.

Sampling for frozen ground requires greater attention to avoid thermal disturbance. Select suitable sampling techniques and equipment based on project-specific needs and as determined by an experienced field engineer. Obtain samples that represent the subsurface conditions. Special care is required to maintain samples in their frozen state in the field, in transit, and in storage. Take specific care when machining samples, particularly for mechanical tests. For more information on field sampling, as well as sample handling of frozen soils, field testing, and instrumentations in frozen ground, see *Frozen Ground Engineering*, by Andersland and Ladanyi.

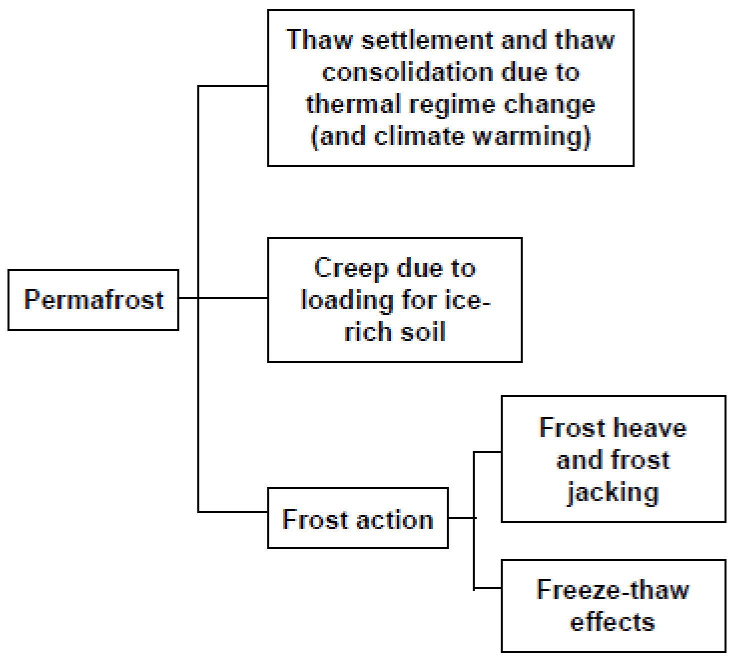
3-6.3 Geophysical Methods.

The use of geophysical methods to characterize the permafrost and ground ice has increased in recent decades. Because physical properties depend on freezing of interstitial water in soils and rocks, successful delineation of permafrost requires supplementary information (such as core data) and knowledge of geophysics methods for frozen ground. Find further information on using geophysics in frozen ground in *Frozen Ground Engineering*, by Andersland and Ladanyi, and *Improving Design Methodologies and Assessment Tools for Building on Permafrost in a Warming Climate*, by Bjella et al.

3-7 FOUNDATIONS FOR STRUCTURES.

Planning, design, and construction of Arctic and Subarctic foundations requires a thorough consideration of ground characteristics as well as the physical, mechanical, and thermal properties of the foundation soil (Figure 3-1). Permafrost and frozen soils respond to foundation loads differently than normal, unfrozen soils, requiring the appropriate type of foundation to address those differences. Comply with UFC 3-130-03 and references therein for requirements of foundation planning, design and construction in cold regions.

Figure 3-1 Consideration Factors for Foundation Design



3-7.1 Considerations.

The major principles to consider for foundation design are bearing capacity and settlement. Because foundation soils vary, the following are additional factors to consider:

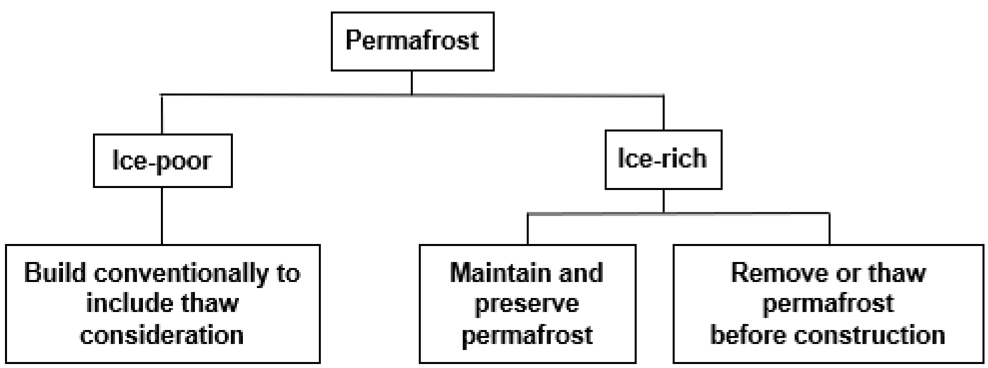
- Thaw settlement and thaw consolidation associated with thermal changes—When thaw settlement occurs, the volume of the soil structure decreases due to melting ground ice or permafrost and the subsequent draining of meltwater, causing ground settlement and creating uneven ground. Thaw consolidation occurs when frozen soil thaws but meltwater is trapped and soil remains undrained, reducing soil strength.
- Long-term strength and creep—The presence of ice causes frozen soil to take on stress-strain behavior characteristics like ice. The strength and deformation of frozen soils depend on loading, temperature, and time.

Therefore, frozen soil subjected to load responds with an instantaneous deformation and a time-dependent deformation. Determine allowable loads by conducting laboratory creep tests (such as ASTM D5520).

- Frost action—Frost action is the process of alternate freezing and thawing of moisture in soil, rock, and other materials and evaluating the resulting effects on materials and on structures placed on, or in, the ground. The process can involve frost heave, frost jacking, and other freeze–thaw effects. Frost heave is an upward ground movement due to ice formation in the underlying soil. Frost jacking is a cumulative upward displacement of objects embedded in the ground, caused by frost action. Freeze–thaw effects not only cause displacement but also change the hydraulic and strength properties of the thawed soil.

The principles for foundation design in permafrost are divided into two categories: ice-poor permafrost and ice-rich permafrost (Figure 3-2).

Figure 3-2 General Approach for Foundation Design



3-7.2 Foundation Design for Permafrost Under Ice-Poor Conditions.

Conditions under ice-poor permafrost are not adversely affected by thaw as they contain little or no ground ice. Materials within this permafrost are clean, granular soils or rocks. Consider the following principles for foundation design in permafrost areas with ice-poor conditions:

- Place foundation below the active layer with protection as needed against uplift acting in adfreezing shear and against frost overturning or sliding produced by frost thrust.
- Design with proper drainage to continue to remove water prior to freezing.
- Support the structure on a compacted, non-frost-susceptible fill capable of limiting freeze and thaw effects.
- Use normal temperate zone approaches if the foundation-supporting conditions will not be adversely affected by thaw.

3-7.3 Foundation Design for Permafrost Under Ice-Rich Conditions.

Ice-rich permafrost conditions are usually fine-grained soils or rocks with significant ground ice, which are adversely affected by thaw. These materials are found in continuous and discontinuous permafrost zones. Consider the following principles for foundation design in permafrost areas with ice-rich conditions:

- Maintain the existing thermal regime.
- Modify the foundation conditions prior to construction.
- In the design and construction, identify and account for the thermal regime changes.

Further, consider this additional guidance:

- Support the structure on a compacted, non-frost-susceptible fill capable of limiting freeze and thaw effects.
- Use thermal insulation, foundation loading, foundation soil replacement, heat to thaw ice-rich soil or removal of heat by freezing the soil, or combinations of these.

3-8 BUILDING DESIGN PRACTICES.

Specialized cold regions building design criteria and guidance are discussed in UFC 3-130-04*,* and design criteria and guidance pertinent to foundations are presented in UFC 3-130-03. General considerations include building type or use, building materials, doors, entrances, roofs, windows, sliding snow and falling ice, wind, snowmelt, icing, drifting of snow, and many other aspects of building design for Arctic and Subarctic environments. Consider requirements as part of a system of interrelated elements under broad design, construction, operation, and maintenance of facilities. Give special attention to foundations, exposure, and adaptation to the extreme environmental conditions.

3-9 UTILITIES.

Use UFC 3-130-05 for criteria and guidance for utilities in the Arctic and Subarctic. Connections of utilities to buildings are discussed in UFC 3-130-04. Utilities include water, wastewater, utilidors, fire protection, electrical, and communication systems. Many elements of these systems, such as electric generators and water-treatment mechanical equipment, are standard items that require no modifications for use in the Arctic and Subarctic if they are appropriately protected from extreme temperatures, snow, and ice and if back-up systems or power are provided as necessary. However, other items require special approaches. For example, protect water distribution pipes in the Arctic from freezing to maintain flow, prevent bursting, and withstand differential thaw settlement or frost heave. Design wastewater treatment facilities to resist frost heave or thaw; settlement damage to pipes, tanks, and other structural elements; and adverse effects of low temperatures on treatment processes. Achieve acceptable grounding conditions by finding areas where soils are less likely to freeze, by installing ground rods or piles in warmer soils, or both; UFC 3-130-05, paragraph 11-2, discusses this further.

3-10 HORIZONTAL INFRASTRUCTURE (AIRFIELD PAVEMENTS AND ROADS).

3-10.1 Airfields and Roadways.

Comply with the cold regions requirements for road, pavement, and airfield design in UFC 3-250 and UFC 3-260 series as listed in the references. In addition, several cold regions textbooks present detailed information on pavement-specific topics

- *Cold Regions Pavement Engineering*, Doré and Zubeck;
- *Introduction to Cold Regions Engineering*, Freitag and McFadden;
- *Permafrost Engineering Design and Constructio*n, Johnston; and
- *Construction in Cold Regions: A Guide for Planners, Engineers, Contractors, and Managers*, McFadden and Bennett.

Several factors affect roadway and airfield surface performance in cold regions. Factors include loading, surface characteristics, subsurface drainage, freeze and thaw, subgrade properties, resilient modulus, moisture change, icing, snow and ice removal, and many others. Consider the following detrimental effects when designing airfield pavements and roads in the Arctic and Subarctic:

- Seasonal frost heave and settlement, commonly differential
- Reduced bearing capacity during and after thaw
- Pavement pumping (the ejection of water and base and subgrade material through joints and cracks or at the pavement edge under traffic loading)
- Pavement cracking
- Deterioration of pavement surfacing
- Progressive increase of pavement roughness
- Loss of compaction
- Restriction of subsurface drainage by frozen ground
- Wintertime surface drainage problems
- Snow removal and icing problems
- Degradation settlement from thawing of permafrost, commonly differential
- Adverse surface drainage effects from permafrost degradation

All but the last two effects are observed to some extent in temperate zone frost areas. The most difficult conditions are in areas near the boundary between permafrost and unfrozen soils. Here the depth of seasonal freezing is at a maximum and permafrost, where present, is the least thermally stable. The detrimental effects of seasonal frost action on pavements are discussed in cold regions textbooks, particularly in *Cold Regions Pavement Engineering*, by Doré and Zubeck. In permafrost regions, the change of ground-surface conditions caused by construction can initiate permafrost degradation and invariably create differential settlement.

3-10.2 Unsurfaced Airfields and Roadways.

Unsurfaced roads and airfields have unbound, aggregate surfaces as an uppermost layer, meaning there is no asphalt or cement layer as a wearing surface. The typical material used for an aggregate wearing surface is compacted gravel with a specified gradation. Guidance for basic design elements, construction, and maintenance of gravel roads is listed in the Federal Highway Administration (FHWA-OTS-15-002). The Alaska Department of Transportation also provides guidance for gravel roads design and maintenance. Army and Air Force only, use UFC 3-250-09FA cold regions requirements for designing unsurfaced roadways and unsurfaced airfields.

3-10.3 Winter—Ice, and Snow Roads.

In very cold and remote areas, winter roads constructed using snow and ice, or both, are viable. Snow roads are built with compacted snow. Ice-capped snow roads use water to produce a bond between snow particles, adding stability to the road.[2] Design, construction, and maintenance techniques for ice and snow roads are described in *Introduction to Cold Regions Engineering*, by Freitag and McFadden, *Permafrost Engineering Design and Construction*, by Johnston; and *Construction in Cold Regions: A Guide for Planners, Engineers, Contractors, and Managers,* by McFadden and Bennett. Ice and snow roads are viable only when sufficient ice thickness forms on the surface of a body of water to carry the vehicle loading or enough snow cover and sufficiently frozen layers exists in the ground. Snow roads (compacted snow) are common in the high Arctic and at McMurdo Station in Antarctica. See Appendix A, paragraph A-18, for snow roads best practices and procedures used by other agencies.

3-10.4 Ice and Snow Runways.

Ice and snow runways are successfully constructed in cold regions. Snow runway design is based on strength properties and bearing capacity similar to that of conventional roads and runways. The design for an ice runway is like a snow runway, except the stress loading characteristics are based on the flexural strength of the ice rather than the shear resistance of a snow layer. The complex nature of snow and ice mechanics presents unique challenges to constructing snow and ice runways. Detailed information on the design and construction methods of a first-of-its-kind snow runway capable of supporting a wheeled aircraft as heavy as a C-17 is documented in *A Snow*

[2] "Winter Roads in Manitoba," Kuryk.

Runway for Supporting Wheeled Aircraft: Phoenix Airfield, McMurdo, Antarctica, by Haehnel et al. Guidance for snow and ice runways, specifically for Antarctica, is in FC 3-260-06F, *Air Force Design, Construction, Maintenance, and Evaluation of Snow and Ice Airfields in Antarctica*. See APPENIDX A, paragraph A-18, for other methodology on the design and construction for snow and ice runways.

3-11 DRAINAGE AND GROUNDWATER.

Although annual precipitation intensity rates are relatively light in much of the Arctic and Subarctic, except in coastal regions, control of surface and subsurface water movement around structures is necessary to prevent icings, erosion, and permafrost degradation. Sources of surface water include snowmelt (see paragraph 3-3), rain, groundwater seepage, and flooding. Also, sources of groundwater may include melting subsurface permafrost ice. In this context, icing is a sheetlike mass of layered ice formed on the ground surface by freezing of successive flows of water that seep from the ground. UFC 3-130-03 provides criteria and guidance for surface drainage design and to control icing in Arctic and Subarctic regions. UFC 3-130-03 presents criteria and guidance for drainage around structures, including brief guidance for seepage control.

3-11.1 Surface Water.

A frequent cause of damaging floods in cold regions is the temporary damming of rivers by ice jams formed by melting winter snowpack along river and tributary areas. The following are two examples of guidance for flood design:

- FEMA developed the *Design Guide for Improving Critical Facility Safety from Flooding and High Winds* (FEMA 543), which includes recommendations incorporating hazard mitigation measures into all stages, and at all levels, of critical facility planning and design for new construction, reconstruction, and rehabilitation of existing facilities.
- The Department of Commerce, Community and Economic Development, which is a department within the state of Alaska, provides *The Floodplain Management in Alaska Quick Guide*.

The frozen condition of the ground during much of year makes it necessary to assume that the rate of infiltration in the Arctic, for surface drainage design, is zero. Construct relatively deep and narrow surface channels to direct and carry away surface water to reduce the channel surface area and minimize heat loss that leads to ice formation and reduces flow capacity. Preferably, line the channels to prevent excess infiltration into the soil and prevent permafrost degradation. Oversize culverts to account for ice. Flowing surface water in channels can be a significant cause of permafrost thawing. In Subarctic regions, such channels, once formed, may continue to thaw and deepen year after year. Avoid drainage ditches that cut into ice-rich permafrost.

3-11.2 Groundwater Seepage.

Icings generally occur in upland areas where seeps or springs provide a continuous source of groundwater to the surface during winter. Icings are undesirable near buildings, roadways, culverts, or other structures as they are a serious problem when they interfere with road travel or drainage. Control of icings can be surprisingly difficult to achieve. Icing impacts can sometimes be circumvented if the flow can be redirected to locations where it does no harm. Include a steam pipe in culverts susceptible to icing to allow culvert thawing when necessary.

3-11.3 Groundwater.

Control groundwater flow where possible to prevent erosion, or permafrost degradation, and differential settlement. In practice, there are few options for controlling groundwater. Some control over the direction of summer drainage flow in the active layer is possible by modifying surface conditions to selectively control depth of thaw. Modifying downstream water levels can influence the flowrate of groundwater. Injecting water into the ground, such as from leaking water, sewer, or steam pipes, can seriously degrade permafrost and must be avoided. When wells drilled through permafrost encounter water under artesian pressure, great care is necessary to stabilize the unstable soil around the casing to avoid losing control of the well.

3-12 EARTHWORK: EXCAVATION, GRADING, AND FILL.

Conduct a site assessment before performing any earthwork and excavation activities to characterize ground conditions and identify the appropriate methods for excavation. Comply with requirements for site assessment in UFC-3-130-02.

3-12.1 Excavation.

Techniques used for excavation of frozen soils depend on the time of the year and ground conditions. Mechanical methods to fracture, break, and rip frozen materials include excavating by machine and cutting equipment, hydraulic dredging, drilling, and controlled explosive loading or blasting. Other approaches, such as thawing frozen ground, are applicable under certain conditions. Methods for thawing frozen ground include solar thawing, steam injection, water injection, and electric heating. Detailed discussion on excavation techniques and other related factors are described in various cold regions textbooks (see Appendix D).

3-12.2 Earthwork and Fill Placement.

Earthwork of frozen soil is feasible, but significant care and effort are required. Earthwork and placement of fill material can be extremely challenging if conducted during freezing temperatures. Relative compaction varies depending on temperatures, soil type, and ice contents. See cold regions textbooks such as *Introduction to Cold Regions Engineering*, by Freitag and McFadden, *Frozen Ground Engineering*, by Andersland and Ladanyi, *Construction in Cold Regions: A Guide for Planners, Engineers, Contractors, and Managers*, by McFadden and Bennett, and *Permafrost*

Engineering Design and Construction, by Johnston, for detailed information and guidance, including handling on earthwork, placement, and compaction of frozen materials. Use required tests and standards, including ASTM D4253, for determining the minimum thawed dry density of a material.

In general, the placement of frozen materials is prohibited unless the materials can be satisfactorily compacted and maintained in a frozen state for the life of the structure.[3] If material contains a significant amount of ground ice, instability due to thaw settlement will result from melting. Frost heaving can be an issue if the fill materials used are frost susceptible. Whenever possible, use non-frost-susceptible soils for fill materials. The magnitude of frost heave and subsequent thaw weakening is determined by the frost susceptibility of the soils. The frost design classification of soils provides an approximation of frost susceptibility. However, when accurate measurements are needed, ASTM D5918 provides the procedures to determine the frost-heave and thaw-weakening susceptibility of soils.

3-13 EROSION CONTROL.

Adapting to coastal erosion and bank erosion resulting from increased disturbances in hydrological cycles is an evolving field in higher-latitude areas. No specific design guidelines are currently available; however, base erosion-control designs on a solid understanding of the erosion processes involved (fluvial versus terrestrial), the mechanisms of the permafrost environment, and other applicable environment factors. Special consideration of sea ice and sea ice dynamics is necessary for coastal design. Attention to unique issues, such as river overflow during the breakup period and of formation of strudel scour for structures near rivers, is a must. Published erosion-control approaches are listed in Appendix A, paragraph A-19.

3-14 EMBANKMENTS.

Deformation such as settlements and lateral spreading of materials are common embankment failures in cold regions. Settlement of embankments in permafrost regions are attributed to thaw settlement, creep, and freeze–thaw cycling. Consider engineering measures during design to protect the permafrost underneath the embankment. Analysis such as numerical modeling is a viable approach to analyze the embankment deformation for heat transfer, creep, soil compression, and thaw consolidation. Other embankment design techniques are described in Appendix A, paragraph A-20.

3-15 GROUND AND SLOPE STABILITY.

Use general requirements for slope stability in UFC 3-220-01, paragraph 2-4.10. Ice-rich permafrost slopes can create significant creep deformation. Find analyses and design considerations for slopes in thawing permafrost and in frozen soils as well as slope stabilization methods in *Frozen Ground Engineering*, by Andersland and Ladanyi. Comply with UFC-3-130-03 to mitigate slope failures and stability of slopes during thaw.

---

[3] *Permafrost Engineering Design and Construction*, Johnston.

3-16 CONSTRUCTION MANAGEMENT AND PRACTICES.

Designs, cost estimates, and construction management and procedures in the Arctic and Subarctic regions differ from those in temperate regions because of deep seasonal frost, permafrost, and extreme climate. The environment and short construction season critically affect field operation schedules. Remote, isolated construction sites served by long and difficult supply lines mean that mistakes in planning are time-consuming and costly. A highly competent management team, with decentralized authority and centralized support, must carefully plan and organize field activities and conduct an intensive field inspection effort.

3-16.1 Methods of Transportation.

3-16.1.1 Air.

Air transport is a principal mode of transport to Arctic and Subarctic field sites. If a landing strip does not exist near the site, use helicopters or float-, ski- or wheel-equipped small planes in initial project stages, depending on available surface conditions. In winter, heavy wheel-equipped planes can use ice landing surfaces. Constructing a serviceable conventional runway facilitates regular heavy plane operations.

3-16.1.2 Water.

A suitable road or waterway, or an expedient access road, allows delivery of construction materials and equipment to the construction site. However, rivers and the Arctic coastal waters have only limited ice-free periods for water transport. Sometimes a north-flowing river may be open for upstream navigation before its mouth becomes sufficiently ice-free in the breakup period that permits entrance from the sea.

3-16.1.3 Ground.

Low-ground-pressure tractor trains can transport personnel, materials, and equipment over frozen, snow-covered terrain in winter. Frozen lakes and rivers are frequently used very effectively for such transportation. Wheeled, tracked, or sled equipment can use ice bridges to cross rivers and lakes. Stockpile materials at convenient locations during the summer for surface transport in winter. For protection of the terrain, operations on the natural tundra surface in summer are prohibited in Alaska. Vehicles with low-ground-pressure rubber tires (1 to 2 lb/in^2 [7 to 14 kPa]) are an exception. In some areas, such as nature preserves, other restrictions or permit requirements may apply.

3-16.2 Construction Equipment.

Heavy equipment is essential in Arctic and Subarctic construction. Winterize all motorized equipment, including insulated cabs and facilities, fire-retardant engine shrouds, and heaters to protect personnel from severe cold, wind, and snow. Removable cleats on tracked vehicles (such as grousers) or other special traction devices and winches are frequently necessary. Preventive maintenance plays a key role in equipment operation. Maintain a strict lubrication schedule on all equipment. Equipment operators must adhere to freezing-weather preoperation, starting, warm-up, and operating procedures. Unused “cold-soaked” hydraulic systems are especially vulnerable to failure on start-up at about 30°F (−1.1°C) or lower. Tires in extremely low temperatures become brittle and are easily punctured. Metal parts are vulnerable to brittleness at temperatures around 40°F (4.4°C) or lower and can lead to potential safety and operation problem. Inspect all equipment regularly to locate cracks and breaks. Repair all cracks when first observed by preheating before welding and replacing broken parts. Additional information on the effects of cold on equipment performance are described in *Construction in Cold Regions: A Guide for Planners, Engineers, Contractors, and Managers*, by McFadden and Bennett.

3-16.3 Cold and the Worker.

The efficiency of labor on construction projects in the Arctic and Subarctic varies with the experience, attitude, and morale of the workers, as well as working conditions. Cold and darkness during the winter months create safety and operational problems that directly limit productivity. The degree of worker climate acclimation and their cold adaptability is important across all classes of labor and directly affect productivity.

3-16.4 Construction Operations.

The special conditions that prevail in the Arctic and Subarctic impact all aspects of construction, such as excavating frozen soil or frozen rock; placing embankments, backfill, or concrete; and protecting the work. The following are examples of factors that require careful consideration:

- Difficulty of excavating frozen materials
- Difficulty of handling wet, thawed material in summer
- Adherence of ice-filled frozen materials to equipment at low temperatures
- Direct effects of low temperatures on equipment, including brittle fracture of metal
- Shortness of the above-freezing summer season
- Shortness of daylight hours in fall and winter
- Difficulty of achieving satisfactory fills and backfills when temperatures are below freezing
- Problem of placing concrete and achieving adequate strength gain without thaw of underlying permafrost
- Problems protecting work from cold, heat, drying, dust, wind, and precipitation
- Enclosure of work to maintain worker efficiency
- Fire safety and fire protection

3-16.5 Placing Concrete.

Whenever possible, conduct concrete placement work during above-freezing temperatures. Refer to UFC 3-301-01, paragraph 2-7, for requirements.

A combination of several techniques and methods are used to prevent damage to concrete placement during freezing conditions. These techniques include enclosures or tents, insulation, heating of materials, additives, and others that are described in various cold regions textbooks (see Appendix D). Refer and conform to the American Concrete Institute (ACI) *Guide to Cold Weather Concreting* (ACI 306R-16) for recommendations, test methods, mixing, placing, and preparation for cold weather concreting.

3-17 MAINTENANCE AND MONITORING CONSIDERATIONS.

Once facilities or structures are in use, maintenance and monitoring are important given the extreme temperatures and change in thermal properties that impact a facility's life cycle in the Arctic and Subarctic environments. Maintenance includes a collection of actions as well as monitoring to ensure the continued function and sustained service of facilities or structures. There are two aspects to monitoring infrastructure in cold regions: (1) monitoring ground conditions around a building and (2) monitoring the intrinsic aspects of the structure itself. Monitoring is the process of measuring to assess whether facilities or structures are performing as intended. Monitoring can include, but is not limited to, qualitative (like visual observation) assessments and quantitative measurements (such as using sensors).

For foundations and utilities, the most important factor influencing the performance in permafrost is the ground thermal regime.[4] In addition, accumulated snow and ice build-up adjacent to foundations and utilities can disrupt airflow, drainage, or surface flow. Monitoring results can identify performance failures due to factors influencing the distribution or existence of permafrost, the properties and behavior of frozen soil, or freezing and thawing effects. Regular inspection and monitoring programs are essential to ensure that the ground thermal regime is stable and identifies any concerns that affect structures. Note the following signs:

- Subsidence of fills
- Sloughing of natural and manufactured slopes
- Settlement of foundations
- Differential movement of structures
- Ponding of water
- Cracking of the ground and water flowing from under the fill
- Other indications of potential thawing, frost action, or drainage problems

[4] *Permafrost Engineering Design and Construction*, Johnston.

Soil temperature measurements conducted at critical locations beneath a structure (load-bearing points, heating-source proximity, and building geometry) measure the performance of subgrade foundation soils. Consider an early warning detection system consisting of temperature sensors installed at various locations to provide managers and engineers advance knowledge of changing conditions that risk foundation damage as discussed in *Improving Design Methodologies and Assessment Tools for Building on Permafrost in a Warming Climate*, by Bjella et al. More importantly, identify the limiting performance tolerances for which monitoring is being performed. This includes tolerance criteria such as allowable total and differential settlement for structures, limiting stress and strain criteria during pile driving, and minimum acceptable embankment fill compaction. The intent is to identify possible approaching adverse performance conditions and prepare options for engineering mitigation.

CHAPTER 4 RISK AND RESILIENCE CONSIDERATIONS

4-1 INTRODUCTION.

Currently, there is no standard or approach for risk assessment explicitly for Arctic and Subarctic conditions. The harsh Arctic and Subarctic conditions contain inherently significant risks to engineering and construction. The risks are heightened due to natural disasters and climate change. In Arctic and Subarctic regions, resilience is an increasingly important factor in developing and maintaining infrastructure against both the intrinsically extreme environmental conditions and potential climate change impacts. Some overarching updates on risk and resilience directives are available in the following:

- *Army Climate Resilience Handbook*, by Pinson et al., provides methodology and processes to assess climate hazards and incorporate risk into existing Installation Master Plans.
- *Air Force Civil Engineer Severe Weather/Climate Hazard Screening and Risk Assessment Playbook*, by the U.S. Air Force, provides a framework for screening and assessing severe weather, climate hazards, and their associated current and future risks.

Updates to the DoD Installation adaptation and resilience planning handbook and resources on resilience planning are available in the Whole Building Design Guide website.

4-2 RISK ASSESSMENT AND DESIGN FOR RELIABILITY.

Risk assessment is an analysis of a project that identifies and quantifies specific risks according to a hazard probability of impact, while design for reliability refers to the performance of a system within a given environment for the expected life cycle and the likelihood of success or failure in the operation when the system is subjected to hazards. The fundamental guidance for risk assessment is highlighted in the following UFCs:

- UFC 1-200-02 addresses climate change risk consideration and requirements.
- UFC 2-100-01 includes potential risks associated with climate change and formulates potential solutions. Paragraph 2-2.17 has risk-related planning and climate resilience that include processes for an Installation Climate Resilience Plan (ICRP).
- UFC 3-201-01, Chapter 2, includes flood-hazard-related risks.
- UFC 3-220-01 includes geotechnical-related risks.
- UFC 3-301-01 covers risk categories of building types.

Best practices and other guidance on risk assessments used by various agencies are available and listed in Appendix A, paragraph A-21.

4-3 RISK IN THE ARCTIC AND SUBARCTIC.

The general hazards that incur risk in Arctic and Subarctic areas include, but are not limited to, changes in earthquake frequency, precipitation patterns, higher temperatures and more frequent heat waves, potential flooding, wildfires, and thawing of permafrost. Higher temperatures and more heat waves pose risks for irregular thermal thawing of landforms, creating uneven thawing of ice-rich permafrost or permafrost degradation. Other risks include an increased thawing active layer, potentially destructive collapse of slopes because of thawing of near-surface permafrost, and thaw slumping. All of these affect the ground stability and induce changes in the soil's mechanical behavior, such as bearing capacity for the support of infrastructure, which must be evaluated and considered. Apply appropriate risk methodology by using the literature to quantify factors such as thermal stability, thaw sensitivity, and stability of the permafrost landscape, as well as other factors affecting ground instability due to climate change.

4-3.1 Methods.

4-3.1.1 Risk Methodology.

Apply appropriate risk assessment methods to identify various risk factors for design and construction in cold regions. There are two types of risk assessment methods applicable for cold regions (and see Appendix A for more details):

- Qualitative evaluation is based on experienced experts' judgment and evaluation of on-site risks. This method is simple, subjective, and develops a risk index value.
- Quantitative evaluation typically uses methods that analyze the interactions between various factors and quantifies the degree of influence of these factors on the stability and safety of infrastructure for predicting and evaluating the risks to infrastructure.

4-3.1.2 Design for Reliability.

The traditional steps in the design for reliability theory include (1) outline performance objectives, (2) select the mathematical formulation of limit state function or define random variables affecting the limit states of the problem and their probabilistic distributions, (3) create a structural model and conduct analysis to evaluate the limit state functions, and (4) compute the probability of failure and reliability index. See Appendix A for additional information and find examples that are appropriate to use for the project.

4-3.2 Risk Factors Associated with Permafrost.

4-3.2.1 Thermal Stability.

The risk to thermal stability includes factors such as the characteristics of permafrost and its phase changes (such as annual mean ground temperature and radiation balance), the thermal disturbance caused by engineering activities and construction, and the damages due to deformation. Thermal stability analysis includes a comprehensive consideration of climate factors, surface conditions, soil conditions, topography and geomorphology, engineering disturbance, and other influencing factors.

4-3.2.2 Thermal Thaw Sensitivity.

The factors influencing the permafrost thermal thaw sensitivity include the annual mean ground temperature, the permafrost table temperature, the freezing and thawing process, the seasonal thawing depth, and characteristics of ice content in the frozen soil.

4-4 RESILIENCE.

UFC 2-100-01 provides guidance that includes processes for the ICRP. Currently, there is no guidance or approach explicitly for Arctic and Subarctic conditions for assessing the vulnerability or resilience of engineering infrastructure. However, best practices are available that are applicable to military projects in cold regions environments and are listed in Appendix A, paragraph A-22. Incorporating resilience techniques into the design and construction of facilities in the Arctic and Subarctic environment is site or Installation focused and project specific.

This Page Intentionally Left Blank

APPENDIX A BEST PRACTICES

A-1 INTRODUCTION.

The Best Practices Appendix is guidance and not requirements. Its main purpose is to communicate proven facility solutions, systems, and lessons learned but may not be the only solution to meet the requirement. It identifies additional background information and practices for accomplishing infrastructure planning, design, and construction in the Arctic and Subarctic. The DoR must review and interpret this guidance as it conforms to criteria and contract requirements and apply the information according to the needs of the project. If a Best Practices document guideline differs from any UFC, the UFC takes precedence. For Best Practices guidelines not discussed in a UFC, the DoR must submit to the Government Project Manager a list of the guidelines or requirements being used for the project with documentation sufficient for review and approval prior to completing the design.

A-2 WHOLE BUILDING DESIGN GUIDE.

The Whole Building Design Guide (WBDG) provides additional information and discussion on practice and facility design, including a holistic approach to integrated design of facilities. The WBDG provides access to all Construction Criteria Base criteria, standards and codes for the DoD Military Departments, and other agencies. These standards include UFC, UFGS, Performance Technical Specifications, design manuals, and specifications. For approved government employees, it also provides access to nongovernment standards.

Installation Facilities Standards are also available on the WBDG website https://www.wbdg.org/airforce/ifs. Installation Facilities Standards provide guidance on

- Installation elements (such as streets, open and spaces),
- site develop (such as utilities, parking areas, stormwater management, sidewalks, bikeways and trails, landscaping, site furnishings, signage, and exterior lighting),
- and facilities design (both interior and exterior elements).

A-3 ENGINEERING RESOURCES.

The Colleges of Engineering at both the University of Alaska Anchorage and UAF offer fundamental courses in Arctic Engineering that address cold regions engineering problems and current solutions. These courses are approved and required by the State of Alaska Board of Registration for Architects, Engineers, and Land Surveyors. Their websites are given in Appendix C.

A-4 COLD REGIONS PUBLICATIONS.

There are several online sources for cold regions publications and databases. The ASCE Cold Regions Engineering Division, formerly the Technical Council on Cold Regions Engineering, sponsors conferences, publishes reports on the effects of cold regions environments on engineering design and on construction and operations, and publishes the *Journal of Cold Regions Engineering* (https://ascelibrary.org/journal/jcrgei). Another source of Arctic and Subarctic papers is the *Cold Regions Science and Technology* journal (https://www.journals.elsevier.com/cold-regions-science-and-technology). The Cold Regions Research and Engineering Laboratory (CRREL) library maintains an extensive collection of cold regions scientific and technical literature on the U.S. Army Engineer Research and Development Center (ERDC) Library Resources website https://www.erdc.usace.army.mil/Library/. In addition, the International Permafrost Association (IPA) disseminates from national and international members information pertinent to cold regions science and engineering. The IPA has a network of permafrost data sets and publications, including conference proceedings.

A-5 PERMAFROST AND GROUND ICE.

A-5.1 Distribution and Features.

The IPA defines Arctic and Subarctic limits in accordance with permafrost distribution and then divides these regions into classifications based on geographic continuity within the landscape (IPA website https://www.permafrost.org/what-is-permafrost/). Permafrost extent is also classified by ground-ice content (Figure 2-1 and 2-2). Data to derive these maps is available from the National Snow and Ice Data Center (NSIDC) (search for “frozen ground” at https://nsidc.org/). A permafrost map for Alaska is available from “Permafrost Characteristics of Alaska,” by Jorgenson et al.

Estimations of permafrost distribution are modeled across the northern hemisphere in “Northern Hemisphere Permafrost Map Based on TTOP Modelling for 2000–2016 at 1 km^2 Scale,” by Obu et al., and throughout Alaska in “Distribution of Near-Surface Permafrost in Alaska: Estimates of Present and Future Conditions,” by Pastick et al., and in “Permafrost of Northern Alaska,” by Kanevskiy et al. These papers discuss factors affecting permafrost existence and distribution.

A-5.2 Resources.

Several textbooks and papers discuss the different types of landforms and the cryostructures, or frozen ground structures, present in cold regions. These include *Cold Climate Landforms*, by Evans, *The Periglacial Environment*, by French, and “Permafrost of Northern Alaska,” by Kanevskiy et al.

Cold Region Structural Engineering, by Erranti and Lee, *Construction in Cold Regions: A Guide for Planners, Engineers, Contractors, and Managers*, by McFadden and

Bennett, and *Frozen in Time: Permafrost and Engineering Problems*, by Muller, discuss the associated challenges for engineering and design that ground ice presents.

A-5.3 Databases.

Archived data of permafrost conditions from the global network of permafrost observatories are available from IPA (https://www.permafrost.org/data/). The IPA website provides global and regional data sources, including active layer information and permafrost temperature and distribution.

A-6 CLIMATE DATA SOURCES.

Ground-based observation records are available from NOAA NCEI (https://www.ncei.noaa.gov/products/land-based-station). Numerous Alaska observation stations (Figure 2-3) are listed by NWS (https://www.weather.gov/aawu/stnlist).

Several global observational networks are searchable on the internet. Historical weather, climate data, and related information for numerous locations across Canada are available at Government of Canada, Historical Climate Data (https://climate.weather.gc.ca/). The Danish Cooperation for Environment in the Arctic publishes temperature and wind conditions for Arctic Sea ice and the Greenland ice sheet at the Polar Portal website http://polarportal.dk/en/greenland/. The “Frozen Ground” link at this website provides ground-temperature profiles at two southern sites, Sisimiut and Kangerlussuaq, and the colder northern site of Ilulissat.

Databases with compiled climate data exist. For example, the WorldIndex database provides global climate data and is used in the Pavement-Transportation Computer Assisted Structural Engineering (PCASE) software.[1] The climate data compiled in the WorldIndex database is obtained from NOAA through NCEI (https://www.ncei.noaa.gov/). The PCASE database includes the station name, coordinates, number of years of data used to calculate the average air temperature, number of years of data used to calculate the freezing index, yearly average temperature, and other climatic trends or information used for designing and evaluating pavements on military Installations.

A-6.1 Air Temperature.

Distributed air-temperature data sets (minimum, maximum, and mean temperature) for Alaska for the period 1981–2010 and historical 30-year normal data are available online from Parameter-Elevation Regressions on Independent Slopes Model (PRISM). These downloadable data are produced by the Spatial Climate Analysis Service, Oregon State University (https://prism.oregonstate.edu/projects/public/alaska/grids/). The current set of 30-year normal data covering the period 1991–2020 is available at “NCEI U.S. Climate Normals Quick Access” (https://www.ncei.noaa.gov/access/us-climate-normals/).

[1] “One-Dimensional Computer Models to Estimate Frost Depth,” Barna et al.

A-6.2 Ground Temperatures.

Surface temperatures are available for certain locations and are accessible through global observational networks and observation stations.[2] In Alaska, the Department of the Interior developed a permafrost monitoring network on federal lands in northern Alaska as part of the Global Terrestrial Network for Permafrost. These data sets are also from IPA (https://www.permafrost.org/data/). Simulated ground temperatures near the surface from numerical modeling are available for Alaska[3] and the northern hemisphere.[4]

A-6.3 Precipitation and Snow Distribution.

Precipitation and snowfall vary in the Arctic and Subarctic regions due to the complex interactions between the atmosphere, ocean, ice, and snow, as well as global and local processes and environmental changes.[5] There are a variety of papers focused on satellite-based characterization of snowfall in the Arctic over both land and ice surfaces such as

- “Arctic Snowfall from CloudSat Observations and Reanalyses,” by Edel et al.;
- “Status of High-Latitude Precipitation Estimates from Observations and Reanalyses,” by Behrangi et al.; and
- “Intercomparison of Precipitation Estimates Over the Arctic Ocean and its Peripheral Seas from Reanalyses,” by Boisvert et al.

For example, “Arctic Snowfall from CloudSat Observations and Reanalyses,” by Edel et al., examined the frequency and phase of precipitation as well as the snowfall rates from CloudSat (a polar orbiting satellite) over the 2007–2010 period. They indicated that the mean surface snowfall rates are particularly high on the Alaska Range (approx. 40 in. [1,000 mm] per year) and extremely high over the southeastern coast of Greenland (ranging from 80 in. [2,000 mm] to 160 in. [4,000 mm] per year).

Summaries of climatological conditions such as precipitation, snowfall, and snow depth for Alaska are also available from NOAA NCEI (https://www.ncei.noaa.gov/). NCEI also provides data sets on the “Global Precipitation Climatology Project (GPCP) Clearinghouse” website https://www.ncei.noaa.gov/products/global-precipitation-climatology-project. The GPCP data sets include monthly and daily precipitation data

[2] “Thermal State of Permafrost in North America: A Contribution to the International Polar Year,” Smith et al.
[3] “Numerical Modeling of Permafrost Dynamics in Alaska Using a High Spatial Resolution Data Set,” Jafarov et al.; *Permafrost Characteristics of Alaska*, Marchenko et al.
[4] “Northern Hemisphere Permafrost Map Based on TTOP Modelling for 2000–2016 at 1 km^2 Scale,” Obu et al.; “A Ground Temperature Map of the North Atlantic Permafrost Region Based on Remote Sensing and Reanalysis Data,” Westermann et al.
[5] “Arctic Snowfall from CloudSat Observations and Reanalyses,” Edel et al.; “Winter Northern Hemisphere Weather Patterns Remember Summer Arctic Sea-Ice Extent,” Francis et al.; “Processes and Impacts of Arctic Amplification: A Research Synthesis,” Serreze and Barry.

derived from surface and satellite measurements for 1979–present (1997–present for daily). Also, the NWS's National Operational Hydrologic Remote Sensing Center produces real-time snow-cover-extent maps for the U.S. and the rest of the Northern Hemisphere. The satellite observations are available on NOAA "U.S. and Northern Hemisphere Snow Cover" (https://www.nohrsc.noaa.gov/nh_snowcover/).

A-6.4 Wind and Wind Chill.

The relationship between human temperature tolerance and wind factors are found in literature such as "A New Approach to an Accurate Wind Chill Factor," by Bluestein and Zecher, and "The New Wind Chill Equivalent Temperature Chart," by Osczevski and Bluestein. A wind-chill chart and wind-chill calculator are both available online through NOAA NWS (https://www.weather.gov/safety/cold-wind-chill-chart).

A-6.5 Visibility.

Weather-related hazard warnings and advisories (such as storm, wind, and so on) are available online. For example, alerts for Alaska are available from the "NWS Forecast Office: Anchorage, AK" website https://www.weather.gov/afc/ and for Canada from the Government of Canada "Alerts" website https://weather.gc.ca/mainmenu/alert_menu_e.html. Information on blizzards is available at the NWS "What is a Ground Blizzard?" website https://www.weather.gov/safety/winter-ground-blizzard.

A-7 CLIMATE CHANGE AND PROJECTIONS.

Recurring official reports from the Intergovernmental Panel on Climate Change (IPCC) such as "Climate Change 2021: The Physical Science Basis," by Masson-Delmotte et al., and from NOAA such as *Arctic Report Card 2022*, by Druckenmiller et al., document the changing Arctic environment. The SNAP program at UAF developed climate projections and uses global climate model results from CMIP3 and CMIP5 for twentieth-century conditions and future low-, moderate-, and high-emissions scenarios out to the year 2100.[6] The SNAP future climate projections can be found at the SNAP website https://uaf-snap.org. The IPCC, NOAA reports, and related studies estimate the most likely or significant projected climate impacts affecting the design, building, and sustainability of Arctic and Subarctic infrastructure as described below:

- Projections on permafrost warming and thawing: "Impacts of Permafrost Degradation on Infrastructure," by Hjort et al., summarizes the observed circumpolar degradation of permafrost and the associated damages to infrastructure across North America and Eurasia. They concluded that nearly 70% of current infrastructure in the permafrost domain is in areas with high thaw potential of near-surface permafrost by 2050. Data related to projected permafrost temperature for Alaska is available from the Arctic Environmental and Engineering Data + Design Support System website

[6] "Downscaling of Climate Model Output for Alaskan Stakeholders," Walsh et al.

https://arcticeds.org/physiography/permafrost/ or at the SNAP website https://uaf-snap.org.

- Precipitation projections: Under the SNAP projections, Fresco et al., in *Future Projections of Precipitation for Alaska Infrastructure: Final Report,* developed future projections of the maximum precipitation (as both snow or rain) in 1-hour, 1-day, and 1-month periods, expected over return periods of 2 years to 50 years. In nearly all future model projections from 2020 to 2099, the projections are consistently towards an increasing maximum precipitation across Alaska.

- Sea ice cover: The extent of multiyear sea ice, which is older than 1 year and generally thicker and more stable for on-ice operations, has also decreased from 2.7 million square miles to only 0.6 million square miles (7.0–1.5 million km^2), and sea ice older than 4 years has nearly disappeared.[7]

A-8 PERMAFROST DEGRADATION.

Higher temperature and more heat waves pose risks for irregular thermal thawing of landforms, creating uneven subsidence and thawing of ice-rich permafrost.[8] These changes in the thermal regime produce dynamic responses to changes in soil moisture, collapse of soil structure, vegetation change, or land surface response to thawing permafrost. "Synthesis of Physical Processes of Permafrost Degradation and Geophysical and Geomechanical Properties of Permafrost," by Liew et al., describes the physical processes of permafrost degradation and its effects on physical and mechanical properties.

A-9 VEGETATION AND WILDFIRES.

The literature such as "A Raster Version of the Circumpolar Arctic Vegetation Map (CAVM)," by Raynolds et al., "Evidence for Widespread Wildfires and Their Environmental Impact in the Late Cretaceous Canadian Arctic," by Synnott et al., and "The Circumpolar Arctic Vegetation Map," by Walker et al., provides more current information on vegetation.

Wildfires or forest fires affect vegetation, promote permafrost thawing, and may alter permafrost conditions over many years.[9] In the Alaskan interior, summer is typically the driest and warmest season and, as such, is prone to wildfires. Studies and research on fire-weather conditions and fire impact on vegetation and soil currently under development include "Impacts of Wildfire and Landscape Factors on Organic Soil Properties in Arctic Tussock Tundra," by He et al., "Estimates of Temporal-Spatial Variability of Wildfire Danger Across the Pan-Arctic and Extra-Tropics," by Justino et al., "Circumpolar Spatio-Temporal Patterns and Contributing Climatic Factors of Wildfire Activity in the Arctic Tundra from 2001 to 2015," by Masrur et al., and "Evidence for

[7] "Sea Ice," Meier et al.
[8] "Arctic Landscapes in Transition: Responses to Thawing Permafrost," Rowland et al.
[9] "Divergent Shrub-Cover Responses Driven by Climate, Wildfire, and Permafrost Interactions in Arctic Tundra Ecosystems," Chen et al.

Widespread Wildfires and Their Environmental Impact in the Late Cretaceous Canadian Arctic," by Synnott et al.

A-10 SEISMIC.

Studies and discussions on ground-motion characteristics and stress-wave velocities in frozen soils are available in the literature. Because the average response spectra vary depending on depth of permafrost,[10] local soil conditions (unfrozen soils above the frozen layer), and the interaction between distributed blocks of isolated frozen soil,[11] consider these effects on ground motion in Arctic and Subarctic areas.

Posts and archives of seismic activities worldwide are available on the USGS, Earthquake Hazards Program website. The International Federation of Digital Seismograph Networks (https://www.fdsn.org/networks/detail/DK/) provides similar global data, including Arctic regions. The UAF Alaska Earthquake Center posts earthquake activities in Alaska on their website https://earthquake.alaska.edu/earthquakes.

The National Institute of Building Sciences Building Seismic Safety Council, working for FEMA, published FEMA P-749, which provides an introduction to recommended seismic provisions for new buildings and other structures. FEMA P-749, Chapter 5, describes the seismic design category map for Alaska.

A-11 GEOSPATIAL DATA RESOURCES.

The following are some sources of geospatial data:

- "Arctic DEM Explorer" (https://livingatlas2.arcgis.com/arcticdemexplorer/) automatically produces a high-resolution, high quality DSM of the Arctic by using optical stereo imagery, high-performance computing, and open-source photogrammetry software and allows users to export a particular area of interest.
- NSIDC "Data" (https://nsidc.org/data) is a repository of geographic information systems (GIS) data on snow, ice, and frozen ground.
- Arctic Research Consortium of the United States (https://www.arcus.org/gis/maps-data/metadata) publishes geospatial data on their website.
- Find satellite and remotely sensed data at the Land Processes Distributed Active Archive Center (https://lpdaac.usgs.gov/), a National Aeronautics

[10] "Numerical Analysis of Permafrost Effects on the Seismic Site Response," by Yang et al.
[11] "Seismic Behavior of Buried Energy Pipelines in Northern Permafrost Regions," "Experimental and Analytical Study of Seismic Site Response of Discontinuous Permafrost," "Vulnerability of Buried Energy Pipelines Subject to Earthquake-Triggered Transverse Landslides in Permafrost Thawing Slopes," Dadfar et al.

and Space Administration (NASA)/USGS website. Products include multispectral and hyperspectral imagery for mapping land cover.

Additional sources for topographic maps are commercially available. Sources also include state or federal agencies or other topographic service agencies such as NASA Earth Observations (https://neo.gsfc.nasa.gov). DEM data sets for Alaska, including a 5 m resolution, are available online from the USGS Science Data Catalog (https://data.usgs.gov/datacatalog/data/USGS:e250fffe-ed32-4627-a3e6-9474b6dc6f0b). Other DEM data, such as for Greenland, is available from NSIDC (http://nsidc.org).

A-12 ICE ENGINEERING.

Resources for ice engineering topics are available in EM 1110-2-1612. EM 1110-2-1612 covers information and equations on the following topics:

- Ice processes and properties
- Ice control structures for both nonstructural and structural ice control
- Hydraulic computation and modeling of ice-covered rivers
- Analyses of ice-affected stages and flooding
- Ice forces on structures
- Sediment transport
- Bearing capacity of floating ice sheets, including ice blocks, short-term loads, moving loads, and long-term loads
- Model tests in ice
- Ice jams and mitigation measures
- Winter navigation on inland waterways, river ice management, river ice problem identification, ice forecasting, ice-related hydrometeorological data collection and monitoring, and ice control
- Control of icing on hydraulic structures

In “Modelling of Ice Jam Floods Under Past and Future Climates: A Review,” Rokaya et al. provide practical recommendations for modeling ice-jam floods.

The relationship between bearing capacity and ice thickness is described in EM 1110-2-1612. Arctic warming trends associated with climate change are increasing fall and winter air temperatures, causing fewer very cold days, river breakup to happen earlier, annual precipitation increase, an increase in the occurrence of freezing rain, and a shrinking snow season.[12] Milder winters have resulted in later freeze-up dates, earlier breakup dates, or both, for lakes in the northern United States and Canada.[13]

A-13 SNOWDRIFTS.

Procedures and methodology from case studies in Greenland and Antarctica for analyses of snow transport are found in

- South Pole Station Snowdrift Simulations, by Allen et al.;
- Snow Drift Management: Summit Station Greenland, by Haehnel and Bigl;
- Antarctic Camps Snow Drift Management Handbook, by Haehnel and Weatherly;
- "Blowing Snow Transport Analysis for Estimating Drift Orientation and Severity," by Haehnel;
- "Spatial Snowdrift Modelling for an Open Natural Terrain Using a Physically Based Linear Particle Distribution Equation," by Ohara et al.; and
- "Diagnosing Changes in Glacier Hydrology from Physical Principles Using a Hydrological Model with Snow Redistribution, Sublimation, Firnification and Energy Balance Ablation Algorithms," by Pradhananga and Pomeroy.

Computational methods, such as two-phase computational fluid dynamics modeling of snowdrift around a building, are available to use for estimating the increased rate of drift accumulation on structures in *South Pole Station Snowdrift Simulations*, by Allen et al., and "CFD Modeling of Snowdrift Around a Building: An Overview of Models and Evaluation of a New Approach," by Tominaga et al.

A-14 SNOW HYDROLOGY AND SNOWMELT.

An overview on the distinct aspects of Arctic hydrology, snow, and permafrost hydrology can be found in "Arctic Terrestrial Hydrology: A Synthesis of Processes, Regional Effects, and Research Challenges," by Bring et al., "A Review of Hydrological Models Applied in the Permafrost-Dominated Arctic Region," by Bui et al., and "Progress in Permafrost Hydrology in the New Millennium," by Woo et al. Surface hydrology is influenced by permafrost depth (active layer), snow loading, and the potential retention of winter or late-season rain events.[14] Refer to "A Review of Hydrological Models Applied in the Permafrost-Dominated Arctic Region," by Bui et al., for a comprehensive review and comparison of various hydrological models for limitations, suitability, and functionality.

---

[12] "Alaska Terrestrial and Marine Climate Trends, 1957–2021," Ballinger et al.
[13] "Historical Trends in Lake and River Ice Cover in the Northern Hemisphere," Magnuson et al.
[14] "Hydrological Response of a High-Arctic Catchment to Changing Climate Over the Past 35 years: A Case Study of Bayelva Watershed, Svalbard," Nowak and Hodson.

Snow hydrology and snowmelt with a hydrologic routing model is available at USACE Hydrologic Engineering Center–Hydrologic Modeling System (HEC-HMS) (https://www.hec.usace.army.mil/software/hec-hms/). The U.S. Army guidance on snowmelt estimation is found in EM 1110-2-1406.

The formation of aufies is controlled by local or regional surface topography, groundwater, climate, soil conditions, and permafrost presence and distribution.[15] Aufeis plagues infrastructure, including accumulation on road surfaces;[16] erosion of stream channels; [17] ground uplift and subsidence due to ice accumulation and thaw; and frost sorting of ground materials, leading to unstable conditions. The fundamental characteristics are available in the textbooks, and practical mitigation options to reduce icing are presented in "Denali Park Access Road Icing Problems and Mitigation Options," by Vinson and Lofgren, and "Observations of Arctic Snow and Sea Ice Cover from CALIOP Lidar Measurements," by Lu et al.

A-14.1 SWE Spatial Distribution.

Estimate the SWE spatial distribution in watersheds of interest using ground-based measurements or gridded estimates of SWE.

A-14.1.1 Ground-Based Measurements of SWE.

Ground-based measurements of SWE are typically made using a snow sampler. It is a hollow rod that is driven through the snowpack from top to bottom to extract a representative sample of snow. The filled snow sampler is then weighed to determine the SWE, Figure A-1.[18] The measurements are generally made at up to 10 separate locations along a line and averaged to account for variations in the snowpack depth and density. This is known as a snow course or snow survey. Samples are also retrieved and melted to determine SWE. In many cases, only the snow depth is measured, generally using a ruler or other measuring tool. Use the procedure in "Estimating Snow Water Equivalent Using Snow Depth Data and Climate Classes," by Sturm et al., to convert snow depth measurements to SWE if required.

[15] "The Distribution and Dynamics of Aufeis in Permafrost Regions," Ensom et al.
[16] "Denali Park Access Road Icing Problems and Mitigation Options," Vinson and Lofgren.
[17] *Aufeis Formation in Jarvis Creek and Flood Mitigation,* Daly et al.; "Aufeis Formation and Remediation," Zufelt and Daly.
[18] *Snow-Survey Sampling Guide*, U.S. Department of Agriculture (USDA).

Figure A-1 Weighing a Snow Sample in the Field to Measure SWE

A-14.1.2 Sources of Ground-Based Measurements of SWE.

The Global Historical Climatology Network is a worldwide database of daily weather data from over 107,000 surface stations compiled by NOAA's NCEI and available at "Global Historical Climatology Network Daily" (https://www.ncei.noaa.gov/products/land-based-station/global-historical-climatology-network-daily). The depth of snow on the ground is one of five core elements reported. More than 15,000 of these stations also report the water equivalent of the snow on the ground as the depth of the melted snow. The Global Historical Climatology Network includes data from four networks that provide snow information: CoCoRaHS, COOP, SNOTEL, and WBAN networks.

- CoCoRaHS—The Community Collaborative Rain, Hail, and Snow Network (CoCoRaHS) (https://www.cocorahs.org/) started in 1998. The network is sponsored by NOAA and the National Science Foundation and includes locations in all 50 states. Canada locations were added in 2012. Observers use a snow ruler to measure the snow depth on the ground and record the average depth to the nearest 0.5 inch. Reporting the water equivalent of total snow on the ground is optional.

- COOP—The NWS's Cooperative Observers Program (COOP) (https://www.weather.gov/coop/Overview) records daily United States observations. Snow depths are recorded in whole inches, and the water content of the snow on the ground is reported to the nearest 0.1 in. (2.5 mm).

- SNOTEL—The USDA Natural Resources Conservation Service Snowpack Telemetry (SNOTEL) network comprises over 865 automated sites at remote, high elevations in the western U.S. states, including Alaska. Data is available at the National Weather and Climate Center (https://wcc.sc.egov.usda.gov/nwcc/rgrpt?report=swe). Site instrumentation includes a sonic snow depth sensor and a snow pillow instrumented with a pressure transducer. The snow depth sensor has 0.5 in. resolution. The snow water equivalent is calculated from the snow pillow measurements with a 0.1 in. resolution up to 250 in. (6.35 m) of water as a maximum limit.

- WBAN—Weather Bureau Army Navy (WBAN) network consists of over 430 stations in the U.S. and over 83 stations outside the U.S. Snow depth is reported in whole inches whenever there is more than a trace of snow on the ground. The water equivalent of snow on the ground is reported with a 0.1 in. (2.5 mm) resolution at designated stations at 1800 UTC if the average snow depth is at least 2 in. (50 mm).

A-14.1.3 Gridded Estimates of SWE.

Gridded estimates of SWE are produced using observations and models. Typically, the models ingest surface observations, satellite data, and other data sources to determine the snowpack state at each model time step. In choosing a gridded snow product, it is important to ensure that the model spatial resolution, time step, time period, and level of accuracy are appropriate for the project. Typically, gridded snow products are distributed as large digital files that require special knowledge to process. There are many gridded snow products available. Listed below are three useful gridded snow products for snow hydrology:

- SNODAS—The NWS National Operational Hydrologic Remote Sensing Center (NOHRSC) provides a near-real-time 1 km^2 spatially distributed estimate of SWE and other snow properties across the continental United States through its SNODAS (Snow Data Assimilation System) data set available from NOHRSC (https://www.nohrsc.noaa.gov/). SNODAS data cover 2003 to the present. SNODAS integrates combined downscaled forcing data, an energy balance snow model, and assimilated observations in the SNODAS daily gridded SWE product to arrive at the best estimate of the snow characteristics over the United States and to minimize error associated with any individual method.

- University of Arizona SWE—The University of Arizona developed a 4 km gridded daily SWE data set covering 1982 to 2017 for the continental U.S. as presented in *Daily 4 km Gridded SWE and Snow Depth from Assimilated In-Situ and Modeled Data Over the Conterminous U.S. Version 1*, by Broxton et al. This data set interpolates SWE and snow depth from SNOTEL, the NWS COOP network sites, and other precipitation and temperature data.

- MERRA-2—The Modern-Era Retrospective analysis for Research and Applications, Version 2 (MERRA-2), is available from NASA's Global Modeling and Assimilation Office, Modern-Era Retrospective Analysis for Research

Applications, Version 2 (https://gmao.gsfc.nasa.gov/reanalysis/MERRA-2/). The MERRA-2 data set begins in 1980, offers worldwide coverage, provides estimates several times a day, and has a spatial resolution of ½° latitude by ⅝° longitude. MERRA-2 includes many parameters, including snow data.

A-14.1.4 Snow Mapping.

Snow mapping describes the process of analyzing ground-based measurements of snow, gridded snow products, satellite imagery, or other data to produce spatial distribution maps of the SWE for the watersheds of interest at the start of the snowmelt period. In general, GIS techniques are used to produce the maps. Required information includes base maps, a DEM, watershed boundaries, stream-channel layout, and land cover data. There are several considerations:

- Variation of SWE with elevation—In areas with significant elevation range, the snowpack depth is likely to increase as the elevation increases. Interpolation schemes using point measurements of SWE or other snow properties must take the relationship between elevation and snow depth into account.

- Variation of SWE with land cover—In areas with abrupt changes in land cover, such as forested "tree islands" found in prairies, snow conditions found in the tree islands are not representative of the general land cover found in the standard areas. Point measurements of SWE in these types of locations can produce erroneous results if used in interpolation schemes. (See *Wintertime Snow and Precipitation Conditions in the Willow Creek Watershed Above Ririe Dam, Idaho,* by Giovando et al., for an example.)

- Areas with no significant elevation range—It is difficult to produce accurate snow maps for large watersheds with no significant elevation range. In these areas, the snow spatial distribution is strongly influenced by wind, storm tracks, and other processes that are difficult to capture by interpolation. In these areas, gridded snow products produce better results than ground-based measurements.

- Determination of snow-covered area (SCA)—It is difficult when using an interpolation scheme to accurately estimate the spatial limits of the SCA in a watershed. In these cases, additional information provided by the MOD10A1 Cloud-Gap-Filled Snow-Covered Area (referred to as CGF-SCA) product is useful. CGF-SCA is a gridded, global, fractional SCA product based on satellite imagery that provides cloud-free daily estimates of snow-covered area.[19] It is produced daily by the NSIDC (https://nsidc.org/data/MOD10A1F/versions/61).

A-14.2 Snowmelt Modeling and Flow Routing.

As mentioned in paragraph A-14, USACE HEC-HMS (https://www.hec.usace.army.mil/software/hec-hms/) combines snowmelt models and a

[19] "MODIS Snow and Sea Ice Products," Hall et al.

variety of loss method, transform methods, baseflow estimation methods, and routing schemes to estimate snowmelt runoff. The model is GIS based and has extensive capabilities for performing many types of hydrologic analysis. A brief description of its snowmelt capabilities follows. For more information, see the HEC-HMS manuals available online.

- HEC-HMS has two spatial modes for snowmelt modeling. Snowmelt is estimated on a gridded or an elevation-band basis. The gridded approach divides the watershed into grids that are of constant size but can change to match project conditions. The snowmelt is estimated separately for each grid cell. Separate meteorological conditions driving the snowmelt are required for each grid cell. The gridded approach is appropriate for watersheds with significant elevation ranges or watersheds with significant spatial variations of weather during snowmelt events. The elevation-band approach divides the watershed into several bands, with each band covering a specific range of elevation. Snowmelt is estimated separately for each band. HEC-HMS estimates the temperature for each band based on an observed temperature at a known elevation and a known lapse rate of air temperature with elevation. The elevation-band approach is appropriate for mountainous watersheds.

- A temperature index (TI) snowmelt model is available in HEC-HMS. The TI model is empirically based and requires only air temperature to drive the basic melt calculation. The TI model is based on a linear relationship between snowmelt and air temperature.[20] This method was widely used by federal, state, and local agencies, as well as private engineering firms. For best results, it is important to calibrate the relationship between snowmelt and air temperature for each location where the model is applied.

A-15 FROZEN GROUND.

A-15.1 Engineering Properties.

Methods to quantify soil indexes are available in EM 1110-2-1906, which describes testing procedures for determining soil properties. ASTM standards and technical papers also provide additional information on frozen soil testing and properties.

Since frozen saline soils are widely distributed, particularly along the Arctic coast, the unique engineering properties of these soils must be considered.[21] Further discussion can be found in

- *Frozen Ground Engineering*, by Andersland and Ladanyi;

- “Strength Characteristics of Frozen Saline Soils,” by Aksenov et al.;

---

[20] *Snow Hydrology*, U.S. Army, North Pacific Division.
[21] “Frozen Saline Soils of the Arctic Coast: Their Distribution and Engineering Properties,” Brouchkov.

- "Long-Term Pile Load Testing System Performance in Saline and Ice-Rich Permafrost," by Biggar et al.;
- "Frozen Saline Soils of the Arctic Coast: Their Distribution and Engineering Properties," by Brouchkov;
- "Design of Vertical and Laterally Loaded Piles in Saline Permafrost," by Nixon and Neukirchner; and
- "Strength of Frozen Saline Soils," by Hivon and Sego.

A-15.2 Mechanical Properties.

Aside from ASTM standards, other common, nonstandardized frozen-soil test methods used are found in "Practice of Testing Frozen Soils," by Oestgaard and Zubeck, and in "Triaxial Testing of Frozen Soils—State of the Art," by Kornfield and Zubeck. The mechanical properties of frozen soils are available in various textbooks and literature such as *Frozen Ground Engineering*, by Andersland and Ladanyi, "Mechanical Properties of Naturally Frozen Ice-Rich Silty Soils," by Ge et al., and "Sampling, Machining and Testing of Naturally Frozen Soils," by Zubeck and Yang. Additional experimental data for soil properties for ice soils are available in literature (for example, "Sampling, Machining and Testing of Naturally Frozen Soils," by Ge et al., and "Experimental Study on Influences of Water Content and Temperature on Mechanical Properties of Ice-Rich Frozen Soil," by Huo et al.).

A-16 MODELS FOR ESTIMATION OF FREEZE AND THAW IN SOIL.

ModBerg, a one-dimensional linear model, may be used to calculate the depth of frost penetration in pavement structures or in soils.[22] Also, a method called FROST Modeler is available for estimating frost depth.[23] Both the ModBerg and FROST are available within PCASE (https://transportation.erdc.dren.mil/pcase/).

A-17 SITE SELECTION AND GEOTECHNICAL INVESTIGATIONS.

Standards and methods for site selection and geotechnical investigations are available. EM 1110-1-1804 is a guide for planning and conducting geotechnical investigations during the various stages of development for civil and military projects. EM 1110-2-1906 is for general guidance on sampling and storage of soil samples collected in the field.

For frozen soils, special care is required to maintain samples in their frozen state in the field, as well as in transit and storage. "Sampling, Machining and Testing of Naturally Frozen Soils," by Still et al., discusses maintaining samples in their frozen state and

machining frozen samples. An introduction to geophysical exploration for engineering, geological, and environmental can be found in EM 1110-1-1802.

A-18 SNOW AND ICE ROADS.

Snow roads (compacted snow) are common in cold regions. The complex nature of snow and ice mechanics presents unique challenges to constructing snow and ice runways. In "Review of Ice and Snow Runway Pavements," White and McCallum reviewed the methodology on the design and construction for snow and ice runways. In *McMurdo Snow Roads and Transportation: Final Program Summary* and in *Snow-Road Construction and Maintenance*, Shoop et al. provide examples of standard operation procedures and guidance for constructing, maintaining, or repairing snow roads at McMurdo Station, Antarctica. Procedures for ice road construction and a winter road operations handbook are available for northern regions in *Field Handbook Version of the Winter Roads Manual*, from the Ministry of Highways and Infrastructure, and *Overview of Ice Roads in Canada: Design, Usage and Climate Change Adaptation*, by Barrette. Additionally, "Design Considerations for the Use of Ice as a Construction Platform," by Hicks and Fayek, has practical design guidance and ice-loading criteria for short-term (less than 3 minutes) and long-term loading.

A-19 EROSION CONTROL.

Erosion-control approaches are published by the U.S. Arctic Research Commission Permafrost Task Force, in *Climate Change, Permafrost, and Impacts on Civil Infrastructure*, and in

- *Responses to Coastal Erosion in Alaska in a Changing Climate: A Guide for Coastal Residents, Business and Resource Managers, Engineers, and Builders*, by Smith and Hendee;
- "Mapping Sea Ice Overflood Using Remote Sensing: Alaskan Beaufort Sea," by Dickins et al.; and
- "Riverbank Erosion in Cold Environments: Review and Outlook," by Chassiot et al.

A-20 EMBANKMENTS.

Air convection embankments (ACEs) were used successfully for road embankments in Russia[24] and in several other countries, such as the United States, Canada, and Greenland. The ACE design concept is a mitigation approach to prevent permafrost degradation under transportation infrastructure.[25] Traditional ACEs use a highly porous,

[24] Roads and Airfields in Cold Regions: A State of the Practice Report, Vinson et al.
[25] "Modeling the Performance of an Air Convection Embankment (ACE) with Thermal Berm over Ice-Rich Permafrost, Lost Chicken Creek, Alaska," Darrow and Jensen.

poorly graded granular material to construct the main portion of the embankment.[26] The design results in a passive cooling or a natural convection system in a porous embankment with sufficient air permeability. Others have used a modified ACE with ventilation pipes installed in the embankment.[27] Canada applied and assessed methods, guidelines for thermal analysis, and mitigation design techniques for thermal stabilization of embankments built on thaw-sensitive permafrost.[28] Settlement of embankments in permafrost regions are attributed to thaw settlement, creep, and freeze–thaw cycling.[29] Analysis and numerical models are viable approaches to analyze the embankment deformation for heat transfer, creep, soil compression, and thaw consolidation.[30]

A-21 RISK METHODOLOGY.

A-21.1 USACE Risk Management Center.

The USACE Risk Management Center (https://www.rmc.usace.army.mil/) provides resources on risk assessments for various civil works projects, including best practices, software and tools, hazardous substance release, human and ecological effects, and remedial action (EM 200-1-4).

A-21.2 International Organization for Standardization.

Other guidance for risk management is published by the International Organization for Standardization (ISO):

- ISO 31000, *Risk Management—Guidelines*
- ISO/IEC 31010, *Risk Management—Risk Assessment Techniques.*

[26] "Convective Cooling in Open Rock Embankments," "Passively Cooled Railway Embankments for Use in Permafrost Areas," Goering; "Design of Passive Permafrost Cooling System for an Interior Alaska Roadway," Goering and Saboundjian.
[27] "Optimization in the Use of Air Convection Embankments for the Protection of Underlying Permafrost," Jørgensen and Ingeman-Nielsen.
[28] *Thermal Stabilization of Embankments Built on Thaw-Sensitive Permafrost*, Kong and Doré.
[29] "Large-Scale Direct Shear Testing of Compacted Frozen Soil Under Freezing and Thawing Conditions," De Guzman et al.; "Structural Stability of Highway Embankments in the Arctic Corridor," De Guzman; "Optimization in the Use of Air Convection Embankments for the Protection of Underlying Permafrost," Jørgensen and Ingeman-Nielsen; "In-Situ Monitoring of Settlement at Different Layers Under Embankments in Permafrost Regions on the Qinghai–Tibet Plateau," Yu et al.
[30] "Investigation of Embankment Deformation Mechanisms in Permafrost Regions," Ming et al.

A-21.3 Methods Used in Cold Regions.

There are two types of risk assessment methods applicable for cold regions:[31]

- Qualitative evaluation methods are simple, subjective, and develop a risk index value. An example of this can be found in “Qualitative Risk Assessment and Strategies for Infrastructure on Permafrost in the French Alps,” by Duvillard et al., which discusses the risk induced by permafrost warming and thawing on the stability of infrastructure built in mountainous areas.
- Quantitative methods include finite element analysis, the analytic hierarchy process, sensitivity analysis, Monte Carlo simulation, artificial neural networks, the catastrophe progression method, and others. Use a sensitivity analysis method to derive a specific risk value for various influencing factors of engineering risks, followed by an analytic hierarchy process and comprehensive evaluation method to analyze the weight of each influencing factor.[32] Various textbooks provide guidance for using a finite element method for a comprehensive risk assessment to simulate and predict the stability and failure probability.

A-21.4 Design for Reliability.

ISO provides general standards of reliability for structures (ISO 13822 and ISO 2394). There are also various methods used for design reliability. Examples of using Monte Carlo simulations include

- “A Probability-Based Reliability Assessment Approach of Seismic Base-Isolated Bridges in Cold Regions,” by Nassar et al., for evaluating bridge structures regarding earthquake response in cold regions;
- “Reliability-Based Assessment of Deteriorating Performance to Asphalt Pavement Under Freeze–Thaw Cycles in Cold Regions,” by Si et al., for asphalt pavement deterioration under freeze–thaw cycles in cold regions; and
- “Quantitative Risk and Optimal Design Approaches in the Snow Avalanche Field: Review and Extensions,” by Eckert et al., on optimal infrastructure design with risk frameworks for snow avalanches.

[31] “Engineering Risk Analysis in Cold Regions: State of the Art and Perspectives,” Yu et al.
[32] Ibid.

A-22 RESILIENCE.

A-22.1 Assessments.

Best practices for resilience assessments can be found in the following:

- *USACE Guide to Resilience Practices* as described in EP 1100-1-5
- ASCE *Hazard-Resilient Infrastructure: Analysis and Design* (Ayyub)
- ASCE *Climate-Resilient Infrastructure: Adaptive Design and Risk Management* (Ayyub)

A-22.2 Resources.

Academic papers on general resilience concepts include

- "Practical Resilience Metrics or Planning, Design, and Decision Making," by Ayyub;
- Adapting Infrastructure and Civil Engineering Practice to a Changing Climate, by Olsen; and
- "A Novel Framework for Risk Assessment and Resilience of Critical Infrastructure Towards Climate Change," Kumar et al.,

"Resilience and Vulnerability of Permafrost to Climate Change," by Jorgenson et al., focuses on cold regions environments; "Reliability-Based Assessment of Deteriorating Performance to Asphalt Pavement Under Freeze–Thaw Cycles in Cold Regions," by Si et al., on transportation systems; and "Best Practices for HVAC, Plumbing, and Heat Supply in Arctic Climates," by Winfield et al., on utilities. Preliminary guides on thermal resilience for buildings, with general recommendations for the building envelopes and foundations, as well as best practices for HVAC, plumbing, and heat supply in Arctic conditions, are presented in *Guide for Resilient Thermal Energy Systems Design in Cold and Arctic Climates,* by Zhivov, and in "Best Practices for HVAC, Plumbing, and Heat Supply in Arctic Climates," by Winfield et al. At a geological scale, in "Resilience and Vulnerability of Permafrost to Climate Change," Jorgenson et al. (2010) assessed the interdependent factors of air temperatures and ecological variables affecting the resilience or vulnerability of permafrost stability due to climate change.

APPENDIX B GLOSSARY

B-1 INTRODUCTION.

The following acronyms and terms used in this document and are specific to cold regions engineering, design, and construction. ASTM D7099 also provides an excellent reference for these and additional terms.

Additionally, a glossary of permafrost and other terms related to ground ice are available in the Glossary of Permafrost and Related Ground-Ice Terms from IPA (https://www.permafrost.org/publication/glossary-of-permafrost-and-related-ground-ice-terms/).

B-2 ACRONYMS.

ACE	Air convection embankments
ACI	American Concrete Institute
AFCEC	Air Force Civil Engineer Center
AHJ	Authority Having Jurisdiction
ANSI	American National Standards Institute
ASTM	American Society for Testing and Materials
ASCE	American Society of Civil Engineers
ASHRAE	American Society of Heating, Refrigerating, and Air Conditioning Engineers
BIA	Bilateral Infrastructure Agreement
CGF	Cloud-Gap-Filled
CAC	Common Access Card
CATEX	Categorical Exclusion
CCR	Criteria Change Request
CIMP	Coupled Model Intercomparison Projects
CoCoRaHS	The Community Collaborative Rain, Hail, and Snow Network
COOP	Cooperative Observer Program
CRREL	Cold Regions Research and Engineering Laboratory

CX	Categorical Exclusion
°C	Degrees Celsius
°F	Degrees Fahrenheit
DEM	Digital elevation model
DoDI	Department of Defense Instructions
DoR	Designer of Record
DSM	Digital surface model
ERDC	Engineer Research and Development Center
EWD	Engineering Weather Data
FEMA	Federal Emergency Management Agency
ft	Feet
GHG	Greenhouse gas
GIS	Geographic information system
GPCP	Global Precipitation Climatology Project
GSOD	Global Surface Summary of Day
h	Hours
HEC-HMS	Hydrologic Engineering Center's Hydrologic Modeling System
HQUSACE	Headquarters, U.S. Army Corps of Engineers
HNFA	Host Nation Funded Construction Agreements
IBC	International Building Code
ICRP	Installation Climate Resilience Plan
in.	Inches
$in.^2$	Square inches
IPA	International Permafrost Association
IPCC	Intergovernmental Panel on Climate Change

ISO	International Organization for Standardization
kg	Kilograms
km	Kilometers
kPa	Kilopascal
km^2	Square kilometers
lb	Pounds
m	Meters
MERRA-2	Modern-Era Retrospective Analysis for Research and Applications, Ver. 2
mm	Millimeters
mph	Miles per hour
NAVFAC	Naval Facilities Engineering Command
NCEI	National Centers for Environmental Information
NEPA	National Environmental Policy Act
NFS	Non–frost susceptible
NOAA	National Oceanic and Atmospheric Administration

SWE	Snow water equivalent
TI	Temperature index
UFC	Unified Facilities Criteria
USDA	U.S. Department of Agriculture
USGS	U.S. Geological Survey
UAF	University of Alaska Fairbanks
WBAN	Weather Bureau Army Navy

B-3 DEFINITION OF TERMS.

B-3.1 General.

Installation: With a capital "I," this refers to any DOD post, base, station, camp, fort, ranges or training areas.

B-3.2 Regions.

Arctic: The northern region in which the mean temperature for the warmest month is less than 50°F (10°C) and the mean annual temperature is below 32°F (0°C). In general, Arctic land areas coincide with the tundra region north of the limit of trees.

Subarctic: The region adjacent to the Arctic in which the mean temperature for the coldest month is below 32°F (0°C), the mean temperature for the warmest month is above 50°F (10°C), and there are less than four months having a mean temperature above 50°F (10°C). In general, Subarctic land areas coincide with the circumpolar belt of dominant coniferous forest.

Seasonal frost: Those areas of the earth having significant ground freezing during the winter but without development of permafrost. In seasonal frost areas, seasonal temperatures cause frost that affects earth materials and keep these frozen during only the winter; the occurrence of ground temperatures below 0°C appear only part of the year.

B-3.3 Soil and Frost Terms.

For common cold regions' soil terminology, see ASTM D7099, *Standard Terminology Relating to Frozen Soil and Rock*.

Active layer: The top layer of ground subject to annual freezing and thawing with a permafrost layer below.

Aggradation: Progressive increase in the thickness of permafrost, taking place over a period of years due to a change in climate or terrain conditions.

Annual frost zone: The top layer of ground subject to annual freezing and thawing. In Arctic and Subarctic regions where annual freezing penetrates to the permafrost table, the active layer, suprapermafrost, and the annual frost zone are identical.

Closed system: A condition in which no source of free water is available during the freezing process beyond that originally contained in the voids of soil.

Creep: Extremely slow, continuous strain deformation of materials under stress, at rates so slow as to usually be imperceptible except by observations of high precision or of extended duration.

Degradation: Progressive lowering of the permafrost table, occurring over a period of years.

Excess ice: Ice in the ground that exceeds the total volume of the pores that the ground would have under natural unfrozen conditions.

Free water: That portion of the pore water that is free to move between interconnected pores under the influence of gravity.

Freeze–thaw cycle: A freezing followed by thawing of a material over time.

Freezing (of ground): The changing of phase from water to ice in soil or rock.

Freezing front: The advancing boundary between frozen (or partially frozen) and unfrozen ground.

Freezing point: The temperature at which a pure liquid solidifies under atmospheric pressure; the temperature at which a ground material starts to freeze.

Freezing-point depression: The number of degrees by which the freezing point of an earth material is depressed below 0°C (32°F).

Freezing pressure: The positive pressure developed at ice–water interfaces in a soil as it freezes.

Frost action: A general term for the alternate freezing and thawing of moisture in materials, such as soil. It also covers the effects on these materials and on structures of which they are a part of or with which they are in contact. The term “frost” is often used to refer to frost action in general.

Frost boil: The breaking of a limited section of a highway or airfield pavement under traffic and ejection of soft, semiliquid subgrade soil. This is caused by the melting of the segregated ice formed by frost action. May also occur on unpaved ground surfaces, resulting in a small soil mound.

Frost creep: The ratchet-like downslope movement of particles because of frost heaving and subsequent ground settling on thawing. The heaving is normal to the slope and the settling more vertical.

Frost heave: The upward or outward movement of a ground surface (or objects on or in the ground) due to ice formation in the underlying soil. As the freeze front progresses downward, moisture migrates to the front, producing accelerated expansion and heaving.

Frost penetration: The movement of the freezing front into the ground during freezing.

Frost slough: A shallow slide that occurs when the stability of frost-loosened and moisture-saturated fine-grained soils on slopes is reduced during thaw.

Frost-stable ground: Soil or rock in which little or no segregated ice forms during seasonal freezing.

Frost-susceptible soil: Soil that will experience significant ice segregation when the requisite moisture and freezing conditions are present.

Frozen fringe: The zone in a freezing, frost-susceptible soil between the warmest isotherm at which ice exists in pores and the isotherm at which the warmest ice lens is growing.

Frost table: The surface, usually irregular, that represents the level, at any time in spring and summer, to which thawing of seasonal frozen ground has penetrated.

Frost thrust: A force due to frost action.

Frozen zone: A range of depth within which the soil is frozen.

Ground ice: A body of soil-free ice within frozen ground, including ice in pores, cavities, voids, or other openings in soil or rock, including massive ice; a general term referring to all types of ice in freezing and frozen ground.

Ground settlement: The downward movement of the ground, lowering the ground surface, resulting from the melting of ground ice more than that contained in pore fillings.

Hard-frozen ground: Frozen soil or rock which is firmly cemented by ice.

Heat capacity: The amount of heat required to raise the temperature of a unit mass of a substance by one degree. It is commonly expressed in Joules per kilogram per degree Kelvin.

Heterogeneously frozen soil: A soil with part of its water frozen as macroscopic ice occupying space more than the original voids in the soil.

Homogeneously frozen soil: A soil in which water is frozen within the material voids without macroscopic segregation of ice.

Ice lens: A lens-shaped body of ice ranging in thickness from hairline to 0.3 m. Ice layers more than 0.3 m in thickness are better termed massive ice beds.

Ice lenses: Lenticular formations of ice in soil occurring parallel to each other, normal to the direction of heat loss, and commonly in repeated layers.

Ice-rich permafrost: Perennially frozen ground that contains ice more than that required to fill pore spaces.

Intrusive ice: Ice formed from water intruded or injected under pressure into soils and rocks.

Ice segregation: The growth of ice within soil more than the amount produced by in-place conversion of the original void moisture to ice. Ice segregation occurs most often as distinct lenses, layers, veins, and masses, commonly, but not always, oriented normal to the direction of heat loss.

Ice wedge: A wedge-shaped ice mass, usually with its apex pointing downwards, in permafrost. Usually associated with fissures on trough-type polygons.

Ice wedge polygon: Any polygon surrounded by troughs underlain by ice wedges.

Latent heat of fusion: The amount of heat required to melt all the ice (or freeze all the pore water) in a unit mass of soil or rock.

Non-frost-susceptible materials: Cohesionless materials such as crushed rock, gravel, sand, slag, and cinders in which there is no significant ice segregation under normal freezing conditions.

Normal period: The time of the year when there is no alteration in strength of foundation materials because of frost action. In seasonal frost areas, it extends from mid- or late spring to mid- or late fall.

Open system: A condition where more free water than originally contained in the voids of the soil is available to move within the soil and to form segregated ice in frost-susceptible soil.

Percent heave: The ratio, expressed as a percentage, of the amount of heave to the depth of frozen soil.

Permafrost: Perennially frozen ground. A thermal condition in soil or rock where temperatures below 32°F persist over at least two consecutive winters and the intervening summer; moisture in the form of water and ground ice may or may not be present.

Permafrost base: The lower boundary surface of permafrost, above which temperatures are below 32°F, and below which temperatures are above 32°F.

Permafrost, continuous: Permafrost occurring everywhere beneath the exposed land surface throughout a geographic region, except for widely scattered locations.

Permafrost, discontinuous: Permafrost occurring in some areas beneath the ground surface throughout a geographic region where other areas are free of permafrost.

Permafrost table: An irregular surface within the ground that represents the upper boundary surface of permafrost.

Residual thaw layer: A layer of thawed or unfrozen ground between the permafrost and the annual frost zone. This layer does not exist where annual frost (active layer) extends to permafrost.

Seasonally active permafrost: The uppermost layer of the permafrost that undergoes seasonal phase changes due to the lowered thawing temperature and freezing-point depression of its pore water.

Segregated ice: Ice formed by the migration of pore water to the freezing plane, where it forms into discreet lenses, layers, or seams, ranging in thickness from hairline to greater than 10 m (32 ft). The ice is formed by ice segregation.

Snowdrift: An accumulation of wind-blown snow, often much thicker than the surrounding snow cover.

Snowline: The boundary of a highland region in which snow never melts.

Snowmelt: Melting of the snow cover; the period during which the melting of the snow cover occurs at the end of winter.

Solifluction: The perceptible, slow downslope flow of saturated unfrozen soil over a base of impervious or frozen material. Movement takes place primarily when melting of segregated ice or infiltration of surface runoff concentrates excess water in the surface soil, which then behaves like a viscous fluid. Solifluction features lobes, stripes, sheets, and terraces.

Suprapermafrost: The entire layer of ground above the permafrost table.

Sporadic permafrost: A subzone of the zone of discontinuous permafrost: In North American usage, it is permafrost underlying less than 30% of the exposed land surface; in Russian usage, it is permafrost underlying from 3% to 20% of the exposed land surface.

Tangential adfreeze shear: Tangential shear between frozen ground or ice and another material to which it is bonded by freezing.

Thaw consolidation: The process by which a reduction in volume and increase in density of a soil mass occurs, following thaw, in response to the escape of water under the weight of the soil itself, an applied load, or both. Thaw consolidation may proceed for many years.

Thaw-sensitive permafrost: Perennially frozen ground that, on thawing, will experience significant thaw settlement and suffer loss of strength to a value significantly lower than that of a similar material in an unfrozen condition.

Thaw settlement: The differential downward movement of the ground surface resulting from the escape of water on melting of excess ice in the soil and the thaw consolidation of the soil mass.

Thaw slumping: A type of mass movement caused by the conversion of ice into water in a soil by ground thaw, creating the kind of landslide that most closely resembles the more temperate climate earth flow with a well-developed breakaway scarp front.

Thaw-stable frozen soils: Frozen soils that do not, on thawing, show loss of strength below normal, long-time thawed values nor produce detrimental settlement.

Thaw-unstable frozen soils: Frozen soils that show, on thawing, significant loss of strength below normal, long-time thawed values or significant settlement as a direct result of the melting of excess ice in the soil.

B-3.3.1 Temperature-related Terms.

Average annual temperature: The average of the average daily temperatures for a particular year.

Average daily temperature: The average of the maximum and minimum temperatures for one day or the average of several temperature readings taken at equal time intervals for one day, hourly.

Average monthly temperature: The average of the average daily temperatures for a particular month.

Breakup period: The period of the spring thaw during which the ground surface is excessively wet and soft and ice is disappearing from streams and lakes. Duration of the breakup period usually varies usually from 1 to 6 weeks, depending on regions or local climatic conditions.

Degree-days: The degree-days for any one day equal the difference between the average daily air temperature and 32°F. The degree-days are negative when the average daily temperature is below 32°F (freezing degree-days) and positive when above 32°F (thawing degree-days). Degree-days may be computed in either Fahrenheit or Celsius units; this manual uses Fahrenheit degree-days.

Design freezing index: For design of permanent pavements, the design freezing index is the average air freezing index of the three coldest winters in the latest 30 years of record. If 30 years of record are not available, substitute the air freezing index for the coldest winter in a 10-year period. For design of foundations for average permanent structures, compute the design freezing index for the coldest winter in 30 years of record, or estimate to correspond with this frequency if the number of years of record is limited. Use the latest available periods of record. To avoid the necessity for adopting a new and only slightly different freezing index each year, the design index at a site with continuing construction need not change more than once in five years, unless the more recent temperature records indicate a significant change.

Design thawing index: The design thawing index is computed on the same frequency and basis as the design freezing index, except that summer thaw conditions are used.

Freeze-up period: The period during which the ground surface freezes and an ice cover is forming on streams and lakes. The duration of the freeze-up period varies from 1 to 3 months, depending on regional or local climatic conditions.

Freezing index: The number of degree-days between the highest and lowest points on a curve of cumulative degree-days versus time for one freezing season. It is a measure of the combined duration and magnitude of below-freezing temperatures occurring during any given freezing season. The index determined for air temperatures at approximately 4.5 ft above the ground surface is commonly designated as the air freezing index, while that determined for temperatures at, or immediately below, the ground surface is known as the surface freezing index.

Freezing season: That period during which the average daily temperature is below 32°F.

Frost-melting period: An interval of the year during which ice in the ground is returning to a liquid state. It ends when all the ice in the ground melts or when freezing starts again. Although in the generalized case there is only one frost-melting period, beginning during the general rise of the air temperatures in the spring, one or more significant frost-melting intervals may take place during a winter season.

Geothermal gradient: The temperature gradient in the ground below the zone of annual temperature fluctuations, produced by the continuous flow of heat from the Earth's hot interior toward the Earth's cool surface.

Mean annual temperature: The average value taken from several years of annual temperature averages.

Mean daily temperatures: The average taken from the averages of the daily temperatures for a given day for several years.

Mean freezing index: The freezing index determined from mean temperatures.

Mean monthly temperature: The average taken from the averages of the monthly temperatures for a given month for several years.

Mean thawing index: The thawing index determined from mean temperatures.

Period of weakening: An interval of the year that starts at the beginning of the frost-melting period and ends when the subgrade strength has returned to normal-period values or when freezing starts again. In seasonal frost areas, the period of weakening may be longer than the frost-melting period; but in permafrost areas, the periods coincide.

Strudel scour: An Arctic phenomenon that occurs every spring when the fresh-water rivers melt and form off-river deltas when river discharge drains through holes in the sea ice cover. Strudel scours constitute a major design consideration for subsea pipelines or other structures near rivers.

Thawing index: The number of degree-days between the lowest and highest points on a curve of cumulative degree-days versus time for one thawing season. It is a measure of the combined duration and magnitude of above-freezing temperatures during any given thawing season. The index determined for air temperatures at 4.5 ft above the ground is commonly designated as the air thawing index, while the temperature at or immediately below the ground surface is known as the surface thawing index.

Thermal regime: The pattern of temperature variations found in the ground with time and at a certain depth from the surface.

Thermal erosion: The erosion of ice-rich permafrost by the combined thermal and mechanical action of moving water or air (sublimation).

Thermal expansion (or contraction) coefficient: The volume change per unit volume of a substance due to a one-degree change in its temperature.

Thermal pile(s): Structural piling modified to passively remove heat from the ground whenever the ambient air temperature is lower than the ground temperature.

Total annual freezing index: The cumulative number of degree-days, calculated by adding all the negative mean daily air temperatures (in degrees Celsius) for a specific station during a calendar year.

Total annual thawing index: The cumulative number of degree-days, calculated by adding all the positive mean daily air temperatures (in degrees Celsius) for a specific station during a calendar year.

Wind chill: The excess rate of removal of body heat from exposed skin by moving air compared to still air at low temperatures. It is often expressed as a lower equivalent air temperature that is a function of actual air temperature and wind speed.

B-3.4 Terrain Terms.

Frost mound: A localized mound-shape on the land surface caused by frost action with or without hydrostatic pressure.

Icing: A surface ice mass formed by freezing of successive sheets of water from seepage, flow from a spring, or emergence from below river or lake ice through fractures.

Muskeg: Poorly drained organic terrain consisting of a mat of living vegetation overlying an extremely compressible mixture of partially decomposed peat, varying in thickness from a few inches to many feet.

Patterned ground: A general term describing ground patterns that result from frost action, such as polygons, circles and nets, stripes, and solifluction features.

Pingo (hydrolaccolith): A large ice-cored frost mound, often 100 ft high or more, consisting of a core of massive ice, produced primarily by injection of water and covered with soil and vegetation.

Strudel scour: A localized, seasonal scour formation that occurs in the spring when melting fresh water in rivers and streams flows over the surface and drains through holes of frozen shore-fast ice.

Thermokarst: The irregular topography resulting from differential thaw settlement or caving of the ground because of excess ice melting in thaw-unstable permafrost; the process by which characteristic landforms result from the thawing of ice-rich permafrost.

Tundra: Treeless terrain of grasses and shrubs characteristic of the Arctic, found at both high latitudes and high altitudes.

FOREWORD

The Unified Facilities Criteria (UFC) system is prescribed by MIL-STD 3007 and provides planning, design, construction, sustainment, restoration, and modernization criteria, and applies to the Military Departments, the Defense Agencies, and the DoD Field Activities in accordance with USD (AT&L) Memorandum dated 29 May 2002. UFC will be used for all DoD projects and work for other customers where appropriate. All construction outside of the United States, its territories, and possessions is also governed by Status of Forces Agreements (SOFA), Host Nation Funded Construction Agreements (HNFA), and in some instances, Bilateral Infrastructure Agreements (BIA). Therefore, the acquisition team must ensure compliance with the most stringent of the UFC, the SOFA, the HNFA, and the BIA, as applicable.

UFC are living documents and will be periodically reviewed, updated, and made available to users as part of the Military Department's responsibility for providing technical criteria for military construction. Headquarters, U.S. Army Corps of Engineers (HQUSACE), Naval Facilities Engineering Systems Command (NAVFAC), and Air Force Civil Engineer Center (AFCEC) are responsible for administration of the UFC system. Technical content of UFC is the responsibility of the cognizant DoD working group. Defense Agencies should contact the respective DoD Working Group for document interpretation and improvements. Recommended changes with supporting rationale may be sent to the respective DoD working group by submitting a Criteria Change Request via the Internet site listed below.

UFC are effective upon issuance and are distributed only in electronic media from the following source:

- Whole Building Design Guide website http://www.wbdg.org/dod.

Refer to UFC 1-200-01, *DoD Building Code*, for implementation of new issuances on projects.

TABLES

CHAPTER 1 INTRODUCTION

1-1 BACKGROUND.

The field of Arctic and Subarctic engineering, also known as cold regions engineering, covers a wide range of multidisciplinary topics and principles. Unique issues exist in the planning, design, construction, and operation of infrastructure and facilities in Arctic and Subarctic regions. Among them are permafrost, seasonal ground frost heave and thaw settlement, extreme low temperatures, high wind loads, heavy snow loads, and remote construction sites. Additionally, the implications of the rapidly changing climate in Arctic and Subarctic regions exacerbate these unique challenges.

The Unified Facilities Criteria (UFC) Arctic and Subarctic series includes five volumes that summarize relevant information and the most feasible approaches and solutions for planning, design, construction, and maintenance of infrastructure and facilities in the Arctic and Subarctic areas of the globe.

1-2 NEED FOR SPECIAL APPROACHES.

The importance of selecting the proper project site in Arctic and Subarctic regions cannot be overemphasized. The type of data collected for site selection is essentially the same as that used for engineering design in temperate regions, but due to the high probability of heterogenous ground ice conditions in the Arctic and Subarctic, it is essential to collect more detailed information. It is not feasible to provide a detailed list of the information required for a given site-selection problem because each project requires unique judgment in the development of an adequate program of investigation and analysis; however, understanding the basic principles and considerations of cold regions site assessment and selection is crucial. Observations made in the Arctic and Subarctic, or cold regions, of North America form the basis for this UFC, and while local details may vary considerably, the basic concepts presented are generally applicable.

1-3 REISSUES AND CANCELS.

This document supersedes and cancels inactivated UFC 3-130-02, dated 16 January 2004.

1-4 PURPOSE AND SCOPE.

The Arctic and Subarctic UFC series provides technical guidance and available technical requirements for planning, design, construction, and maintenance of DoD facilities worldwide for all service elements in Arctic and Subarctic environments. These guidance and technical requirements are based on the International Building Code (IBC) and the requirements in UFC 1-200-01. The UFC 3-130 series covers many aspects of Arctic and Subarctic engineering with the specific exception pavements, which is incorporated into the UFC 3-250 and 3-260 series as discussed in UFC 3-130-01, paragraph 1-6.3. In addition to this volume, there are four other series volumes:

- UFC 3-130-01, *Arctic and Subarctic Engineering*. UFC 3-130-01 serves as an introduction to the Arctic and Subarctic UFC series.

- UFC 3-130-03, *Arctic and Subarctic Foundations for Freezing and Thawing Conditions*. UFC 3-130-03 includes horizontal and vertical foundations, considerations affecting foundation design, and construction and monitoring of facilities in the Arctic and Subarctic areas.

- UFC 3-130-04, *Arctic and Subarctic Buildings*. UFC 3-130-04 includes building design in the Arctic and Subarctic areas.

- UFC 3-130-05, *Arctic and Subarctic Utilities*. UFC 3-130-05 provides criteria and guidance for the design of utility systems for military facilities in Arctic and Subarctic regions.

This UFC provides criteria and guidance for selecting sites for military facilities in Arctic and Subarctic regions. Only criteria and guidance unique to cold regions, where extreme low temperatures, permafrost, and seasonally frozen ground are likely to occur, are provided. UFC 3-130-02 is in no way all inclusive, and other cold regions resources are cited to provide sources of additional information. These minimum technical requirements are determined by UFC 1-200-01. Where other statutory or regulatory requirements are referenced, the more stringent requirement must be met. This UFC describes a phased approach to site assessment; the phases include planning, preliminary assessment, ground reconnaissance, detailed geotechnical site investigation (geophysical and geotechnical subsurface exploration), and reporting. Additional topics include general considerations for site characterization and, within the phases, data and data acquisition, desktop survey, remote sensing, ground reconnaissance, and geotechnical data analyses.

1-5 APPLICABILITY.

This UFC follows the same applicability as UFC 1-200-01, paragraph 1-3, for those geographic locations in Arctic and Subarctic regions worldwide.

1-6 GENERAL BUILDING REQUIREMENTS.

This UFC is an integrated part of the Arctic and Subarctic UFC 3-130 series. Use the other documents of this series in conjunction with this UFC to address construction aspects unique to cold regions. See UFC 3-130-01, Chapter 2 for the definitions of Arctic and Subarctic.

Often, conventional construction practices are acceptable in Arctic and Subarctic regions with appropriate modification to account for extreme cold temperatures, frost heaving soils, and permafrost areas. This UFC modifies and supplements the criteria found in the core UFCs. Utility provider’s or Installation specific requirements must be considered.

1-7 LEVEL OF CONSTRUCTION.

See UFC 1-200-01, paragraph 1-3.2, for the definitions of permanent construction, temporary construction, and facilities in support of military operations.

1-8 CYBERSECURITY.

All facility-related control systems (including systems separate from a utility monitoring and control system) must be planned, designed, acquired, executed, and maintained in accordance with UFC 4-010-06, and as required by individual Service Implementation Policy.

1-9 BEST PRACTICES.

In cold regions engineering planning, design, and construction, much of the state of the practice is not codified. Lessons learned and the experiences of the Installation engineering staff are invaluable and may help avoid costly and catastrophic infrastructure failures. Appendix A, Best Practices, provides guidance for accomplishing certain utilities design and engineering services in extreme Arctic and Subarctic environments. The Designer of Record (DoR) must review and interpret this guidance as it conforms to criteria and contract requirements and apply the information according to the needs of the project. If a Best Practices document guideline differs from any UFC, the UFC takes precedence. For Best Practices guidelines not discussed in a UFC, the DoR must submit a list of the guidelines or requirements being used for the project to the Government Project Manager, with documentation sufficient for review and approval, prior to completing the design.

1-10 GLOSSARY.

Appendix B contains acronyms, abbreviations, and terms. See UFC 3-130-01 for definitions of additional terms that are specific to cold regions.

1-11 REFERENCES.

Appendix C contains a list of references used in this document. The publication date of the code or standard is not included. Unless otherwise specified, the most recent edition of the referenced publication applies. In addition, the fundamentals for Arctic and Subarctic engineering are widely available in cold regions textbooks. See Appendix C in UFC 3-130-01 for a list of these resources.

This Page Intentionally Left Blank

CHAPTER 2 PLANNING

2-1 INTRODUCTION.

Use UFC 3-201-01 for general site development, design, and planning requirements and for specific issues, such as natural hazards, drainage, grading, and infrastructure siting. Also see UFC 3-220-01 prior to starting the project design phase to determine geotechnical requirements and other site classification requirements.

2-2 COORDINATION.

Site selection planning requires coordinated processes, including knowledge of environmental requirements, land use restrictions, building setbacks, flood hazard areas, utility connections, utility offsets, vehicle circulation, and buffers from natural and manmade features.

Coordinate all site work, including topographic, hydrographic, and soil surveys, with representatives of the Command, District, and Installation engineering staff and with other design personnel. The exact location of the geotechnical subsurface exploration, whether by drilling or excavation, must be approved by the appropriate authorities, such as the local utility service or a company hired by the geotechnical engineering firm to locate utilities.

2-3 APPROVALS AND PERMITS.

See UFC 3-130-01, paragraph 1-13, for the general approval and permit processes for Arctic and Subarctic planning, design, and construction, including site investigation and its associated drilling and excavations.

2-4 PERSONNEL.

Project site selection requires personnel who are cognizant of engineering problems peculiar to Arctic and Subarctic regions and familiar with the various types of data collection and interpretation used in site assessments. To ensure the best possible site is selected and that an optimal amount of accurate and detailed information is obtained, the combined effort of a number of specialists is essential. Different phases of the site assessment require different expertise and different personnel.

Interpreting remote sensing data requires trained, experienced interpreters who, if possible, participate in the field verification program to enhance their understanding of the terrain patterns to be viewed from acquired data. For high-risk and mission-critical Installations, personnel should include an air photo analyst, a coordinator who is a civil or geological engineer and is familiar with the immediate and ultimate uses of the Installation, a geotechnical engineer, a civil engineer (hydrologist), a geologist, and an ecologist. Ground and subsurface surveys require a survey crew and party chief, a geophysical technician and data interpreter, a drill crew and foreman, and a guide to provide local knowledge. Frequently, crews are required to go into the field with preliminary soil and terrain maps as their only means of orientation. In undeveloped regions where readily identified cultural features, such as roads, structures, and cleared areas, are absent, field crews must be able to identify landforms on the ground and on profile maps to aid in their interpretation.

2-5 UNCERTAINTY.

A large part of permafrost analysis, in the context of this UFC, relies on the likelihood of occurrence and variability based on surface expression. Ground ice content is inherently difficult to predict in Arctic and Subarctic regions because of the complex, mutually dependent, and highly dynamic nature of the many factors influencing permafrost occurrence and expression. Surficial expressions commonly associated with ice intrusion and freeze-thaw processes are used as markers and are assigned a high or low likelihood of indicating permafrost based on how closely tied they are to perennially frozen ground and its co-existing features. These surficial features must be interpreted while considering climate, region, topography, vegetation, and so on. The presence of multiple surficial features in the same area increases the likelihood that permafrost is present. Unfortunately, an absence of markers does not necessarily indicate a lack of permafrost. Due to the complex, codependent, and dynamic nature of climate, hydrology, vegetation, and landform in cold regions, evaluating surficial features is the best starting point from which to determine areas most likely to be underlain by permafrost.

2-6 RISK.

UFC 3-130-01, Chapter 4, discusses risk assessment principles as they apply to cold regions. For site selection, the intensity of the site assessment process is proportionally dependent on the risk and sensitivity of the proposed construction, as outlined by the risk assessment method appropriate to the project. Risk reflects unknowns and relates to the variability of the site conditions, which are described by the site characterization. The characterization process consists of a range of resolutions and costs, from low resolution, perhaps using remote sensing methods, to high-resolution geotechnical investigations with drilling and sampling. Installation risk and risk assessment must be carefully considered throughout the site selection process to determine which resolution and methods of site characterization are appropriate. Risk assessment is to occur on a project-by-project basis.

2-7 SITE SELECTION AND ASSESSMENT PROCESS.

Arctic and Subarctic regions are host to unique site characterization features that are not found in temperate regions and require additional attention for engineering planning, design, and construction purposes. Use UFC 3-130-01 for guidance on various factors that may be encountered when working in cold regions and are critical to effective site assessment and selection. This UFC is broken into chapters to describe both the general workflow and the step-by-step processes for site characterization.

2-7.1 General Workflow.

The primary objectives of site selection and assessment are to obtain data on the

- boundaries of frozen and thawed zones within the depth influenced by construction activities,
- amount and mode of occurrence of ice in frozen soil, and
- composition and properties of the soil itself.

The type of exploration is dictated, to a large extent, by the relative inaccessibility of many northern areas, expensive and limited logistics, and climatic limitations. In addition, special techniques are frequently required for explorations in frozen ground due to its properties. Figure 2-1 illustrates general steps and strategies, from preliminary characterization to quantitative examination, for site evaluation and assessment. However, all site assessment must be performed and documented as prescribed in the approved contract documents.

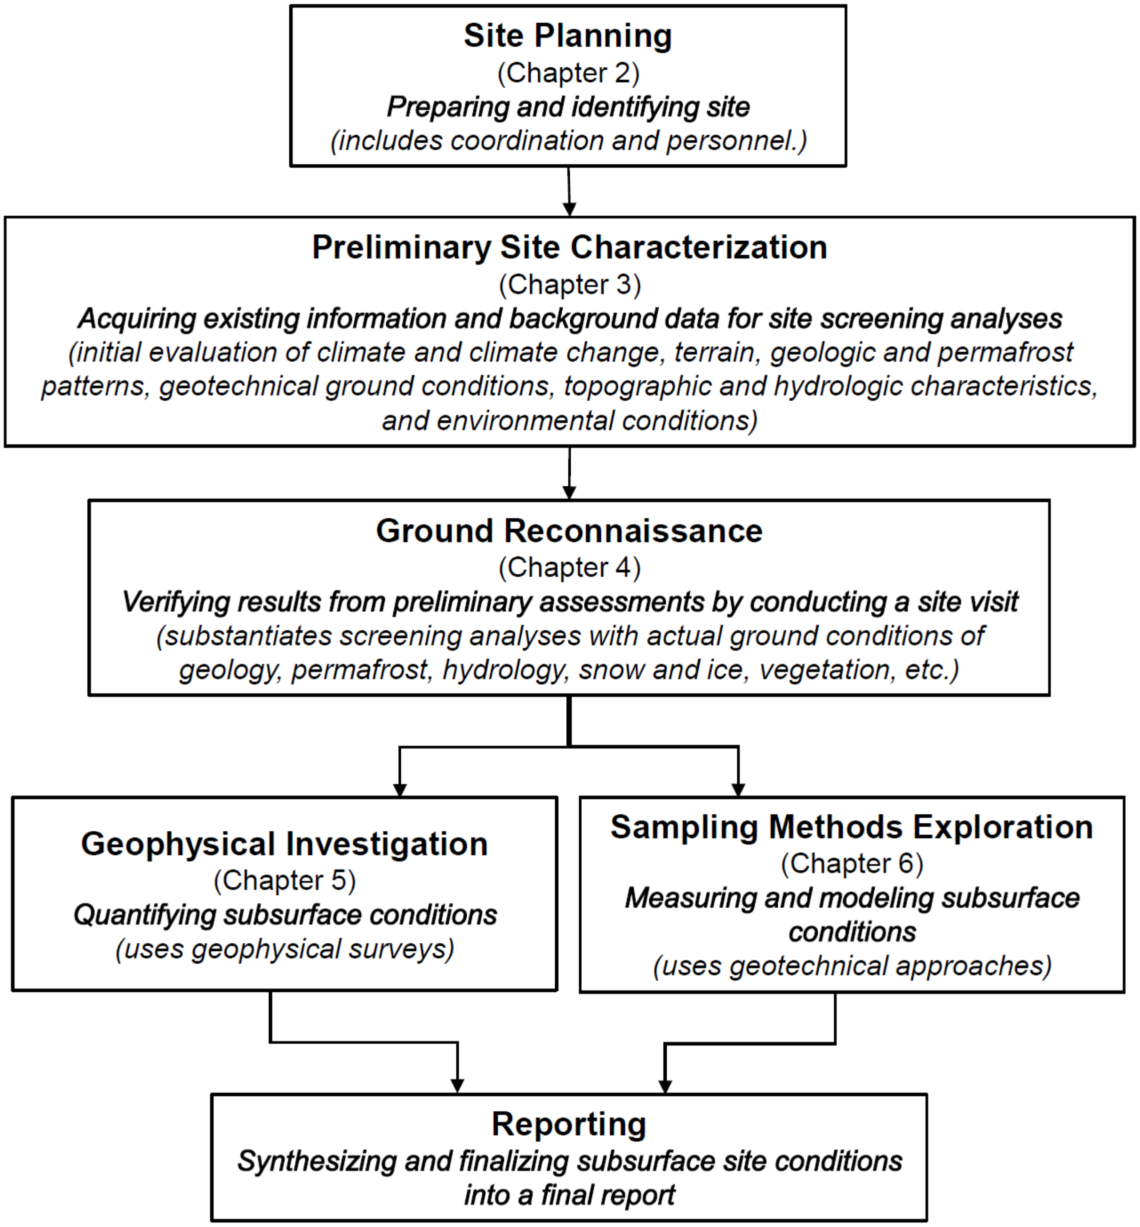
2-7.2 SUBSURFACE EXPLORATION WORKFLOW.

Once background data have been collected, detailed geophysical and geotechnical investigations (described in Chapters 5 and 6) can begin. An example workflow is shown in paragraph A-2 and highlights detailed processes. This workflow applies to organizing geotechnical investigations for both large projects, such as multibuilding installations and linear infrastructure developments (such as dams, roads, airfields, pipelines, or dikes), and small-scale projects.

2-7.3 Final Reports.

The site selection and assessment final report is the product of the investigation, as shown in Figure 2-1. The report synthesizes the final geotechnical profile, ground conditions (such as ground ice), and material properties of the site. More detailed reporting requirements are project or design specific (for example, draft and final reports; 35%, 65%, 95%, and 100% design submittals; number of document copies submitted and format; review procedures). The outline of the report includes, but is not limited to, the scope of the project, climate conditions, site screening, seismicity, geology, geomorphology, ground water, vegetation, permafrost (profile and spatial distribution), active layer, snow, ice, geotechnical properties, recommendations, and limitation of investigation. However, final reports must be followed as prescribed in the approved contract documents.

Figure 2-1 Arctic and Subarctic Site Selection and Assessment Process



CHAPTER 3 PRELIMINARY ASSESSMENT

3-1 INTRODUCTION.

Conduct detailed consultations with the Government to clearly define requirements and preferences. Use UFC 2-100-01 to develop a preliminary approach that is appropriate for the site and adjacent facilities and integrates sustainable strategies with a long-term outlook on the climate. Conduct a preliminary site analysis by obtaining photographs of the site. Research and obtain the Installation's master plan, utility maps, and as-built record drawings for information related to topography, utilities, and storm drainage availability in the project vicinity. Evaluate the likelihood of abandoned and unmapped utilities. Research and review available subsurface investigation data and reports to evaluate subsurface conditions. Identify flood hazard areas in accordance with the International Building Code (IBC), Section 1612, and UFC 3-201-01, paragraph 2-7.1. Research and adhere to safety requirements. Consult with the Government Project Manager to establish contact with the Installation's environmental personnel to determine if the site has environmental concerns, such as radon, pesticides, or known contamination. Evaluate the need for additional analysis based on project requirements and site conditions.

3-2 DATA ACQUISITION AND NECESSARY INFORMATION.

When preparing for site selection and development, existing information and data pertinent to the project requirements are essential for enhancing understanding of the climate, terrain, geologic and permafrost patterns, geotechnical ground conditions, topographic and hydrologic characteristics, and environmental conditions. Adequate maps and existing reports are beneficial for the selection of the site for any structure. In more populated areas, a wide variety of maps and reports are available. In more remote areas, there may be a limited number of preexisting maps and data available. Geographic information systems (GIS) are very useful for displaying data, creating maps, and storing collected information. The information required for a given site varies considerably according to the size and complexity of the project and the Installation's importance or focus, its geographical location, and whether the proposed facilities are in an unmapped or undeveloped area or are an addition to an existing Installation. Important considerations in information types with respect to Arctic and Subarctic regions are discussed in the sections that follow.

Existing reports and records published by various government agencies, engineering firms, mining companies, researchers, and others that give information on the characteristics of the terrain and on the climate, hydrology, and geology of the site must be thoroughly examined. These sources provide excellent background information for preliminary site assessment. Make effort to investigate and acquire reports from the project area because they may contain pertinent information for future construction or information on known conditions in an area. Reports of any type must be critically examined to ensure conclusions drawn hold true for current site conditions.

3-2.1 Access.

The availability of existing commercial and military surface, water, and air routes for the transportation of personnel and materials, the location of way stations and terminals, and prospective sites for such facilities must be determined. Obtain information on existing or abandoned access roads. Determine navigable depths of rivers, lakes, and harbors where water transportation is contemplated. Obtain data on the beginning and end of shipping seasons where shipments of materials, equipment, and supplies by oceangoing vessels may be scheduled. Determine the availability of calm water for the landing of float planes. Analyze weather phenomena, such as fog prevalence, low ceiling prevalence, and high wind conditions, that affect the availability of air operations. Determine appropriate vehicles to be used for overland transportation during winter and summer.

3-2.2 Climate.

UFC 3-130-01 discusses where to obtain data on climate. Obtain temperature information so that freezing and thawing indexes can be computed for use in estimating depths of freeze and thaw and so that possibilities of degradation or aggradation of permafrost can be determined. UFC 3-130-01 also describes the effects of climate change on the project. In particular, the long-term effect on the mean annual ground temperature (MAGT) is important when constructing in a manner that utilizes the strength of the frozen ground for bearing or adfreeze capacity.

3-2.3 Snowfall.

Snow data can come in several forms, such as snowfall maps, snow depth maps, and snow water equivalent maps. See UFC 3-130-01.

3-2.4 Vegetation.

Profiles of vegetation type and distribution must be carefully constructed. Also, past vegetation reports and characterizations must be considered. Current vegetation distribution maps can be constructed based upon remote-sensing data and recent imagery. See paragraph 2-5 for surface indicators and see UFC 3-130-01 for general descriptions of vegetation characteristics.

3-2.5 Geological.

Accurate information on surface and subsurface conditions is very important; in many instances, it may be the determining factor in the selection of a site. Geological maps are an important basis for terrain mapping and site characterization, and they depict the type and distribution of surficial discernable geological features in a region. These features can include soil and rock units and geologic structures such as faults and stratigraphic orientations, and they may identify areas of specific geotechnical hazard (for example, landslides). Obtain soil maps, if possible, because they depict the type and distribution of soils in a region; soil maps are useful for determining areas of thaw-stable or thaw-unstable material.

Well-drained gravels and sands are frequently found in coastal plains, river terraces, glacial deposits, and outwash plains. Such soils are generally ideal for almost any type of construction in Arctic and Subarctic regions because they are generally ground-ice poor to ground-ice free, and thus thawing is not a major problem. However, any type of construction can be troublesome if located on frost-susceptible soils, such as clays and silts. Where such foundation materials must be built upon, it is usually necessary to employ special design and construction measures to maintain structural stability. These measures are discussed in UFC 3-130-03. Obtain subsurface information to a degree commensurate with the importance, complexity, and size of the proposed structures. Minimum laboratory soil tests typically include density, moisture content, and Atterberg limits for various horizons, while additional tests, such as permeability, consolidation, shear strength, and compaction, may be required to support the project design. These test results, coupled with the survey data regarding topography, ground type, and location, can be compiled into a terrain unit map (see paragraphs 3-2.5.3 and 3-3.3.4).

3-2.5.1 Permafrost.

In Arctic and Subarctic regions, permafrost is often a determinant in the selection or rejection of a building site. Additionally, it can have major impacts on costs and the functionality of an Installation if it is not properly addressed early in the process. As such, it is important to determine the extent and characteristics of permafrost under any proposed building site. Update permafrost maps as more detailed data become available. Until confirmed through geophysical and geotechnical investigation, permafrost maps should be treated as probability-of-occurrence maps.

Knowledge of the extent and nature of the permafrost is vital where segregation ice occurs because this is generally the result of a supersaturated condition. Determine the depth and thickness of the permafrost layer, the depth of the annual freezing or thawing zone (active layer), and the nature of the soils present. Information on whether the permafrost contains massive ground ice and if the ice is homogeneously or heterogeneously distributed is very important. The frozen versus thawed boundaries within discontinuous permafrost, as often found in the Subarctic latitudes, are important because the thawed zones most often provide more stable foundation conditions. Also, baseline data are especially important in areas where permafrost may be discontinuous or sporadic; where ground temperature is relatively warm, defined as >28° to 30° Fahrenheit (F) (>−2 to −1° Celsius [C]); or where saline conditions may be present in coastal areas (such as around Utqiagvik [formerly Barrow], Alaska) that have been influenced by historic changes in sea level. Permafrost is generally continuous north of the Arctic Circle (latitude 66.56° N) and in Antarctica, some mountainous areas, and offshore in northern latitudes.[1] See UFC 3-130-01, paragraph 2-2, for the description, characteristics, and distribution of permafrost.

[1] "Recent Advances in the Study of Arctic Submarine Permafrost," Angelopoulos et al.; "Northern Hemisphere Permafrost Map Based on TTOP Modeling for 2000–2016 at 1 km^2 Scale," Obu et al.

3-2.5.2 Drainage and Groundwater Table.

Hydrological maps detail waterways, drainages in an area, and general maximal and minimal runoff data. Hydrological reports detail the movement of water in an area via rainfall, runoff, evapotranspiration, and so on. Hydrological studies can be useful for site characterization in several ways, such as classifying groundwater and soil permeability and identifying permafrost occurrence markers. For structures located near a river, information on stream-flow variations throughout the year and on the levels and frequency of flooding are of substantial importance for proper selection of the site. Obtain information on the ice-forming characteristics of the stream and on the locations of previous ice jams. For any structure or other infrastructure such as pavements, drainage is an important consideration. Define the usefulness of existing drainage courses for the removal of excess storm water. Where applicable, determine the position of the water table and patterns of subsurface flow.

When the groundwater table is encountered, provide the stabilized groundwater elevation with the anticipated variation and the local causes for variation (for example, seasonal or tidal). Measure the stabilized groundwater elevation 24 hours after drill-hole completion, unless determined otherwise by the registered design professional. If drilling techniques that prevent the measurement of the water table levels are used, the contractor should install at least two piezometers per drilling site to accurately measure the depth to the water table. Obtain a sufficient number of readings (locations) to establish a representative groundwater depth profile for the project site. Piezometers are required for stormwater pond investigations. Piezometers are not required if the groundwater levels can be accurately measured during drilling operations, if significant seasonal variations in groundwater level are not anticipated, or if there is good evidence that the water table is not within the depth of the borings or zone of influence for the foundation or structure.

3-2.5.3 Terrain Unit.

A terrain unit is a delineation of landscape elements often outlining zones of thaw-stable or thaw-unstable soil types and ice-rich or ice-poor soils of the site. Terrain-unit maps are generally derived from soil maps or aerial photographs. These map types are useful in the selection of stable foundation sites and material sources. Terrain-unit maps are most likely found in geotechnical reports or foundation reports from existing construction. They can also be generated as iterations of published geologic maps or surficial geologic maps. Terrain-unit maps must be as detailed as possible and updated as more detailed data, including the mechanical and engineering properties, become available.

3-2.5.4 Topography.

Accurate topographic information, including data on surface features and vegetative cover, is necessary. Obtain survey information for planning drainage, roads, and infrastructure layout. In investigations for airbases, consider topography in accordance with UFC 3-260-01 and for future snow removal operations on the airfield. For structures adjacent to bodies of water, information on shorelines, harbor lines, high-water marks, hydrographic and bathymetric data, and wave action is important.

Topographic maps or digital elevation models (DEMs) exist for nearly all areas of the earth's surface and should be acquired at both higher and lower scales for the given region. Topographic maps provide a ready base map on which to build further site characterizations (such as hydrological and vegetative). See UFC 3-130-01, Appendix A, for sources for topographic maps. Refer to UFC 3-201-01, paragraph 2-4.2.1, for additional resources and considerations.

3-2.5.5 Seismology.

See UFC 3-130-01, paragraph 2-10, for additional information on seismic considerations when performing site assessments. For site assessments, take note and examine any evidence of seismic activity in or near the selection area (such as active or potentially active faults, surface breaks or ground subsidence from past seismic events, and offset drainage and topographic features). Information regarding regional seismic features (from maps or reports) must also be consulted to construct a full seismic assessment of the selection area.

Seismic maps and site-specific seismic hazard assessment reports (if available) depict the likelihood and possible severity of an earthquake event based on known seismic hazards, past events, or conditions likely to result in seismic events.

3-2.6 Water Supply and Wastewater.

Obtain information on the feasibility of developing a water supply for the needs of the Installation. Perform pumping tests and water analyses for proposed wells. In some instances, a dam site may need to be selected for impounding water. In addition to determining sources of potable water and possible means of waste disposal, location conditions and regulations must be examined to avoid conflict. If water supply is to be developed from surface water, possible pollution sources must be identified. It may prove necessary in the Arctic to develop water supplies from two different sources, one for summer and one for winter. For example, where groundwater supplies cannot be developed and surface sources freeze in the winter, the surface source may be used during the summer, while melted snow or ice or storage tanks may have to be the source of supply in winter. See UFC 3-130-05 for additional information.

3-2.7 Construction Materials.

Knowledge of the location of suitable sources of quarry stone or rock deposits, gravel, and sand for aggregates is essential. Identify local sources of materials to aid in the production of pavements and concrete and determine the nearest points at which non-native materials and supplies can be obtained.

3-2.8 Existing Construction.

Map any construction or land development on or near the selection area, including both current structures and past projects. Maps of existing construction projects provide useful information regarding data sources in the form of previously collected construction reports.

3-2.9 Electrical Grounding.

Frozen earth materials offer high resistance to electrical current flow, preventing adequate earth grounding that is typically required for safe electrical distribution operations at structure locations. Locations are required to allow for a common electrical grounding site, where earth ground is created in a district configuration. These locations may be near water features (rivers or lakes), where the heat from the water allows limited thawed ground to exist. Grid arrays have been placed in such thawed areas or laid in water bodies, such as salt-water bays, where seasonal ice does not reach to the depth of the water body. See UFC 3-130-05 for further discussion.

3-2.10 Existing Reports.

3-2.10.1 Construction.

Construction reports are likely to contain as-built drawings and information on the scope of the construction project, permitting, engineering reports, storm water and hydrology mitigation planning, and site condition. Construction companies or state and federal regulatory bodies may have these reports.

3-2.10.2 Geological and Soil Survey.

Geological and soil survey reports, and their accompanying maps, contain important site details that aid with infrastructure siting. Locate previous geological and soil surveys conducted in the area of interest when possible. Surveys adjacent to areas of interest may be of use as well. State and federal geological or agricultural services may have these geological and soil survey reports.

3-2.10.3 Geophysical.

Geophysical reports detail the process and returns of geophysical survey methods, such as ground penetrating radar (GPR), electrical resistivity, electrical conductivity, and seismic refraction. Geophysical reports contain site characterizations, descriptions of the geophysical method used, data collected, and an interpretation of subsurface conditions based upon the collected data. Geophysical reports are useful in the interpretation of subsurface conditions over the survey area but are best verified by geotechnical means. Mining operations, academic sources, and construction site evaluations may have these geophysical reports.

3-2.10.4 Geotechnical.

Locate and examine geotechnical reports in and around areas of interest because they contain information pertaining to previous subsurface exploration, site evaluation, laboratory and field test results, and soil and rock conditions. State and federal geological or transportation services, academic sources, mining operations, and survey and construction companies that have operated in the region of interest may have these reports.

3-2.10.5 Mining.

Mining reports and mineral exploration literature generally contain information regarding subsurface mineral deposits, geotechnical data, and geological characterization. Mining reports can be a dense source of information regarding characterization of an area. State and federal geological services and mining companies may have these reports.

3-2.11 Local Considerations.

If possible, consult local knowledge sources. Local records and long-time residents are excellent sources of information on prevalent seasonal and weather patterns, changes in weather and natural conditions, changes in permafrost and ground freezing conditions, and other points of interest.

3-2.12 Remote Sensing.

Remote sensing encompasses a wide variety of sources and platforms, from satellites, to high altitude aerial platforms, to low altitude and geophysical methods and platforms, including multispectral imaging, radar, and lidar. Some of these remote-sensing platforms and methods are relatively recent, so older datasets may not exist. However, there may be legacy datasets of satellite imagery and archival air photos or aerial imagery for most regions of the globe. Make effort to locate and incorporate legacy datasets into site characterization because changes over time are difficult to account for without a long-term dataset. Air photos and satellite imagery are useful for locating boundaries of soils with different characteristics, identifying the extent of frozen and unfrozen soils, and predicting the engineering characteristics of soils in a given area. Air photos can also be used to eliminate the selection of totally undesirable areas and to suggest possible usable sites.

The resolution of remote-sensing data is an important consideration in regard to ground surface. Obtain datasets of the highest spatial resolution for the purpose of site characterization. Use image resolutions of 1:10,000 or better when possible. In addition, obtain other geospatial datasets in the highest resolutions possible.

3-3 INITIAL DESKTOP ASSESSMENT.

In the selection of a suitable site for military Installations, information is usually available (from maps, aerial imagery, or other sources) for the identification of general areas that may be suitable. To identify a specific site of interest within a general area, more detailed information, if available, is required prior to conducting any site reconnaissance. Begin initial investigations and preliminary assessments with a comprehensive desktop survey of current and historical maps and records pertaining to the general area.

3-3.1 Climate Profile.

Climate characterization must include expected or observed winter precipitation because snow and ice loading can have a significant effect on the design of an Installation. Snow loading can also have major effects on the hydrological characterization and regime of an area. See UFC 3-130-01 for snow considerations.

Climate profiles of an area provide context for site characterization and aid in analyses of later steps in the process. A large part of Arctic and Subarctic site selection is permafrost based, and accurate and complete climate profiles improve permafrost likelihood estimates, both directly (climatic conditions do or do not favor permafrost occurrence and growth) and indirectly (vegetation profiles are influenced by the occurrence of frozen ground). Accurate climate profiles on a regional scale provide information on possible permafrost conditions occurring where mean annual air temperature (MAAT) values are near 31°F (−0.5°C). Important parameters to be collected are air thawing degree-days (ATDD), air freezing degree-days (AFDD), MAAT, MAGT, wind rose for month of the year, mean seasonal precipitation (rain and snow), and graphs of hours of daylight versus months of the year.

3-3.2 Aerial Reconnaissance.

Aerial reconnaissance is especially valuable in initial regional studies to obtain data on factors such as flooding and icing conditions, the presence of flight hazards, possible access-route locations, the suitability of lakes and clearings for landing small aircraft, and military considerations, such as logistics and defense. Large areas can be covered in a relatively short time, and the less-constructable sites can be eliminated. Aerial reconnaissance is also valuable in recognizing geologic and environmental ground conditions (such as faults and delineations of landslides and rock outcrop features with erosion potential and distinctive changes in vegetation cover) that may otherwise be difficult to visualize from on-site inspection.

3-3.3 Analysis and Mapping.

Utilizing current or most recent datasets, construct a base map and overlays of the entire region. Historical images are used to track changes in slope stability, permafrost degradation, drainage, and settlement over time. Include the entire area of interest in the initial analysis of remote-sensing data, with an emphasis on ground conditions. A special note is needed to plot the construction sequence of existing structures. Note any changes in the natural condition due to infrastructure placement. Include the focus areas discussed in paragraphs 3-3.3.1 through 3-3.3.6 in the analysis. GIS is a very powerful tool that allows for plotting, viewing, and analyzing the mapped data. In addition, vast amounts of metadata can be stored with the GIS layers and shapefiles.

3-3.3.1 Vegetation.

Use image analysis to construct vegetation profiles of the region, and focus on large-scale trends such as forested areas, brush land, shrub land, tundra, and so on. Subdivide forested areas into evergreen and deciduous. Note stand density and height when possible. Differentiate areas of scrub brush and second-growth brush and tundra as possible. Demarcate forest fire scarring if present. If resolution allows, look for tussock ground, grasses, and heavy moss layers. Mapping must be accompanied by documentation of local vegetation types and identifiers to aid in the mapping process. Research characteristics of local vegetation types; specifically, average root depth and general habitat (such as well drained, wetland, or marshland).

3-3.3.2 Topographic.

Generate topographic overlays and DEMs for the area of interest.

3-3.3.3 Geological.

Map geological conditions via image analysis, as possible, noting origin, deposition type, and areal extent of soil and rock units. Indications of underlying geologic structure (such as apparent fault traces, surface lineations, exposed rock outcrops, areas of subsidence, and possible unstable slopes) as obtained from imagery and local or regional published information should also be delineated. Estimate geological characteristics of each soil and rock unit based upon site location, local geomorphology, and unit type. Published geological maps provide an initial baseline from which to begin geologic mapping for engineering design study. It is common for existing published geological maps to be incomplete or inaccurate at the scale needed for a detailed investigation. When existing information is incomplete or outdated, supplemental information and data and detailed information taken from field reconnaissance are required.

3-3.3.4 Terrain-Unit Maps

Construct terrain-unit maps, as possible, based on geological maps, aerial photographs, historical boring data, drainage patterns, and vegetation patterns. Update preliminary terrain-unit maps based on on-site observations and investigations to be performed.

Terrain-unit maps should map the extent of, and characterize, each unit on the map by its composition and basic engineering properties. There are many ways to map rock and soil units. Where time and budget constraints preclude a complete detailed mapping effort, prioritize mapping in the following order:

1. Type, extent, and location of permafrost terrain units
2. Type, extent, and location of major rock and soil units
3. Orientation and location of contacts between major soil types
4. Orientation and location of contacts between major rock types

5. Orientation of major faults and weak zones
6. Orientation and location of erosion, landslides, and subsidence features
7. Surface properties of discontinuities

3-3.3.5 Permafrost.

Construct permafrost feature maps using available remote-sensing data. Note beaded streams, pothole lakes, pingos, polygonal ground, thermokarst, and other permafrost surface expression features when discernable.

3-3.3.6 Hydrology.

Hydrological details of the area of interest should include all waterways, drainages, watersheds, and so on when discernable.

3-3.4 Interpretation.

The culmination of remote sensing data is to create a detailed base map (elevation and imagery) of the entire area of interest with overlays delineating vegetation, geology, terrain unit, and hydrology. Compile historical information collected during the desktop survey into separate overlays (GIS layers) and contextualize it on the base map. Once data compilation is complete, areas can often immediately be identified as undesirable and can be eliminated from selection based upon inferred ground-ice content, soil type, hydrology, topography, geology, hydrology, and so on. Conversely, sites of interest can be selected for further investigation. Verifying the unsuitability of previously eliminated sites may also be a part of further investigation.

CHAPTER 4 GROUND RECONNAISSANCE

4-1 INTRODUCTION.

Ground reconnaissance is used to verify results from preliminary assessments based on remote sensing and historical datasets, collect detailed information on site conditions, improve site profile resolution, and further refine criteria for desirable versus undesirable building sites. Features that may not be visible in remote-sensing datasets or unexpected occurrences can be addressed during ground reconnaissance.

4-2 GEOLOGICAL CHARACTERIZATIONS.

Ground-based geological characterizations of a site provide more detailed information than is possible with remote-sensing datasets. These written reports include maps of particular soil and rock units and geological features. Much of the geological characterization is focused on the site features in paragraphs 4-2.1 through 4-2.4, but note any anomalous geological features in detail.

4-2.1 Lithological Profile.

The lithological profile is a characterization or description of the stratigraphic section of geologic units in the project area. The geologic units are composed of surficial deposits, typically soils and sediments, and bedrock formations. The lithological profile describes all the geologic units of the project area in order, from youngest to oldest.

4-2.1.1 Bedrock.

Bedrock units are typically divided into three primary lithologic divisions, which are as follows:

- Igneous rocks—Igneous rocks are formed when molten rock cools and crystalizes. Igneous rocks are classified based on texture and composition, where texture describes the physical characteristics of the minerals, such as grain size, and this relates to the cooling history of the molten magma from which it came. Composition refers to the rock’s specific mineralogy and chemical composition. Cooling history is also related to changes that can occur to the composition of igneous rocks. Identifiers include color, texture, alteration, and accessory minerals. Color is taken from the Munsell Rock Color Chart (Munsell Color [https://munsell.com/color-products/color-communications-products/environmental-color-communication/munsell-rock-color-chart/]). Alteration is a description of the chemical and physical weathering processes that are dominant in a rock. Accessory minerals are a list of secondary minerals that are visible in a hand sample. An example of igneous rock is granodiorite of the Talkeetna Formation.
- Metamorphic rocks—Metamorphic rocks are formed when a source rock is subjected to high temperature or to high-pressure geologic processes,

including, but not limited to, contact with plutons or lava sources or tectonic burial and exhumation, that alter the parent rock's original structure and minerology. Metamorphic rocks are classified based on foliation (orientation of mineral texture in rock), field relationships, the chemical composition of the rock, and inferred pressure–temperature conditions of metamorphism. An example is of metamorphic rock is schist of the Neruokpuk Formation.

- Sedimentary rocks—Sedimentary rocks are formed by weathering or decomposition of rock masses and redeposition of weathered particles via wind or water or by chemical processes in sedimentary basins where the particles are compacted over time and lithify to form rock. Sedimentary rocks are classified as chemical (formed by chemical precipitates), evaporates (formed by evaporation of sea water and consolidation of remaining chemical constituents), or clastic (formed by lithification of weathered detritus). An example of sedimentary rock is sandstone of the Sagavanirktok Formation.

4-2.1.2 Structural Classification of Rocks for Engineering Purposes.

Rocks are typically classified by petrologic type, such as from an intact hand sample (for example, coarse-grained granite), and are then described with physical properties of the larger rock mass as occurs in the field, which may be broken by numerous discontinuities (such as planes of weakness, including faults, shears, joints, and fractures). Physical properties of rock that are of interest in engineering analysis include, but are not limited to, the following:

- Rock strength
- Weathering or alteration
- Hardness
- Discontinuity description and orientation
- Joint or fracture infilling
- Mineralogy affecting foundation performance
- Specific gravity and unit weight
- Moisture content and porosity

For more information on the classification of rock types, refer to "Classification of Rocks," by Travis.

4-2.1.3 Soil and Sediment.

Soil and sediment can be classified in several different ways. In the engineering profession, soil is typically described via the Unified Soil Classification System (USCS) and follows ASTM D2487.

The field description of soils is based on the size and distribution or volume of coarse-grained particles and the volume and behavior of fine-grained particles in a given representative sample of soil. In the absence of laboratory testing, USCS symbols and descriptions can be used in accordance with the visual-manual procedure of ASTM D2488. Typically, soils are broken down into the following constituents:

- Boulders—rocks 12 in.(30 cm) in diameter or greater
- Cobbles—rocks with diameters between 3 and 12 in. (7.5 and 30 cm)
- Gravel—particles of rock with diameters between 0.19 in. and 3 in. (0.48 and 7.5 cm)
- Sand—particles of rock with diameters between 0.003 in. and 0.19 in. (0.0075 and 0.48 cm)
- Silt—soil particles that are smaller than 0.003 in. (0.0075 cm) but exhibit little or no plasticity and have negligible dry strength
- Clay—soil particles that are smaller than 0.003 in. (0.0075 cm), exhibit plasticity within a range of certain moisture contents, and have significant dry strength
- Organic soil—soil composed primarily of organic matter in various stages of decomposition

4-2.2 Surficial Lineation.

Natural surficial lineation can have many implications for design. Surficial lineation often indicates the presence of faults, which are tectonic structures occurring at the point where rock formations fracture and slide past, over, or under each other as they are driven by tectonic forces. The actual plane of fracture and movement is the fault line, which is a planar surface that can be measured spatially. Faults have serious implications for construction because they can destroy structures by shearing foundations with relative fault movement or with severe seismic-induced vibrations from earthquakes. For design purposes, active faults are of the utmost concern and are typically classified as active when the oldest movement on the fault is Holocene (11,650 years) or younger. Linear drainages, tree lines, or offset drainages along a linear path are often good indicators of a fault line.

The wide majority of faults are not active; however, significant fault zones may still have negative impacts on site development due to changes in drainage patterns and rock lithologies below the site and the presence of low strength zones of sheared rock along the fault trace.

Other surface expressions commonly associated with fault lines include the following:

- Abrupt and imposing hillside fronts
- Linear base on scarps

- Sharp V-shaped canyons
- Suddenly increasing stream gradients (fault benches)
- Springs along the base of the scarp
- Sudden loss of drainage on down-gradient side of scarp

Another significant feature of outcropping or underlying bedrock is its resistance to weathering. Distinct changes in slope angle, debris material size, and stratigraphic contact occurs when stronger rock abuts weaker rock. These lineations are easily identified in the field and from aerial and satellite imagery.

4-2.3 Ground Disturbance.

In Arctic and Subarctic regions, disturbed ground can indicate recent changes in the hydrological or permafrost regime, among other changes. Disturbed ground includes, but is not limited to, landslides, tension cracking, area subsidence, thermokarst, erosion, and heaving. Take special note of the chronological sequence of the disturbed ground.

4-2.4 Geo-Hazard Assessment.

Geologic-hazard assessments at the reconnaissance level begin with desktop identification and assessment of terrain units and geomorphological features. Some terrain units are associated with common geological hazards, including the following:

- Permafrost terrain units—These units commonly contain geological hazards, including ice-rich permafrost, ice wedges, thermokarst, retrogressive thaw slumps, and perched water tables.
- Bedrock terrains with intersecting joint sets, bedding planes, or foliation planes—These units have potential for planar, wedge, or toppling risks if adversely oriented along slopes and excavations.
- Terrain units with clay—It is common for clay to exhibit excessive shrinkage and expansion.
- Soil slopes with groundwater seepage, shallow active layers, or hummocky terrain—It is common for landslides in these units.
- Artesian conditions and water tables—These present a significant risk, especially if the potentiometric surface is above the permafrost table, where it can cause widespread accelerated permafrost degradation if drilled.
- Seismic—Seismic history is required to understand the overall seismic hazard of the project area. In general, the seismic hazard (liquefaction hazard) is low provided the site location remains in the frozen condition; it increases by many factors if the site has been forcefully thawed.
- Flooding—Examine the flood recurrence interval and look for surficial indicators of scour to determine if flooding is a risk in the project area.

- Aufeis—Groundwater flowing over frozen terrain in the winter season causes sheets of slow moving ice to move toward and across valley bottoms. This is known as aufeis, and it occurs chronically or intermittently at a certain area. Often, these sheets of ice block river and drainage flow, creating flooding and difficult maintenance operations for roadways and airfields (see paragraph 4-5.1).
- Volcanic hazards—Construction in volcanically active regions may be at risk of damage from mudflows, pyroclastic flows, airfall tephra, lava flows, floods or tsunamis, and even direct blast hazards. Although rare, permafrost regions composed of historic lava flows require special attention because this porous rock may be mischaracterized as containing detrimental percentages of matrix (pore) ice.
- Frozen debris lobes (products of hillside erosion)—Contained on steeper slopes, frozen debris lobes may have a central core of ice that slows the movement downslope, where the debris lobe may be masked or determined to not be an immediate hazard. Careful examination can find entire overturned trees, the lobe front moving at only meters per year, and basal water generation during winter and summer. Over the longer term, frozen debris lobes can cause serious maintenance issues if not avoided or mitigated early on.

4-3 HYDROLOGICAL CHARACTERIZATION.

Identify small-scale hydrological features that are not discernable from airborne or remote sensing during ground reconnaissance.

4-3.1 Surficial Hydrology.

Note any standing water, episodic or seasonal waterways, evidence of past flooding events, and other high water events, such as from river ice jamming. Water-killed standing forests are indicative of rapid changes in the hydrological regime. Drunken forests in permafrost terrain are indicative of thawing ground, often due to flooding or slow inundation.

4-3.2 Hydrogeological Indicators.

At the reconnaissance level, basic surface hydrology can be assessed by first examining the site drainage patterns, where the ground monitoring equipment locations can be planned and installed during the site-exploration phase (Chapters 5 and 6). Drainage patterns are highly indicative of the underlying soil or rock type, the frozen or thawed condition, massive ice features and bulk ground ice content, the degree of slope, and the effect of the vegetation. A list of common drainage patterns is as follows:

- Dendritic—Dendritic drainage patterns are irregular branching streams with confluences oriented at angles less than 90° and depicting a stream pattern that suggests no control by underlying rock structure. This is often a mature drainage pattern that signifies shallow dipping horizontal bedding and is found on shallow dipping slopes.

- Parallel—Parallel drainage patterns are consistently branching streams with parallel drainages in a preferred orientation. These typically form on steep slopes with a relatively uniform gradient and are often found on recently tectonically uplifted terrain.
- Trellis—Trellis drainage patterns show drainage directions in intersecting, sometimes perpendicular, patterns. This drainage pattern requires structural control to form and is typically associated with strongly bedded bedrock. The pattern forms as the water moves along bedding planes and crosses between existing planes via intersecting cleavages.
- Rectangular drainage—This refers to channels created at right angles. This pattern is created by structural control via right-angle jointing and faulting.
- Radial—Radial drainage patterns are multiple semiparallel stream channels branching out away from a certain point. This drainage pattern develops when water is running off a dome.
- Annular—This refers to a ring-like pattern in drainage channels joined together by subparallel drainages perpendicular to the rings. This pattern typically forms on eroded up-warped domes and down-dropped basins.
- Thermo-erosion gullying—This occurs in moderate to high slopes composed of frozen fine-grained materials, such as silts and sandy-silts. Surface water generally migrates through the active layer and at the top of the permafrost table, but in this case, aggressive thermo-mechanical erosion removes frozen material and creates gullies that rapidly expand with continued running water and above freezing air temperatures.

4-4 PERMAFROST CHARACTERIZATION.

Permafrost characterization is best done during midsummer to early fall. During months when snow is prevalent, permafrost markers may not be visible, except in very windy locations. Features indicative of ice-rich permafrost may be difficult to differentiate with snow cover. Frost probing of the active layer is best implemented during late summer or early fall, when the active layer is at its deepest thaw depth of the year.

4-4.1 Surficial Expression.

Permafrost surface expressions of underlying soil types and massive ice features are most often visible during airborne and remote sensing, but at ground level, they may appear as indicators of other features, such as disturbed ground, surface hydrology, and vegetative cover. This is especially the case in many boreal forest areas, where massive ice expression is masked by the trees and ground cover. Identify areas with evidence of recent permafrost degradation (thermokarst). For example, note pothole lakes or standing water with sharp or shear banks, as they may be evidence of rapid degradation with bank-lined trees tilted toward the pothole (drunken forest) or stress cracking occurring parallel to the bank.

4-4.2 Frost Probe.

Current active layer depth and permafrost table depth can be accurately determined by driving a tile probe (rod with T-handle) into the ground by hand and recording the depth of deepest rejection; permafrost tables of 10 to 12 ft (3 to 3.7 m) are detectable. Frost probing is a relatively simple, lightweight, and effective field method of detecting active layer thickness and depth to the permafrost table. However, accurate measurements can only be made at the very end of the summer thawing season, when air freezing degrees become approximately equal to air thawing degrees.

4-5 SNOW AND ICE CHARACTERIZATION.

Snow and ice characterizations may not be possible, depending on the season. If winter reconnaissance is not feasible, probable occurrence based on regional weather patterns and historical records suffice.

4-5.1 Aufeis.

During winter seasons, aufeis may be directly observed as massive, multilayer ice buildup in or near an active stream or waterway, at the toe of a slope, or along the length of a slope. Likely areas of aufeis formation are shallow streams with abundant groundwater under elevated hydraulic head pressures. The toes of hills with perennial water sources should be noted as likely sources of aufeis.[1]

4-5.2 Drifting.

Snowdrifts form on the lee side of an obstacle if prevailing winds are strong enough to transport snow and ice crystals. Drifting severity directly depends upon the prevailing seasonal winds and the relative position of obstacles (or disruption of air currents) that allow a drift to begin forming. Large, open areas upwind of obstacles provide ample opportunity for snow or ice entrainment and provide the source of snow or ice for drift building. Snow is a very efficient thermal insulator. Drifted snow and snow plowed into piles, or deposited along ditches from roadway or airfield snow removal, insulate the ground from the severe winter cold, locally raising the overall permafrost temperature.

4-5.3 Avalanche.

Note evidence of avalanche and slope failure in detail for further analysis. It is important to note that avalanches travel great distances downslope with considerable speed and force. As such, if an area of interest is at the foot of substantial terrain, areas upslope of the site must be evaluated for avalanche hazard.

---

[1] *River Ice Engineering*, Ashton.

4-6 VEGETATION CHARACTERIZATION.

Note vegetation variation and typology during ground reconnaissance because it is often hard to discern from air photos or remote-sensing datasets. With respect to permafrost, give careful consideration to groundcover types because, often, heavy moss layers create a subsurface environment that is conducive to permafrost occurrence.

4-7 INTERPRETATION.

Compile and interpret ground reconnaissance observations as a means of developing a more complete, higher resolution representation of the area under investigation. Many of the characteristics observed during ground reconnaissance are interdependent and should be carefully examined to determine the nature of any possible interactions.

CHAPTER 5 GEOPHYSICAL INVESTIGATION

5-1 INTRODUCTION.

Chapter 5 provides an overview of some of the geophysical methods available for characterizing subsurface conditions. The geophysical methods discussed specifically pertain to characterizing permafrost, such as frozen regions versus thawed regions in discontinuous terrain or ice-rich versus ice-poor regions, because these characteristics are a major consideration when undertaking any construction project in Arctic or Subarctic regions. Alternate geophysical technologies are used to ascertain specific engineering properties, such as seismic refraction used in cross-borehole surveys to determine potential for mobilization during earthquakes.

5-2 GROUND PENETRATING RADAR.

GPR is a geophysical method that transmits high frequency radio waves (10 megahertz [MHz] to 4 gigahertz [GHz]) into the subsurface and records the reflections of these waves from subsurface discontinuities. The velocity of radar waves is altered due to the differing dielectric permittivity of substances. This contrast results in electrical phase changes that visually produce an image for interpretation. Radar waves reflect most readily from regions of dielectric contrast. In most cases, the radar is operated at the surface and the radar energy is directed downward; in this case, horizontal contrasts, such as the top of the water table, the top of the permafrost, and the bottom of the active layer, are most readily imaged.

5-2.1 Strength and Limitation.

GPR provides detailed subsurface returns, often to within inches of accuracy if calibrated to a known dielectric constant. Without calibration, absolute depth is less accurate, but it is still acceptable for shallow (~30 ft [~9 m]) survey depths. GPR survey systems, however, do not provide usable returns to the same depths possible from other geophysical survey methods. The advantages of GPR units include their rapid data acquisition, ease of deployment, and short survey start length. Active layer depth and the depth of permafrost are often defined by a layer of liquid water or heavily saturated soil, and such polarity change between reflective water and dry soils is easily discernable in GPR returns. However, water attenuates radar signal, and it is often difficult to discern features beyond saturated areas with any reasonable accuracy. As a result of the radar–water interaction, GPR systems are not optimal in areas with standing water or heavily saturated soils. Clay and silt-sized earth mineral derivatives are known to absorb radar energy,[1] especially when the material is wet or saturated.

[1] "Complex Permittivity and Clay Mineralogy of Grain-Size Fractions in a Wet Silt Soil," Arcone.

Radar data often require filtering during collection mode to eliminate cultural electronic noise, and postprocessing is almost always required to deconvolute complex reflections, conduct migrations to reveal hidden reflections, and conduct other filtering and resolution gaining processes. This makes the process less user friendly and requires significant training for the operator to be proficient from collection to final data display.

5-2.2 Effective Survey Length.

Radar units can easily produce very long (thousands of feet) survey lengths. Because of the compact nature of GPR units, when the radar survey is initiated the data received is immediate and collected from the soil directly below the radar unit. There is no offset in distance or time between the equipment at the surface and location of data collection at depth.

5-2.3 Resolution.

GPR accuracy under ideal conditions is approximately within one to two feet-scale in the horizontal direction and the inch-scale in the vertical direction. Vertical resolution of this order requires a known depth, to within an inch, to an object easily discernible in the radargrams, which allows for the exact determination of the dielectric constant. Soil drilling and coring, or digging of pits, may be required to determine the depth to subsurface features or material changes that reflect the radar energy.

5-3 ELECTRIC RESISTIVE TOMOGRAPHY.

In electric resistive tomography (ERT), subsurface earth material resistivity is measured by injecting current (galvanic) into the subsurface via two current electrodes and reading the resultant voltage via two potential electrodes. Cable arrays often consist of 50 to 100 electrode positions; therefore, the current and voltage pairs are re-ordered for each pulse measurement, moving through a multitude of configurations per survey setup. Modern systems use a computer to cycle through the many possible pair configurations, greatly reducing work for the operator. By measuring the current, voltage, and geometry of the electrodes, one can calculate the resistivity of the subsurface. Averaging algorithms are then used to calculate the apparent resistivity over a range of depths along an electrode line. This type of system is time consuming to set because the electrodes must be hammered into the subsurface, and each survey is limited to the length of the cables at maximum electrode spacing. Surveys can use different measurement geometries and different electrode pair separation distances to alter the overall survey depth and resolution. Subsequent surveys can be sequentially conducted and overlapped with preceding surveys in what are called *leap-along* surveys.

5-3.1 Strength and Limitation.

ERT provides subsurface returns to depths in the magnitude of hundreds of feet, depending on the surface geometry of the electrode array and the geological conditions. This method is robust in data collection, provided good contact between the electrode array and the ground is maintained. ERT is suitable for a wide variety of ground conditions, and it generally has less noise in return data because of stable ground contact between the electrode array and subsurface. If the physical position of the electrode array is recorded, these surveys can be accurately repeated. Acquisition of raw data via computer switching can take a few hours. The survey method is minimally postprocess intensive because instrument returns require little processing and can be averaged with commercial software rather quickly.

5-3.2 Effective Survey Length.

ERT is a static, array-based method, and survey length is dictated by electrode configuration. The effective depth of the ERT survey directly correlates to array geometry at the surface, primarily to the spacing between electrodes. Most systems can conduct leap-along surveys, where subsequent electrode arrays can be coupled with the previous, allowing for total survey lengths of many thousands of feet. The limitations to this process are computation time and the stability of the averaging algorithms with large amounts of data.

5-3.3 Resolution.

Due to the averaging nature of ERT postprocessing, the resulting pseudosections typically produce graphical changes in color contours, where the colors represent levels of resistivity in units of ohm-meters. The averaged results graphically present boundaries between highly resistive frozen ground (ice-rich) and highly conductive thawed ground (ice free or ice-poor) materials. As a consequence of the averaging process and the large electrode spacings utilized for engineering surveys, these boundaries cannot be depicted by tight contour intervals, such as high resolution. This method is less precise than what can be achieved with the reflection returns from GPR. Based on the electrode spacing, the boundaries between high and low resistive units may be as long as 10 ft (3 m).

5-4 CAPACITIVE-COUPLED RESISTIVITY.

Capacitive-Coupled Resistivity (CCR) surveying is an earth resistivity method that does not require installing stationary electrodes into the ground. The drag-along system uses the earth as one conductor of a parallel plate capacitor. The transmitter and receivers are composed of two coaxial cables, or dipoles. The transmitter sends a continuous-current sine wave through the dipole, polarizing the surrounding earth material; the passing receiver then measures the induced polarization, from which the resistivity can then be calculated. This system does not require inserted electrodes and can continuously collect pulsed readings at one-second intervals while traveling along the surface. Altering the separation between the transmitter and the receivers provides additional survey depths.

5-4.1 Strength and Limitation.

CCR units operate along principles that parallel those of ERT, although they do not require a static array. As a result, CCR units are easier to deploy than ERT arrays and are capable of covering much longer transects in less time, much like GPR. CCR units do not have the capability to penetrate to the same depths as ERT, and they often produce datasets with more noise than ERT. Comparisons of CCR and ERT surveys generally yield very similar to often identical results, when comparing the location and extent of the varied resistive materials. Due to the collection method, the absolute value of the measurements often disagree by hundreds of ohm-meters between CCR and ERT. However, for engineering studies and for determining frozen versus thawed ground, or ice-rich versus ice-poor ground, these differences are not consequential. As with ERT, CCR does not require a substantial amount of postprocessing before interpretable results are available.

The cable dipoles are available in two different lengths, 8.2 ft and 16.4 ft (2.5 m and 5.0 m). As an example, when using the 16.4 ft (5.0 m) cables for deeper surveys, the length of the electronic component of the array is 120 ft (40 m). Additionally, the system requires the transmitter portion to be separated from the receiver portion by a nonconductive rope, and while this separation is variable by the user, it is most often equal to or longer than 33 ft (10 m). The total length of the array is now at least 164 ft (50 m). Careful planning of the transect is required to ensure the array follows the operator in the manner required, and this often requires helpers to keep the system guided on the correct alignment.

When mineralogical clays and silts may be present, especially near the ground surface, careful ground truth analysis is required to ensure masking or amplification of the underlying soils true electrical signature does not occur. In addition to the ability to retain more soil moisture, the mineral content of these soils can cause an increase in electrical conductivity, which can decrease the frozen resistivity value.

5-4.2 Effective Survey Length.

Depending on the geometry of the CCR array, the minimum effective survey length depends on the length of the transmitter and receiver array. One rule of thumb is to assume the minimal effective survey length is 1.5 times the length of the array’s longitudinal footprint.

5-4.3 Resolution.

As with ERT, CCR postprocessing relies on averaging algorithms to produce usable data plots. Because of the capacitive nature of the voltage generation, the boundaries between resistive and conductive bodies can be less definitive than with ERT. However, as with ERT, the value is the information gained in identifying ice-rich versus ice-poor regions, or identifying frozen versus thawed regions. The CCR system collects this information more rapidly and continuously than the ERT system.

CHAPTER 6 GEOTECHNICAL EXPLORATION METHODS

6-1 INTRODUCTION.

Perform soil exploration, testing, and evaluation under the direction of a licensed professional geotechnical or civil engineer who is experienced in cold regions site investigations. Determine the required extent of exploration and testing based on recommendations from the geotechnical engineer, structural engineer (for foundations), and civil engineer (for pavements, wells, septic systems, and retention ponds). Geotechnical site investigations (sampling, testing, and evaluation) must be in accordance with UFC 3-201-01, UFC 3-220-01, UFC 3-250-01, and UFC 3-260-02. EM 1110-1-1804 is a supplementary reference with extensive guidance on performing geotechnical site investigations.

Geotechnical data are the baseline for foundation design in buildings, roadways, airports, bridges, dams, and levees, as discussed in UFC 3-130-3. Upon completion of the initial desktop data acquisition, desktop survey, remote sensing data acquisition, ground reconnaissance, and geophysical data acquisition, detailed geotechnical investigation and exploration can begin. Investigations and evaluations must be in accordance with applicable ASTM standards to the fullest practical extent. Where ASTM methods are not applicable, procedures and apparatuses used must be in accordance with generally accepted cold regions engineering practice. Indicate the results of the subsurface investigation, including boring locations, boring logs, groundwater observations, summary of laboratory test results, and any details required to convey requirements for site preparation, on the contract documents.

6-2 DRILLING AND SAMPLING.

The majority of data collected during a detailed geotechnical investigation is collected from hand samples, drilling, and test pits or trenches. Table 6-1 and Table 6-2 are designed to be used in conjunction with data collected during the desktop study, geophysical data, and field reconnaissance studies to determine which drilling method is most suitable, where the drilling should take place, and the drilling density (number of boreholes).

Table 6-1 Material Tests and Applicable Standards

	Material Quality				Atterberg Limits	
	Los Angeles Abrasion	Degradation	Sodium sulfate loss	Gradation	Liquid limit	Plastic index
Applicable standard	ASTM C131	ATM 313*	ASTM C88	ASTM C117/C136	ASTM D4318	ASTM D4318

*Alaska Test Method (ATM) 313, Degradation Value of Aggregates (*Alaska Test Methods Manual*)

Table 6-2 Data Needs and Drilling Techniques

Note: *SPT is standard penetration test and LPT is large penetration test. These tests provide material for laboratory testing but should not be used for soil consistency or density correlations, as the frozen soils have artificially elevated blow counts. **RQD is Rock Quality Designation.

6-3 HAND SAMPLES.

Hand samples are typically limited in that they can only be collected at the surface or from disturbed samples taken from the auger flights during auger drilling. The advantage of hand sampling campaigns is that they are relatively inexpensive compared to drilling or trenching and require minimal logistical planning and execution, but they are limited in deep-depth collection. Hand samples can be broken down into the construction-related categories presented in Table 6-3.

Table 6-3 Hand Sampling Breakdown

	Typical Sample Size	Generalized Analyses Methods	Limitations	Optimal Uses
Materials	• 25–150 lb (11–68 kg) • Sample size is dependent on test method (small volume for gradation, large volume for quality testing) • Gradation sample size dependent on particle size	• Gradations • Los Angeles Abrasion • Degradation • Nordic Abrasion • Sodium Sulfate Soundness • Acid-Base Accounting	• Limited to surficial sampling, no quantification of material at depth • Contamination with fill is likely	• Material site reconnaissance • Bedrock sampling for quality testing and acid-base accounting
Foundation	• 1–25 lb (0.5–11 kg) • Sample size is dependent on test method (small volume for moisture contents, larger volume for gradations) • Gradation sample size dependent on particle size	• Gradations • Moisture content • Expansion/collapse potential • Atterberg limits • Organic content • Soluble sulfates • Thaw consolidation	• Limited to surficial sampling, no quantification of material at depth • Contamination with fill is likely	Index testing of material on surface where deep fills are to be placed and no subexcavation is needed
Environmental	Variable	Various analyses for contaminants	Limited for surficial contaminants	Baseline screening
Naturally occurring asbestos	1–5 lb (0.5–2.3 kg)	CARB 435* with Transmission Electron Microscopy or Polarized Light Microscopy	Limited to surficial exposures	Documentation of naturally occurring asbestos hazards easily identified in the field.

*California Air Resources Board (CARB) Test Method 435, California Environmental Protection Agency

6-4 DRILLING.

Seven types of drilling are typically used for geotechnical investigations. This section is not intended to be an all-inclusive list of drilling techniques but, rather, to give an overview of the more common cold region geotechnical drilling techniques and the capabilities of each technique. Table 6-2 includes a list of data that are commonly needed in geotechnical explorations and the suitability of each drilling method to fulfill those needs. Specific site conditions (such as include ground ice content, soil type, depth to bedrock, presence of surface and ground water, and allowable risk for structure damage) determine final borehole density and depth. For horizontal projects that cover long distances, such as roads, changing conditions may dictate changes in drilling strategy.

6-4.1 Solid Stem Auger Drilling.

Solid stem auger drilling is generally limited to environments with silty or cohesive soils, or frozen fine-grained soils, because the walls of the boring remain stable throughout the drilling process. The flights on the augers are continuous throughout the drill string and convey cuttings to the surface. Samples are acquired by stopping drilling at the desired depth and pulling (tripping) the entire string to allow for grab-sampling from the lead auger. Alternatively, the drill string is rotated quickly until returns are spun to the surface. This method yields a highly disturbed sample and should only be used to estimate changes in strata or other gross indicators.

In permafrost regions, solid stem augers are useful for documenting depths to frozen soil because the transition from thawed to frozen soil is highly recognizable due to the dramatic change in drilling resistance. Solid stem augers have limited effectiveness for identifying ice content and cryostructure due to the disturbed nature of the samples, although ground ice is often easily discernable and can help to identify massive ice features.

6-4.2 Hollow Stem Augers.

Hollow stem augers advance in the same manner as solid stem augers. The hollow stem allows the use of soil samplers like split-spoons, Shelby tubes, and continuous samplers driven through the auger flight, and in this manner, the hollow stem auger acts as a casing to prevent collapse of the drill hole and allow for continuous sampling. Other geophysical tools, like torvanes, thermistors, and piezometers, can be inserted in the ground through the hollow stem auger. Samples, such as core samples collected with continuous samplers, are collected during drill advancement.

Hollow stem augers are effective in both cohesive and granular soils, where they provide a cost-effective method to collect representative soil samples, blow counts, and samples for determining moisture content and organic content. In permafrost regions, hollow stem augers are a cost-effective method for identifying cryostructure.

6-4.3 Core Drilling.

Core drilling is primarily used in bedrock or in frozen soil or sediment environments. Core drilling is used to recover cylindrical cores. Core tooling consists of a coring bit attached to a core barrel, while the lifter advances the sample through the barrel. Core drilling can be completed using a wide array of barrel types (single, double, and triple tube), and core sizes are widely variable and generally range from 21.5 mm to 85.0 mm in diameter. To facilitate core drilling of frozen soils or sediment, chilled brine can be circulated down the hole to maintain the drill hole and sample in the frozen condition. Samples retrieved in this manner are contaminated with brine fluid on the outside and interior of the core, where fractures and joints may exist. For a more detailed explanation of core drilling, see ASTM D2113 and AASHTO T 225.

6-4.4 Air Percussion Drilling.

In air percussion drilling, both the drill bit (attached to the end of an air percussion hammer) and the casing are advanced at the same time through the use of an under-reamer. Air flows through the rods and the hammer and up the casing, removing the cuttings through the casing up to the surface. Once the desired sampling depth has been reached, the rods and air percussion are removed, and sampling tools are installed.

Air percussion drilling is particularly effective in environments where excessive cobbles prevent time-effective progress using augers, and it is also effective for very deep holes. Air percussion drilling is less effective beneath the water table and in frozen fine-grained materials, where the hot air thaws the frozen soil. Cuttings using air percussion are delivered to the surface relatively instantaneously, although they are pulverized and not closely representative of gradations in situ.

6-4.5 Air Rotary Drilling.

Air rotary drilling is accomplished by advancing a rotating drill bit through the substrate while moving cuttings to the surface via high pressure air. This method is useful in arid environments with soils that have high dry strengths or in thawed silts and clays where the hole stays open. As the drill advances to desired sample depths, the rod and bit can be extracted from the boring, and the sampler is attached to the rods, taking the place of the bit. Cuttings are moved to the surface relatively instantaneously, and this is useful for detailed logging of complex stratigraphy. Maintaining materials in the frozen state is generally not possible with this method.

6-4.6 Macro Core.

Macro core drilling, also known as *direct push technology*, is accomplished by driving a continuous core barrel into the substrate utilizing a high-frequency hammer. The core barrel is filled with a clear plastic liner that receives the sample, and the liner is extruded once at the surface. This method is very useful for logging detailed stratigraphy, particularly in environments with fine-grained sediments. This method also provides for detailed logging of permafrost cryostructure. Larger size core barrels are required for gravelly soils to prevent plugging of the core. Also, sampling in massive ice, such as in ice-wedge features, can cause the ice to compress and, upon retrieval, to expand outward through the end of the sample barrel. However, this can be prevented with experience.

6-4.7 Wash Bore Rotary.

In wash bore, a rotary drilling casing is advanced ahead of a drill bit with a mechanical or sonic hammer. The casing is driven into the ground, and the material in the casing is drilled out with the drill bit. Once the drill bit reaches the desired depth for sampling, the rods are pulled out of the hole, and the sampler is attached to the end of the rod and lowered down to collect the sample.

To stabilize the boring or control heaving sands below the water table, drilling muds (typically bentonite) or polymers are used to keep positive pressure on soils below the bit as the bit is removed. This is generally the most effective method for drilling below the water table. However, samples above the water table are likely to have contaminated moisture contents due to the water required for the drilling process leaking into the system. Examinations of cuttings pumped to the surface between sample intervals are typically accomplished by using a wire mesh sieve or strainer to collect cuttings from the stream of water that is pumped out of the casing at the surface.

6-5 FREQUENCY AND DEPTHS OF BORINGS.

An experienced geotechnical engineer or geologist familiar with the region is required to determine the frequency and depths of borings. In general, the location, frequency, sampling method and interval depend on the type of structure to be built, degree of heterogeneity in subsurface conditions, and type of soil and rock formations. The drilling program is also influenced by the anticipated presence of any geotechnical or environmental conditions of concern to the project (for example, faulting and seismicity, unstable slopes, ground contamination). Geophysical data allows for a higher level of subsurface mapping resolution and can be used to help guide subsurface investigations.

6-6 EXCAVATED TRENCHES AND TEST PITS.

Sampling trenches and test pits are typically excavated with backhoes or excavators and offer superior stratigraphic data collection because sediments can be seen in long horizontal lengths and in vertical detail that is not attainable with drilling techniques. Hand samples can also be collected very effectively in trenches. The disadvantage of test pits and trenching is the depth profile, which is typically limited by the length of the excavator or backhoe armature or water table. However, benching can be conducted to allow for deeper operation levels for the excavating equipment. Frozen ground disaggregation is accomplished with buckets equipped with frost teeth or by the installation of a single tooth ripper attachment. Take proper to ensure the safety of personnel within test pits and trenches, and this may include widening the trench with safe bench intervals or utilizing a trench box.

6-7 GEO-HAZARD ASSESSMENT.

Exercise professional diligence when collecting data for and designing around geologic hazards. Geological hazards cover a wide range of topics. The Alaska Department of Transportation and Public Facilities' *Alaska Geological Field Investigations Guide* provides a list of common geological hazards, which has been supplemented by this publication:

- Permafrost terrain and thaw-unstable soils (yedoma, syngenetic permafrost)
- Organic soils and deep peat deposits
- Unsuitable soil gradations
- Metastable soils (loess, mud flows, permafrost terrain)
- Highly weathered rock with variable competency
- Faults, joints, bedding planes, foliation planes, slickensides, and other planar weakness surfaces in rock (unstable rock slopes)
- Naturally occurring asbestos in soil and rock
- Moisture-sensitive or quick clays
- Landslides and debris flows
- Meandering streams (stream cutoffs and oxbow lakes)
- Preconsolidated glacial soils
- Boulders and cobbles (particularly when not adequately described)
- Loose granular soils, particularly gap-graded soils
- Noxious or explosive formation gasses
- Substandard fill material
- Shallow groundwater, groundwater in artesian conditions, and saturated soils
- Misleading sample data collected from beneath the water table
- Nonrepresentative sample data from coarse-grained deposits
- Contaminated soils

6-8 INSTRUMENTATION.

A wide array of different instrumentation techniques is deployed in geotechnical investigations. A breakdown of some of the most common types of instrumentation, including their function and application, are presented in Table 6-4.

Table 6-4 Downhole Instrumentation

Type	Function	Application
Piezometers	Groundwater level measurement	Groundwater Earthwork and foundation design
Vane shear	Shear strength measurement of soils	Design in plastic soils Slope stability investigation
Thermistors	Ground temperature measurement	Permafrost investigation
Slope indicator tubes	Subsurface movement	Slope stability investigations
Spontaneous potential electric loggers	Record naturally occurring potentials between borehole fluid, formation, and surrounding rock as a function of depth	Determination and correlation of lithology, bed thickness, and salinity of formation water
Resistivity logging	Measures impedance to flow of electricity in rock formations	Lithology determinations
Cone penetrometer test (various downhole sensors)	Measures soil shear strength, shear wave velocity, and pore pressure, with soil classification interpretations	Foundation design Seismic response analyses
Optical and acoustic televiewers	Provide 360° view and interpretation of soil and rock conditions within unlined boreholes	Lithology and geologic structure determinations Foundation design

6-9 SAMPLE ANALYSIS.

Obtain representative samples of soil and rock during the field reconnaissance and field exploration phases of geotechnical investigations in a way that allows them to be classified according to existing classification schemes (for example, AASHTO and USCS soil classification) and to have their engineering properties quantified. Samples are acquired at considerable cost to the project and must be properly stored, preserved, catalogued, and shipped to avoid sample disturbance and loss.

Preserving, protecting, and transporting samples may be accomplished by the following methods:

- Inventory all samples daily and store in a central location. Do not store samples in areas where they can be agitated, especially if they are undisturbed samples.

- Rock cores need to be stored in purpose-built containers (core boxes) that protect the rock from shock. Rock cores must be logged by a trained geologic professional and photographed at the drill site before being transported off-site. Typical core log information includes lithology descriptions, depth of recovery, core run length, percent core recovery, and Rock Quality Designation (RQD).
- Store permafrost samples at temperatures as close to in situ conditions as possible. Do not freeze thaw consolidation samples to temperatures below those of the natural environment for the soil.

A breakdown of some of the more common geotechnical tests is presented in Table 6-1 and Table 6-2. Further information on sampling can be found in the AASHTO *Manual on Subsurface Investigations*, section 7.9, and in EM 1110-1-1804.

APPENDIX A BEST PRACTICES

A-1 INTRODUCTION.

The Best Practices Appendix is considered to be guidance and not requirements. Its main purpose is to communicate proven facility solutions, systems, and lessons learned but may not be the only solution to meet the requirement. It identifies additional background information and practices for accomplishing site assessment and selection in the Arctic and Subarctic. The DoR must review and interpret this guidance as it conforms to criteria and contract requirements and apply the information according to the needs of the project. If a Best Practices document guideline differs from any, the UFC takes precedence. For Best Practices guidelines not discussed in a UFC, the DoR must submit to the Government Project Manager a list of the guidelines or requirements being used for the project with documentation sufficient for review and approval prior to completing the design.

A-2 EXAMPLE ASSESSMENT WORKFLOW.

The steps for organizing geotechnical investigations include basic scenarios, such as those described in Figure A-1, that are applicable for large- and small-scale projects, which are defined here:

- Large scale: multibuilding Installations that cover 50 acres or more on land with three or more terrain units and linear infrastructure developments, including roads, airfields, and pipelines
- Small scale: linear infrastructure and small developments with single buildings

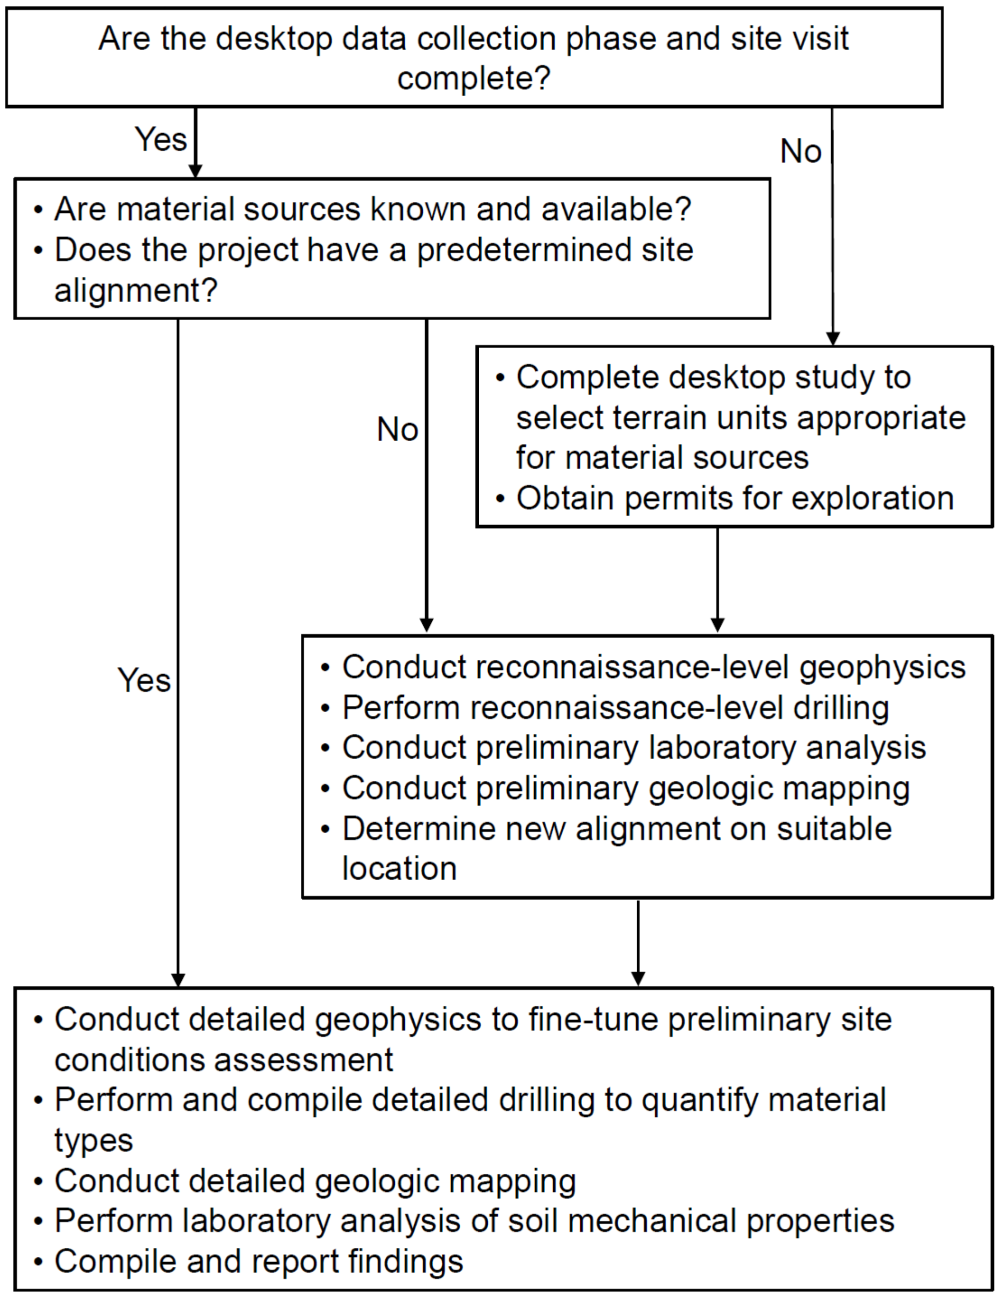
In general, once the background data have been collected, the workflow for most geotechnical investigations follows the flow chart in Figure A-1.

A-3 LARGE-SCALE AND LINEAR INFRASTRUCTURE.

Repair or improvement of large scale (airfields) or linear (roads and pipelines) infrastructure on predetermined or existing alignments requires far less data acquisition as critical infrastructure siting decisions have previously been made. In this case, a single geophysical transect that runs parallel to the centerline followed by detailed geotechnical drilling is typically sufficient unless there is a particular area experiencing geotechnical issues. In the case where predetermined alignment does not exist, geophysical reconnaissance transects designed to obtain the characteristics and boundaries of the terrain units involved is of primary importance.

Borehole spacing and depths are typically controlled by the diversity of terrain units at the reconnaissance level. Identify adverse terrain units (for example, heaving sands, permafrost, and expansive clays) and the more solid foundation soils (alluvial plains, bedrock, colluvium, and so on) at the reconnaissance level, especially if the studies are used to provide a detailed alignment location. Basic geological descriptions of each terrain unit need to be completed in the field along with baseline descriptions of geological hazards present in the project area. Also identify candidate locations for crossings of rivers and canyons at the reconnaissance level.

Figure A-1 Geotechnical Site Investigation Flow Chart



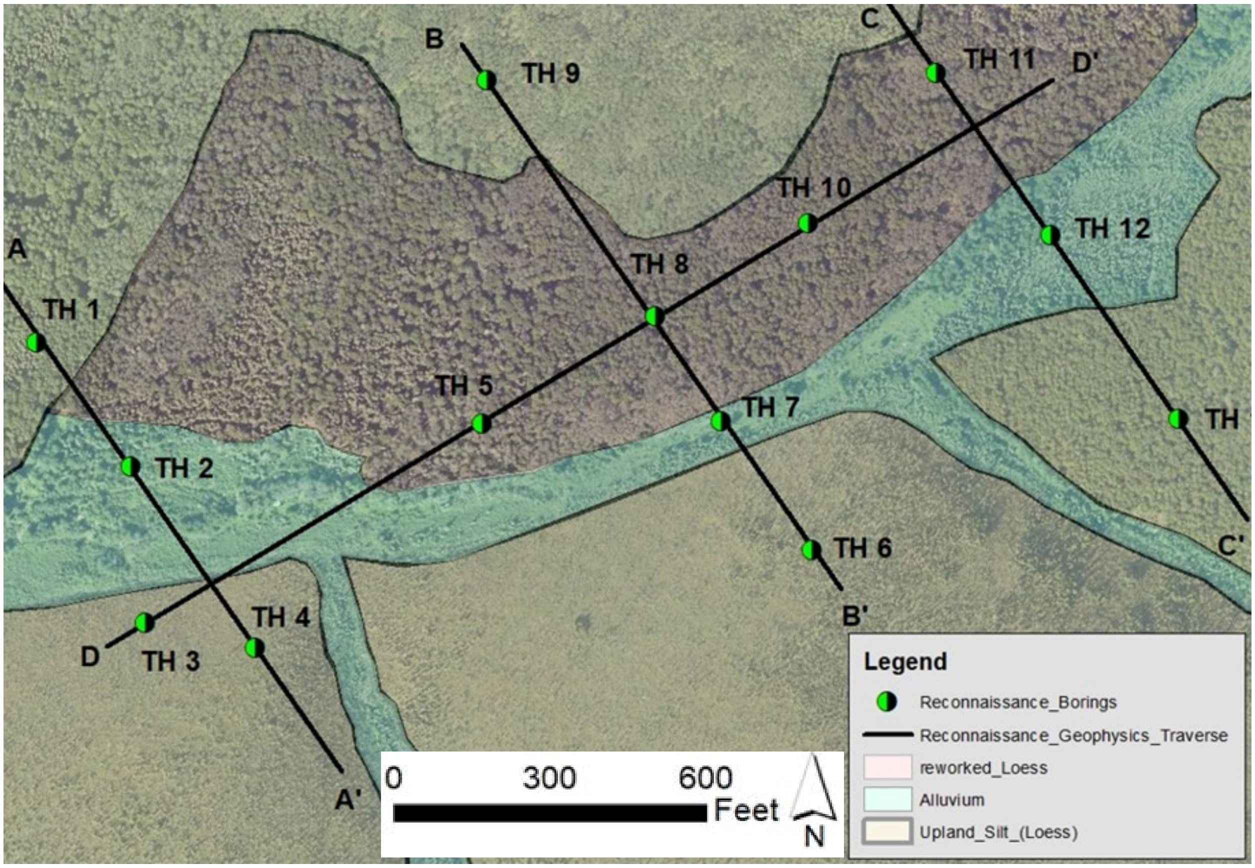
A-4 FIELD RECONNAISSANCE EXAMPLES.

Construction projects for large developments of linear infrastructure and multibuilding vertical construction share many similarities. Both types of development require a multiphase design. Regardless of the type of infrastructure to be constructed, large areas with multiple terrain units are best explored in several phases, the first of which is the reconnaissance phase. In the reconnaissance phase, the primary objectives are as follows:

1. Assess material availability. This is especially important for linear infrastructure, where it is best to have an available material site every 5–10 miles (8–16 kilometers) of pipeline, road, or tunnel alignment.
2. Identify and describe geological features located in geophysical transects, if available.
3. Fine-tune existing terrain-unit maps.
4. Provide preliminary characterization of each of the terrain units present in the area so that the critical structures can be located in the most favorable terrain units and construction can be minimalized on structurally adverse terrain units. The preliminary characterization should including the following:
    - Foundation information at candidate locations for high-load structures
    - Type and extent of adversarial terrain units' characteristics
    - Type and extent of favorable terrain units
    - Geological hazards
    - Drainage assessment
    - Vegetation types

Figure A-2 shows a hypothetical project area with an area of greater than 50 acres and three terrain units. The reconnaissance-level geophysical transects are plotted so that they provide soil deposit geometry via three transects oriented perpendicular to the strike of terrain units and one transect oriented parallel to the strike of terrain units. Reconnaissance-level boreholes are positioned to provide ground truth information and explore anomalies identified in the geophysics information.

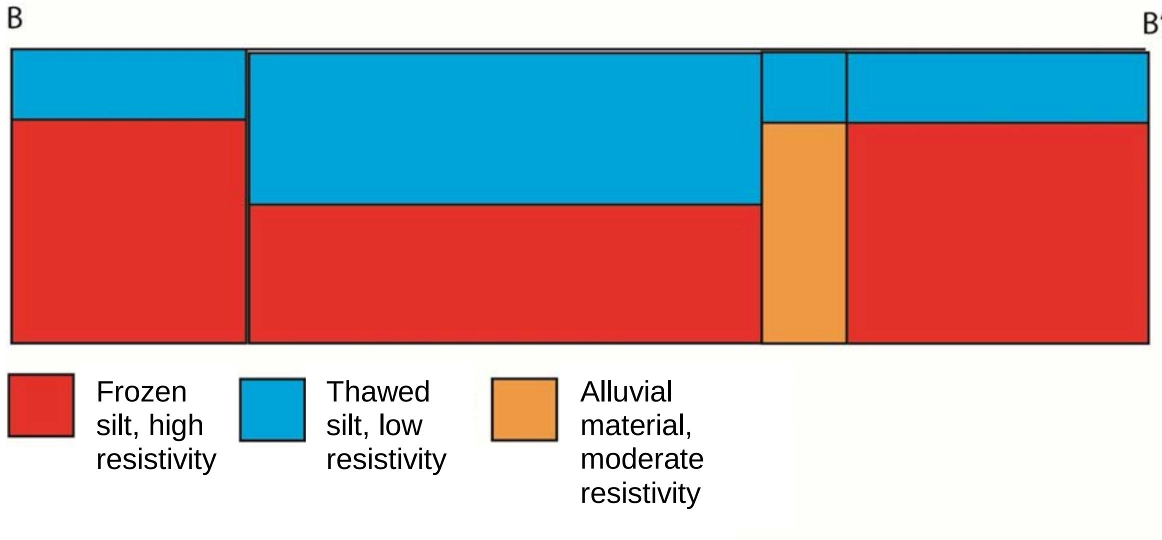
Figure A-2 Reconnaissance-Level Geophysical Transect Layout and Drilling Footprint



The reconnaissance phase relies on both geophysical data and traditional boring data as the backbone of subsurface data on which the detailed geotechnical investigation is built. Identify locations for critical structures in the reconnaissance phase.

Each geophysical transect and subsequent drilling provides a base of data to describe terrain units so that the units with optimum foundation conditions can be identified. Figure A-3 depicts a graphical-type cross section that depicts B-B’ in Figure A-2. In this cross section, we see three terrain units. Two units consist of ice-rich loess (wind-driven silt) and reworked loess, while the third consists of alluvial material. This base-level reconnaissance cross section suggests limiting building locations to the terrain unit with alluvial material in foundation soils. Once favorable locations for key structures have been identified, the detailed phase of investigation begins.

Figure A-3 Generalized Cross Section Showing Resistivity and Corresponding Soil Conditions from Transect B-B' in Figure A-2



A-5 SMALL-SCALE INSTALLATIONS.

For small-scale Installations, of less than 50 acres, and to be built on a predetermined location, a single phase of geophysical and geotechnical drilling data collection is sufficient (Figure A-4). Existing information may be available for the site and geophysics may not be required. When needed, geophysical data should be collected prior to drilling to help identify subsurface anomalies to be explored further with drilling or test pits. For small-scale Installations on land with two terrain units or less, one geophysical transect parallel to the strike of the terrain units and two geophysical transects perpendicular to the strike of terrain units is sufficient. Drilling frequency, spacing, and depth are controlled by design parameters specific to the structure and the acceptable risk; with risk being the detriment to the mission if the infrastructure should need foundation maintenance, foundation repair, or if the infrastructure should become unusable.

A-6 DETAILED DRILLING AND FIELD INVESTIGATION EXAMPLES.

Once baseline reconnaissance has been completed, detailed investigation can begin. Critical structures are ideally constructed on favorable terrain units identified during the reconnaissance phase. Detailed geotechnical investigations consisting of geophysical transects and soil borings are then planned and executed. It is preferred to span the foundation footprint with at least two geophysical transects oriented perpendicular to the terrain unit and at least one geophysical transect oriented parallel to the strike of the terrain unit (Figure A-5). As the geophysics data become available, they can be used to formulate for more geophysics if required and provide planning for the geotechnical drilling campaign (Figure A-4).

Figure A-4 Example of Geophysical Transect Layout in Small-Scale Development with One Terrain Unit

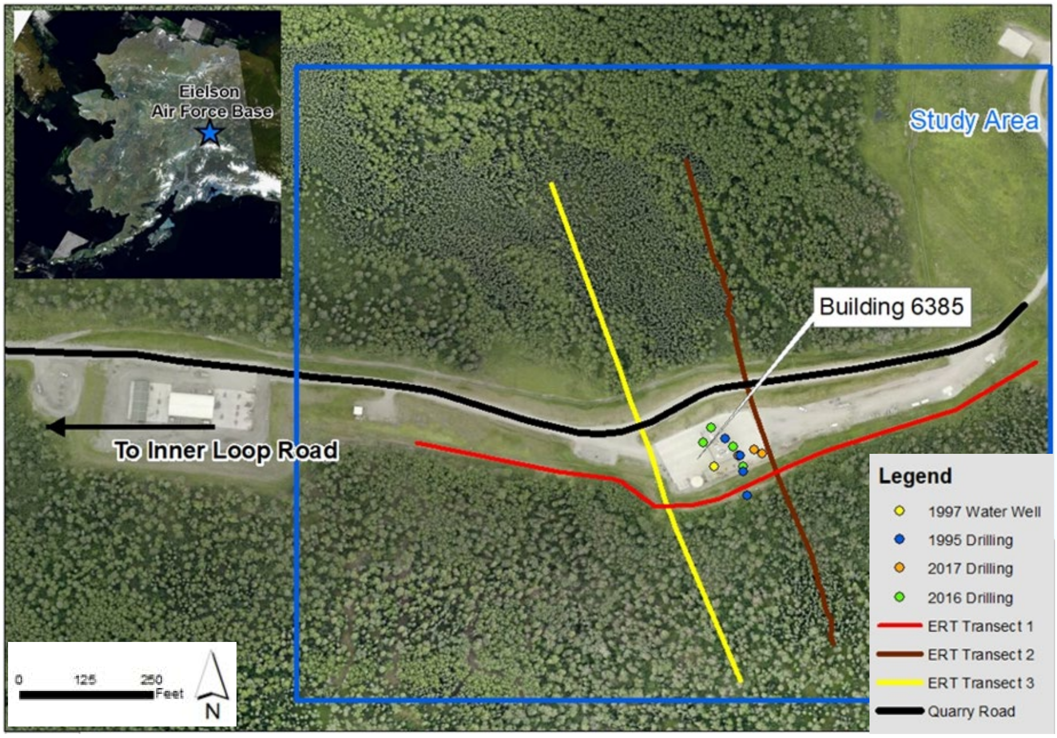


Figure A-5 Orientation of Geophysical Transects and Drilling Footprint for Collection of Detailed Subsurface Data

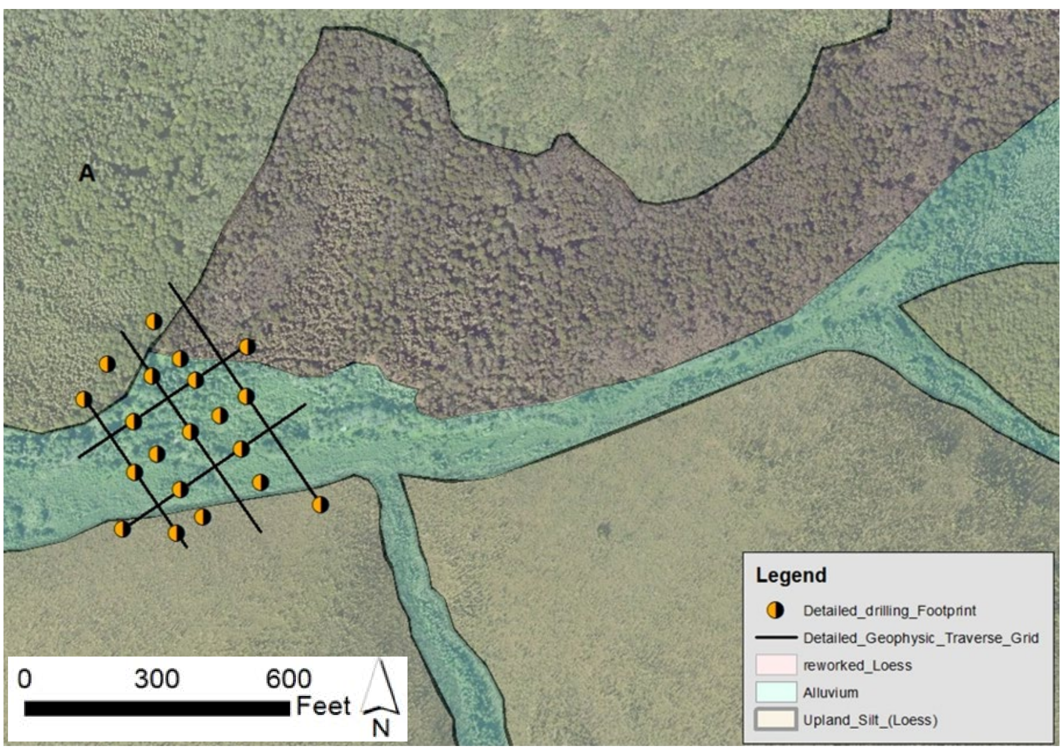

This two-phase approach works well for large projects that cover an area in excess of 50 acres. The reconnaissance-level geophysics and reconnaissance-level drilling allow designers to narrow down the best locations within a large plot of land to build foundation-critical structures. Once the structure's foundation design requirements have been identified (such as refined building footprint, tentative foundation loads, and allowable settlement criteria), the more rigorous geophysical and drilling data can be collected for the design.

APPENDIX B GLOSSARY

B-1 INTRODUCTION.

The following acronyms and terms are used in this document. UFC 3-130-01 provides a more comprehensive list of acronyms and terms for general cold regions engineering.

B-2 ACRONYMS.

AFCEC	Air Force Civil Engineer Center
AFDD	Air freezing degree-days
ATDD	Air thawing degree-days
ATM	Alaska Test Method
BIA	Bilateral Infrastructure Agreements
CARB	California Air Resources Board
CCR	Capacitive-Coupled Resistivity
cm	Centimeters
DEM	Digital elevation model
DoR	Designer of Record
ERT	Electric resistive tomography
FHWA	Federal Highway Administration
ft	Feet
GHz	Gigahertz
GIS	Geographic information systems
GPR	Ground penetrating radar
HNFA	Host Nation Funded Construction Agreements
HQUSACE	Headquarters, U.S. Army Corps of Engineers
IBC	International Building Code
in.	Inch
kg	Kilogram

lb	Pound
LPT	Large penetration test
m	Meters
MAAT	Mean annual air temperature
MAGT	Mean annual ground temperature
MHz	Megahertz
mm	Millimeter
NAVFAC	Naval Facilities Engineering Systems Command
NOAA	National Oceanic and Atmospheric Administration
RQD	Rock Quality Designation
SOFA	Status of Forces Agreements
SPT	Standard penetration test
UFC	Unified Facilities Criteria
USCS	Unified Soil Classification System

B-3 DEFINITION OF TERMS.

Heterogenetic permafrost growth: A mode of permafrost growth whereby freezing temperatures penetrate into previously unfrozen ground of uniform composition.

Syngenetic permafrost growth: A mode of growth of permafrost whereby additional material is deposited on a permafrost site during freezing conditions, causing the permafrost layer to build upward.

Yedoma: Ice-rich silty deposits penetrated by large ice wedges (“Yedoma Permafrost Genesis: Over 150 Years of Mystery and Controversy,” by Shur et al.)

FOREWORD

The Unified Facilities Criteria (UFC) system is prescribed by MIL-STD 3007 and provides planning, design, construction, sustainment, restoration, and modernization criteria, and applies to the Military Departments, the Defense Agencies, and the DoD Field Activities in accordance with USD (AT&L) Memorandum dated 29 May 2002. UFC will be used for all DoD projects and work for other customers where appropriate. All construction outside of the United States, its territories, and possessions is also governed by Status of Forces Agreements (SOFA), Host Nation Funded Construction Agreements (HNFA), and in some instances, Bilateral Infrastructure Agreements (BIA). Therefore, the acquisition team must ensure compliance with the most stringent of the UFC, the SOFA, the HNFA, and the BIA, as applicable.

UFC are living documents and will be periodically reviewed, updated, and made available to users as part of the Military Department's responsibility for providing technical criteria for military construction. Headquarters, U.S. Army Corps of Engineers (HQUSACE), Naval Facilities Engineering Systems Command (NAVFAC), and the Air Force Civil Engineer Center (AFCEC) are responsible for administration of the UFC system. Technical content of UFC is the responsibility of the cognizant DoD working group. Defense Agencies should contact the respective DoD Working Group for document interpretation and improvements. Recommended changes with supporting rationale may be sent to the respective DoD working group by submitting a Criteria Change Request (CCR) via the Internet site listed below.

UFC are effective upon issuance and are distributed only in electronic media from the following source:

- Whole Building Design Guide website https://www.wbdg.org/dod.

Refer to UFC 1-200-01, *DoD Building Code*, for implementation of new issuances on projects.

CHAPTER 1 INTRODUCTION

1-1 BACKGROUND.

The field of Arctic and Subarctic engineering, also known as cold regions engineering, covers a wide range of multidisciplinary topics and principles. Unique issues exist in the planning, design, construction, and operation of infrastructure and facilities in Arctic and Subarctic regions. Among them are permafrost, seasonal ground frost heave and thaw settlement, extreme low temperatures, high wind loads, heavy snow loads, and remote construction sites. Additionally, the implications of the rapidly changing climate in Arctic and Subarctic regions exacerbate these unique challenges.

The Unified Facilities Criteria (UFC) Arctic and Subarctic series includes five volumes that summarize relevant information and the most feasible approaches and solutions for planning, design, construction, and maintenance of infrastructure and facilities in the Arctic and Subarctic areas of the globe.

1-2 NEED FOR SPECIAL APPROACHES.

A defining characteristic of the Arctic and Subarctic in the context of this UFC is the presence of permafrost in soil and rock, as described in Chapter 2 of this UFC and in UFC 3-130-01. One definition of Arctic and Subarctic used by the Arctic Council, an intergovernmental group, includes permafrost and nonpermafrost areas located north of 51° N latitude, including most of Alaska, Greenland, and Iceland, as delineated on the “Geographical Coverage” page of the Arctic Monitoring & Assessment Programme website (www.amap.no/about/geographical-coverage). More broadly, principles described in this UFC apply to areas below the Arctic Circle, based on extreme cold weather and environmental characteristics like flora and fauna.

Frozen soil exhibits unique characteristics because of the ice within its interstitial spaces and the massive ice features that may be present in permafrost. The presence of ice introduces an important variable that can make material properties sensitive to changes over time. As a result, foundation design must consider factors such as variability in ground temperature (both seasonally and over the design life of a facility); ice content and heterogeneity, which affect material behavior under loading and produce additional variability within the frozen soil or rock matrix across a site; and pore water salinity, which changes the freezing point and affects a variety of material properties. Site development, changes in vegetation, and climate must also be considered because they affect permafrost conditions at a project site.

1-3 REISSUES AND CANCELS.

This document supersedes and cancels inactive UFC 3-130-04 and inactive UFC 3-130-06, dated 16 January 2004.

1-4 PURPOSE AND SCOPE.

The Arctic and Subarctic UFC series provides technical guidance and available technical requirements for planning, design, construction, and maintenance of DoD facilities worldwide for all Service elements in Arctic and Subarctic environments. These guidance and technical requirements are based on the International Building Code (IBC) and the requirements in UFC 1-200-01. The UFC 3-130 series covers many aspects of Arctic and Subarctic engineering, with the specific exception of pavements, which is incorporated in the UFC 3-250 and UFC 3-260 series, as discussed in UFC 3-130-01, paragraph 1-6.3. In addition to this volume, there are four other series volumes:

- UFC 3-130-01, *Arctic and Subarctic Engineering*. UFC 3-130-01 serves as an introduction to the Arctic and Subarctic UFC series.
- UFC 3-130-02, *Arctic and Subarctic Site Assessment and Selection*. UFC 3-130-02 provides applicability and technical guidance for geotechnical site assessment for the Arctic and Subarctic environment conditions.
- UFC 3-130-04, *Arctic and Subarctic Buildings*. UFC 3-130-04 includes building design in the Arctic and Subarctic areas.
- UFC 3-130-05, *Arctic and Subarctic Utilities*. UFC 3-130-05 provides criteria and guidance for the design of utility systems for military facilities in Arctic and Subarctic regions.

This UFC addresses foundation planning, design, construction, and maintenance issues pertinent to the Arctic and Subarctic that are related to the technical disciplines of geotechnical engineering, engineering geology, and construction engineering for buildings (vertical structures) and facilities such as roads and airfields (horizontal structures). Careful planning and consideration of both current site conditions and the changes in those conditions that may occur over the life of a project are essential when designing foundations in the Arctic and Subarctic. In addition to unique physical considerations (such as the difference between saline and nonsaline permafrost, variations in ice content within the soil, and geomorphic features such as ice wedges), the designer must also consider how conditions might change over time due to factors such as the following:

- Site development affecting ground thermal conditions and drainage
- Adjacent structures altering snow accumulation and shade sites
- Surface drainages that might change course over time
- Changes in climate affecting ground freezing and thawing

1-5 APPLICABILITY.

This UFC follows the same applicability as UFC 1-200-01, paragraph 1-3, for those geographic locations in Arctic and Subarctic regions worldwide.

1-6 GENERAL BUILDING REQUIREMENTS.

This UFC is an integrated part of the Arctic and Subarctic UFC 3-130 series. Use the other documents in this series in conjunction with this UFC to address construction aspects unique to cold regions. See UFC 3-130-01, Chapter 2, for the definitions of Arctic and Subarctic. This UFC modifies and supplements the criteria found in the core UFCs. Utility provider's or installation-specific requirements must be considered.

1-6.1 Geotechnical and Foundation Engineering.

Conventional foundation practice must be modified and adapted for use in Arctic and Subarctic regions to account for extremely low temperatures and unique ground conditions, such as permafrost, seasonal frost heave and thaw in soils, and climatic changes affecting ground conditions over time (for example, permafrost degradation and slope erosion and instability).

The designer of record (DoR) must also comply with the following UFCs, except when cold regions requirements dictate otherwise:

- UFC 3-220-04FA, *Backfill for Subsurface Structures* (Army and Air Force only)
- UFC 3-220-05, *Dewatering and Ground Control*
- UFC 3-220-08FA, *Engineering Use of Geotextiles* (Army and Air Force only)
- UFC 3-220-10, *Soil Mechanics*
- UFC 3-220-20, *Foundations and Earth Structures*

These documents present regulatory and industry standards that must be considered. They include general requirements that are applicable to foundation systems and are therefore not specifically covered in this document. Other (USACE) Engineering Manuals (EM), such as EM 1110-1-1804, *Geotechnical Investigations*, and EM 1110-2-2906, *Design of Pile Foundations*, may also contain general criteria not specifically covered in this UFC.

1-6.2 Structural.

Use UFC 3-301-01, *Structural Engineering*, and UFC 3-301-02, *Design of Risk Category V Structures, National Strategic Military Assets*, as needed for design and analysis of DoD buildings and other DoD structures assigned to Risk Category V for national strategic military assets (see UFC 3-301-01, Table 2-2).

1-7 LEVEL OF CONSTRUCTION.

See UFC 1-200-01, paragraph 1-3.2, for the definitions of permanent construction, temporary construction, and facilities in support of military operations.

1-8 CYBERSECURITY.

All control systems (including systems separate from an energy management control system) must be planned, designed, acquired, executed, and maintained in accordance with UFC 4-010-06, *Cybersecurity of Facility-Related Control Systems*, and as required by the system's individual service implementation policy.

1-9 BEST PRACTICES.

Much of the state of practice for cold regions engineering, planning, design, and construction is not codified. Lessons learned and the experiences of the facility installation engineering staff are invaluable and may help to avoid potentially costly or catastrophic infrastructure failures. Appendix A presents general guidance on best practices for accomplishing certain foundation design and engineering services in extreme Arctic and Subarctic environments.

The DoR must review and interpret this guidance as it conforms to criteria and contract requirements and apply the information according to the needs of the project. If a best practices document guideline differs from any UFC, the UFC takes precedence. The DoR must submit a list of any best practices guidelines or requirements not discussed in a UFC that are being used for the project, along with documentation sufficient for review and approval prior to incorporation within the design, to the Government Project Manager.

1-10 GLOSSARY.

Appendix B contains acronyms, abbreviations, and a glossary of terms used in this document. See UFC 3-130-01 for definitions of additional terms.

1-11 SUPPLEMENTAL RESOURCES.

Appendix C contains a list of supplemental sources for information on subjects related to cold regions engineering, design, and construction. These resources are valuable tools for the civil engineer and contain additional information on topics pertinent to and affiliated with construction of foundations in the Arctic and Subarctic. See UFC 3-130-01 for additional resources for cold regions engineering.

1-12 REFERENCES.

Appendix D contains a list of references used in this document. Unless otherwise specified, the most recent edition of the referenced publication applies.

CHAPTER 2 PLANNING AND DESIGN

2-1 INTRODUCTION.

This chapter describes general factors to consider during planning and initial selection of the foundation concept and highlights some unique issues associated with foundations in the Arctic and Subarctic that should be considered.

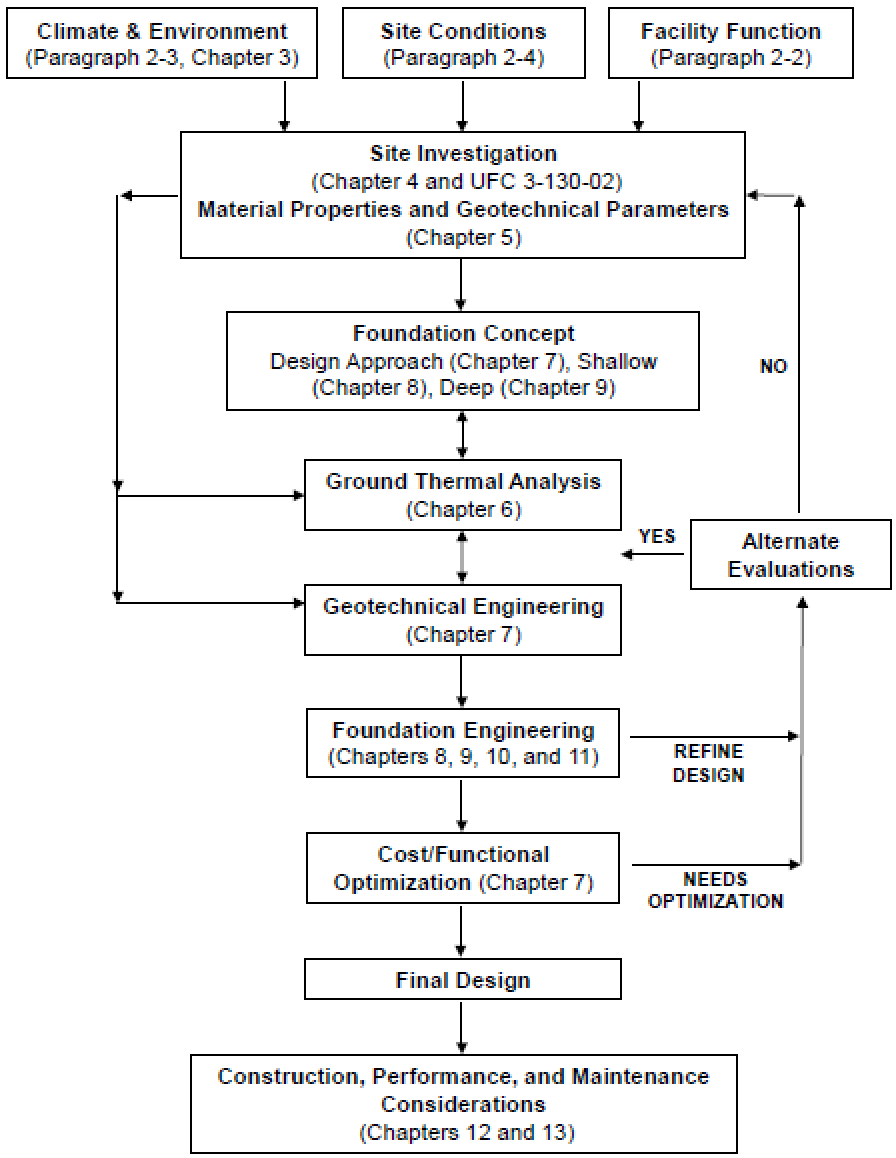
The planning, design, construction, and maintenance of foundations in the Arctic and Subarctic are affected by the unique conditions found in these regions, including the presence of permafrost and deep seasonal frost, extreme air temperatures, and sensitive environmental conditions. Complex supply and construction logistics associated with remote locations add to these challenges. Planning and formulating the foundation concept is an important first step in the design process. Figure 2-1 illustrates general steps to follow when evaluating foundations. As shown in Figure 2-1, facility function, site conditions, climate, and environment need to be considered early in the process because these considerations influence the geotechnical design parameters, the site investigation approach (see UFC 3-130-02), and the laboratory testing approaches. Figure 2-1 also shows how subsequent steps may provide feedback loops, leading to further iterations of site characterization and design before a final solution is selected.

2-2 FACILITY FUNCTION AND OTHER PLANNING CONSIDERATIONS.

The facility function helps define the level of site investigation required and relates to design loads and design life, with mission-critical facilities and life safety concerns typically having more stringent design criteria. Design life is an important consideration because, as noted in paragraph 1-1.2, frozen ground is subject to changes in behavior over time that may be the result of many factors. Changes in frozen ground behavior may include the following:

- Thaw settlement due to warming ground temperatures;
- Seasonal frost heave due to freezing of frost-susceptible soil;
- Changes in active layer depth due to changes in surface conditions;
- Differences in response to load duration and type (such as creep under long-term loads or loss of adfreeze strength due to vibratory loading);
- Changes in soil response because of frost heave; and
- Changes in material properties, depending on factors such as duration of load, change in ground temperature, change in surface conditions, or the duration of load and type of loading.

Figure 2-1 Arctic and Subarctic Foundation Evaluation Process



2-2.1 Approvals and Permits.

See UFC 3-130-01, paragraph 1-13, for the general approval and permit processes for Arctic and Subarctic construction.

2-2.2 Risk and Resilience.

See UFC 3-130-01 and UFC 2-100-01, *Installation Master Planning*, for a discussion of risk and resilience. The concepts of reliability-based design are incorporated into industry standard documents such as American Society of Civil Engineers (ASCE) Standard 7, *Minimum Design Loads and Associated Criteria for Buildings and Other Structures*. Risk assessment and infrastructure vulnerability or resilience assessment are emerging topics for cold regions engineering, and guidance is limited. However,

Figure 2-1 illustrates a feedback loop showing how a design evolves as different factors are considered.

2-2.3 Planning and Logistical Considerations.

In the Arctic and Subarctic, foundation systems are often significant cost items affected by facility use and operational constraints. For example, hangars must have at-grade access for aircraft and require special foundation systems to control potential differential movement between the structure and the apron, whereas one- or two-story buildings may be more easily elevated to decouple heat flow from the building into the underlying soil and ensure permafrost preservation. See UFC 3-201-01, *Civil Engineering*, to conduct a preliminary analysis of the existing conditions at the site; this might include conducting a geotechnical site investigation or a topographic survey and documenting environmental considerations. See UFC 3-130-02 for site analysis topics specific to the Arctic and Subarctic. Installation-specific design preferences and standards may also apply. These installation-specific issues must be considered with input from responsible engineering and operations personnel as part of the system design analysis.

2-2.3.1 Remote Site Logistics.

Military installations in the Arctic and Subarctic are frequently in remote locations and may only be seasonally accessible. Remote site logistics must be considered because these will differ with location and may include seasonal restrictions on access to some sites due to shipping arrival and departure restrictions caused by sea ice and weather and mobility changes that occur as the ground freezes and thaws. Construction schedules may dictate procuring materials up to 12 months in advance or prepositioning equipment and materials because of seasonal restrictions on access. Careful planning is required to establish and maintain construction schedules. Project design teams should be consulted early in the planning process to help identify project criteria with significant logistical impacts.

Modular construction techniques and prefabricated elements are important for military construction because these facilities may need to be expediently constructed in all seasons. Where road or airfield access was possible, truck- and airlift-capable modules have been used successfully in Alaska to expedite the construction of facilities. Additionally, large sealift modules weighing greater than 5,000 short tons (4,500 metric tons) have been used to deploy complex facilities when there were limited windows of operation. If heavy modules are to be moved, it is critical to design roads and module offloading facilities to accommodate loads imposed by self-propelled module transporters used to move heavy modules. Bridges for river crossings are especially important during module movement, and local ground conditions or other logistical considerations will dictate the locations of suitable crossings.

2-2.3.2 Personnel and Equipment.

Personnel and equipment requirements must also be considered. The efficiency and productivity of personnel and equipment are reduced when working in low temperatures, and the combination of wind and blowing snow can create major construction and operational problems even when the total precipitation is low. Equipment often requires winterization to ensure proper operation during periods of very low air temperatures. Logistics may not allow properly sized equipment to be used, thereby constraining the earthwork and foundation construction. See UFC 3-130-01 for additional resources on personnel and equipment operations.

2-2.4 Foundation Materials.

Specific materials, such as low-temperature steel or cement and grout formulated for placement at freezing temperatures, are often required for constructing Arctic and Subarctic foundation systems to ensure proper performance. In addition, earthworks may require nonfrost-susceptible soil (NFS). Specialized cold regions building design criteria and guidance are fully discussed in UFC 3-130-04.

2-3 CLIMATE AND ENVIRONMENT.

Climate and environment are two major elements to consider when planning projects and selecting foundation alternatives in the Arctic and Subarctic. For general information on environmental conditions, see UFC 3-130-01, reports such as *Permafrost and Related Engineering Problems in Alaska,* by Ferrians et al., and other supplemental references listed in Appendix C.

2-3.1 Climate Models and Predictive Tools.

Climate refers to the average weather conditions described statistically over periods of months to years, while *weather* refers to short-term variations in the state of the atmosphere (for example, wind, air temperature, cloudiness, and moisture) that occur over a period of minutes to about 15 days.[1] Climate-related inputs have traditionally been estimated by interpolating datasets that are often limited. While using historical data may be appropriate for estimating conditions in the next 10 to 20 years, observed trends suggest that these data may be less suitable for predicting climate more than 30 to 40 years in the future. Therefore, current practice is evolving toward using global climate models (GCM) to understand both the magnitude and uncertainty of possible changes. Chapter 3 and paragraph A-5 contain further discussion of the application of GCMs and climate modeling.

In addition to GCMs, there are predictive tools, such as the Scenarios Network for Alaska + Arctic Planning (SNAP) tool that was created by the University of Alaska Fairbanks and is available on their website (www.uaf-snap.org). SNAP is based on an average of five GCMs and can be used to facilitate estimating factors such as future air temperature and precipitation when a full analysis of GCM models is not warranted due to limitations in scope, schedule, or budget. Considerable judgement is required when selecting climate inputs for use in design, whether from specific tools or GCMs. Limitations and assumptions built into models must be understood before adopting the results as a basis for design.

---

[1] *Glossary of Permafrost and Related Ground-Ice Terms*, Harris et al.; *Multi-Language Glossary of Permafrost and Related Ground-Ice Terms*, van Everdingen.

2-3.2 Environmental Considerations.

Paragraphs 2-3.2.1 through 2-3.2.4 describe aspects of the environment that can affect site conditions over the life of the project. These elements are also significant factors in ground thermal analyses (see Chapter 6) and are used to forecast the depth of seasonal frost penetration and changes in ground temperature over the life of the project.

2-3.2.1 Vegetation.

The presence or absence of vegetation on a site affects the surface energy balance and ground thermal regime in complex ways.[2] For example, vegetation provides shading that helps keep solar effects low in summer, but it can also enhance snow accumulation that insulates the ground surface, thereby reducing winter cooling. Figure 2-2, which is based on a study of permafrost dynamics near Fairbanks, Alaska, illustrates the effects of vegetation on the depth of the active layer and the top of permafrost.

2-3.2.2 Air Temperature.

In the Arctic and Subarctic, air temperatures have been increasing and are expected to increase further, based on both observed trends and future projections. Air temperature is an important driver of changes in ground surface temperature and, thus, is a factor in the design of shallow and deep foundation systems and passive refrigeration, such as thermosyphons. GCMs tend to have a higher level of agreement (less uncertainty) regarding future air temperature than other environmental parameters. See UFC 3-130-01 for additional information.

2-3.2.3 Precipitation.

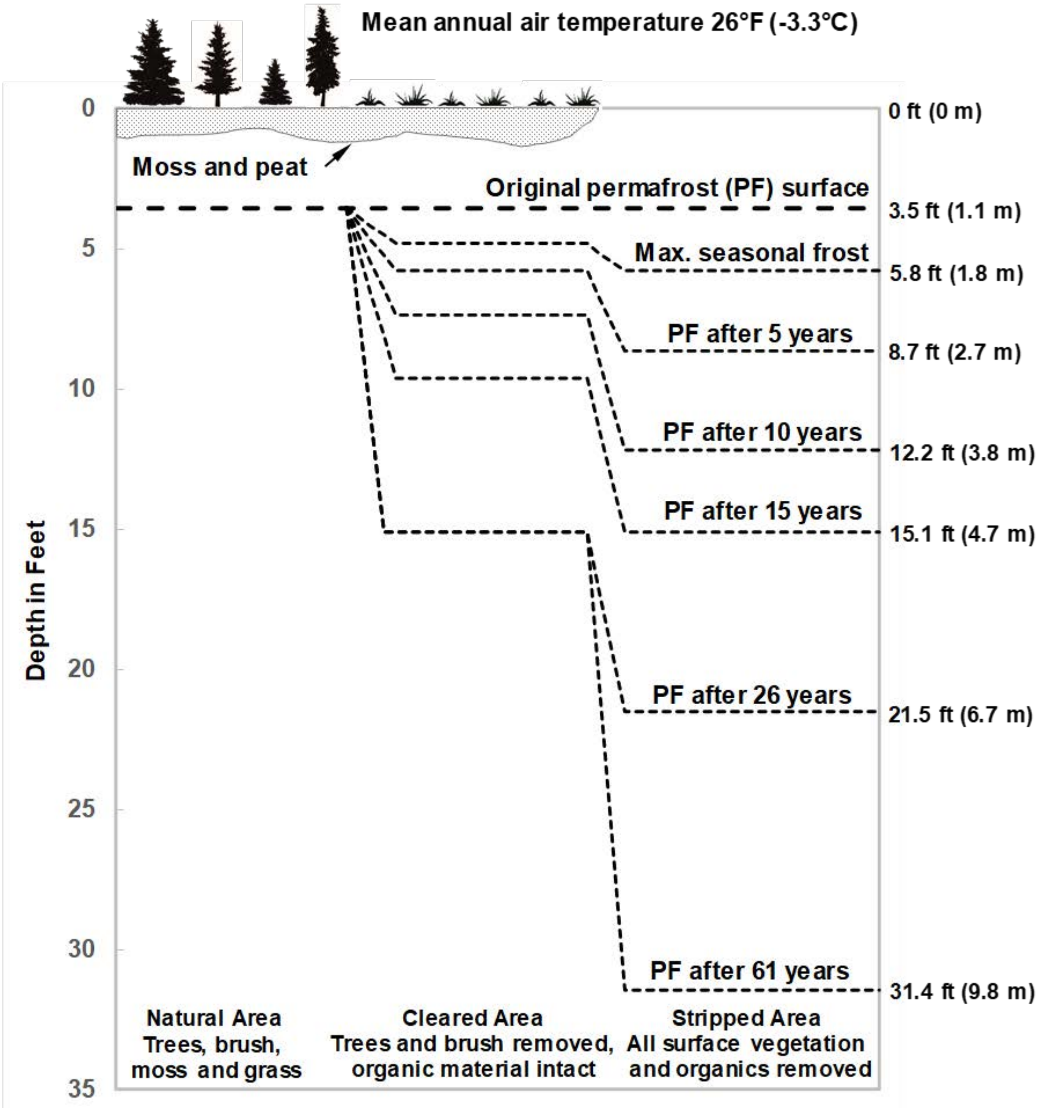
2-3.2.3.1 Effects.

Precipitation in the form of rain or snow can alter ground conditions. Snow insulates the ground surface, locally affecting ground temperature and the depth of the active layer in permafrost areas. Changes in precipitation can also lead to alteration of drainage patterns and saturation in subsurface materials. In seasonal frost areas, increased saturation can lead to increased frost heave and to soil strength changes that affect the performance of horizontal structures. Developing appropriate design criteria for precipitation and runoff may require considering future conditions, which can be predicted using GCMs. However, judgment must be used when interpreting predictions of future precipitation because these often involve a greater amount of uncertainty than temperature predictions (see paragraph 3-3.2).

---

[2] “Permafrost and Terrain Conditions at Northern Drilling-Mud Sumps: Impacts of Vegetation and Climate Change and the Management Implications,” Kokelj et al.; “Ground Temperatures and Permafrost Warming from Forest to Tundra, Tuktoyaktuk Coastlands and Anderson Plain, NWT, Canada,” Kokelj et al.

Figure 2-2 Permafrost Degradation and Vegetation Effects



Source: "Permafrost Dynamics at the Fairbanks Permafrost Experimental Station Near Fairbanks, Alaska," by Douglas et al., Figure 9. Reproduced with permission of the International Permafrost Association.

2-3.2.3.2 Volume and Runoff.

Precipitation volume and patterns of runoff are changing due to changes in climate. These changes influence the design of drainage and hydraulic structures in various ways:

- They exacerbate permafrost degradation, requiring relocation of drainage structures.
- They can affect both surface water and groundwater flow, creating design issues such as increasing aufeis and thermo-erosion of permafrost.

- Increased surface water flow may cause flooding if culverts are not appropriately sized to accommodate increasing flows over time.
- An increase in ponded water intensifies the degradation of permafrost and increases the total depth of thawed soil and the formation of taliks.
- Changes in drainage pathways can lead to increased pore pressures, in turn reducing slope stability and altering the seismic hazard, because shallow surface slope failures may increase if these materials become saturated, and the potential for liquefaction may increase with changes in saturation.

Chapter 11 presents additional drainage considerations.

2-3.2.3.3 Snow Accumulation.

The accumulation of snow around structures must be considered during design. Blowing snow that can cause snow drifts influences the orientation of the facility and the type of foundation that is selected. Specialized modeling may be required to understand snow accumulation patterns for complex structures or for sites with multiple components or terrain variation. See UFC 3-130-01 for information on snow drifts.

2-3.2.4 Wind.

Wind affects surface energy balance and knowledge of wind speed may be required for some analyses of ground freezing. See UFC 3-130-01 for a discussion of snow drifting, wind, and wind chill. Buildings must be designed to ensure snow does not accumulate beneath elevated structures or create drifts that impede access. Deep snow drifts, especially at the margins of work pads and embankments, can affect the thermal balance and result in unanticipated accumulations around buildings.

2-4 SITE CONDITIONS.

Subsurface conditions at sites in the Arctic and Subarctic may be underlain by continuous or discontinuous permafrost or may be seasonally frozen (absent of permafrost). Each of these conditions poses unique challenges for the foundation designer that require some level of site investigation and field testing, coupled with laboratory testing, to determine appropriate geotechnical properties. Ground temperature monitoring, as discussed in UFC 3-130-02, must be considered at sites in permafrost areas. As illustrated in Figure 2-1, the design properties selected will also be influenced by the climate, environment, and facility type or function. Chapter 4 provides further details on site conditions.

2-4.1 Permafrost.

The presence of permafrost is a significant factor to consider when designing foundations; the effects of thawing, creep under sustained load, and changes in strength parameters due to changes in ground ice content and temperature must be considered. The engineering parameters of frozen ground include soil type, soil or rock temperature, moisture (ice) content, saline content, bulk unit weight, unfrozen moisture content, and structure of ground ice. Chapter 5 presents a general discussion of the material properties of frozen ground.

Although ground temperature is used to define permafrost, for engineering purposes ice content and thaw stability are of critical importance when discussing frozen ground. Figure 2-3 and Figure 2-4 illustrate the change that can occur when frozen ground containing excess ice undergoes a phase change from the frozen to the unfrozen state. Note the loss of structure and the production of excess moisture as free water.

Figure 2-3 Frozen Silt with Excess Ice

Figure 2-4 After Thawing (Settlement and Strength Loss)

2-4.1.1 Standard Terminology and Classification.

For definitions of terms describing frozen ground for engineering purposes, see UFC 3-130-01 and ASTM International (ASTM) Standard D7099, *Standard Terminology Relating to Frozen Soil and Rock*. ASTM D7099 references other documents, such as *Multi-Language Glossary of Permafrost and Related Ground-Ice Terms,* by van Everdingen, and *Glossary of Permafrost and Related Ground-Ice Terms,* by Harris et al., that include terminology for permafrost, ground ice, and cryogenic processes.

During site investigations, frozen soil and rock must be classified according to ASTM D4083, *Standard Practice for Description of Frozen Soil (Visual-Manual Procedure)*, in addition to standard logging procedures. This standard describes the classification of important conditions such as ice bonding and the presence of excess ice.

2-4.1.2 Ground Temperature—Seasonal Change.

Ground temperatures change seasonally in the Arctic and Subarctic. Therefore, seasonal freezing and thawing are design considerations in both the Arctic and Subarctic. Additionally, when permafrost is present, variations in ground temperature with depth must be considered during foundation selection and design. The behavior of frozen ground is both temperature and time dependent, and properties such as adfreeze strength can change from strong to weak depending on the season and loading conditions.

Ice strength is a function of temperature and applied stress. In general, the mechanical properties of frozen ground, such as stiffness, improve or increase as ground temperatures decrease. Stiffness dramatically decreases when soils, and the ice within them, change from frozen to thawed. Therefore, it is beneficial to prevent frozen ground from warming and, in some cases, to cool the ground through a combination of refrigeration and insulation. However, the magnitude and duration of load application are also significant because ice in the foundation materials will creep over time.

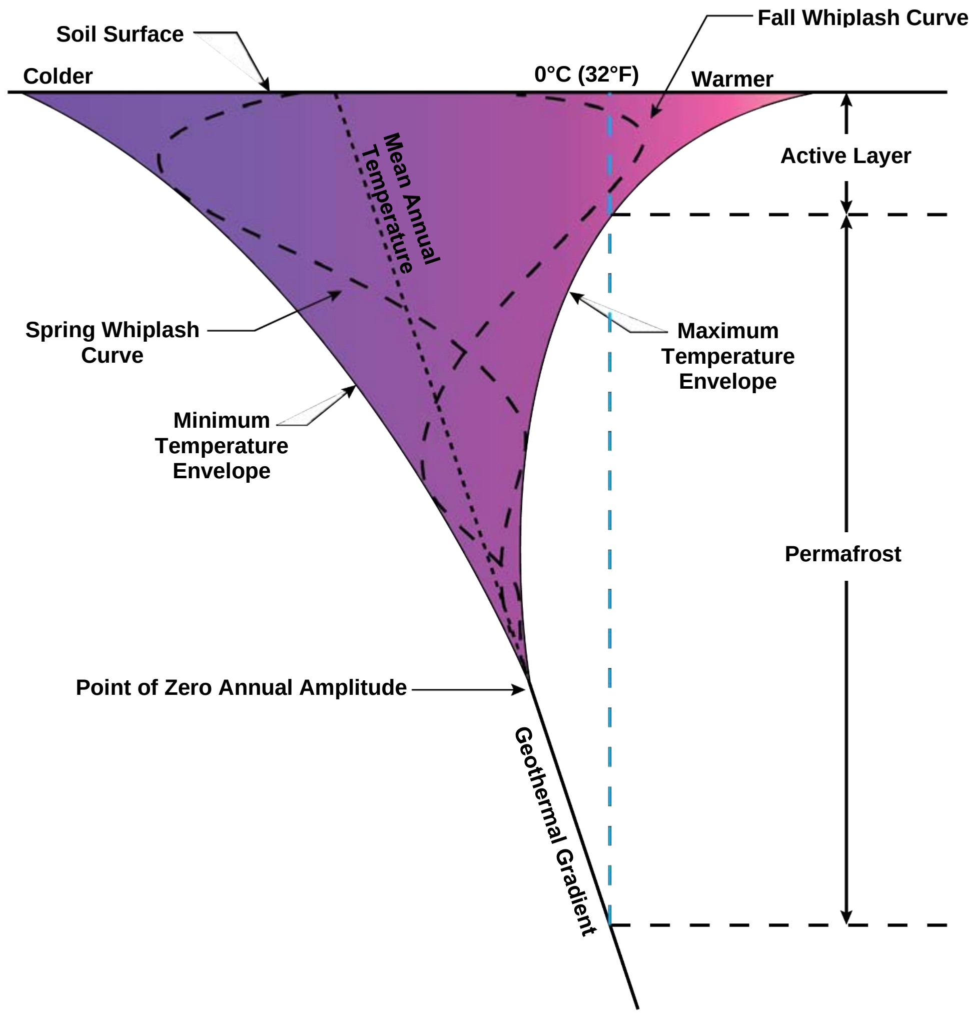
2-4.1.3 The Trumpet Curve.

A trumpet curve like that shown in Figure 2-5 is often used to depict the range of ground temperatures that occur at depth over time. The Figure 2-5 curves are generalized and trumpet curves will differ at each site depending on site conditions and the site's location within the Arctic and Subarctic. Trumpet curves are useful for illustrating important features that are commonly referred to in literature and in engineering documents, such as the following:

- Active layer: The zone of seasonally unfrozen ground extending to some depth below the ground surface in permafrost areas, or the depth of seasonally frozen ground in nonpermafrost areas.
- Whiplash curve: Ground temperature at a given moment; in aggregate, these form the trumpet curve.
- Trumpet curve: The envelope of ground temperature bounding all whiplash curves. The shape and limits of the trumpet curve may shift right or left depending on ground temperature and with time at a given site in response to changes in ground temperature.
- Point of zero annual amplitude: The point where the average ground temperature does not change seasonally.

The zone within 1 ft to 6 ft (0.3 m to 1.8 m) below the base of the active layer is sometimes referred to as the *transient layer*. The transient layer is not defined by its thermal state but is instead characterized as an ice-rich zone that acts as a thermal buffer to protect the underlying permafrost due to its relatively higher ice content and the significant heat needed to thaw this layer.[3] This layer can thaw partially or completely when the active layer deepens due to factors such as climate change or site development, resulting in significant thaw settlement. In areas where permafrost has been degraded, the transient layer may not be present.

Figure 2-5 Trumpet Curve Bounding Changes in Ground Temperature with Depth



2-4.1.4 Sources of Ground Temperature Data.

Direct measurement of ground temperature is preferred during the definition of site conditions, which will support the final design. During planning, site-specific data may not be available, and in this case, reference data can sometimes be obtained from other sites that are part of a global permafrost monitoring network and from UFC 3-130-01. Predictive tools, such as the Permafrost Temperature Tool from the University of Alaska Fairbanks Geophysical Institute Permafrost Laboratory, are also being developed to

[3] "The Upper Horizon of Permafrost Soils," Shur; "The Transient Layer: Implication for Geocryology and Climate-Change Science," Shur et al.

facilitate assessment of ground temperatures within 3 to 6 ft (1 to 2 m) of the ground surface. Synthetic ground temperature profiles can also be generated using numerical modeling, but reference data are still needed for calibration of these models (see Chapter 6).

2-4.1.5 Permafrost Distribution and Extent.

Gathering sufficient baseline data about site conditions in permafrost areas, including ground temperature, the heterogeneity of ice content, and soil and rock types, is an important aspect of early development planning. This is discussed further in UFC 3-130-02. It is important to consider the vertical extent of permafrost present at a site and to understand the ground temperature profile at a given location when planning projects. In the absence of site-specific data, refer to UFC 3-130-01 and to regional maps produced by regional governmental agencies or to other information in technical literature that can provide context that may be useful for estimating baseline conditions for planning studies.

The depth of permafrost exceeds 1,000 ft (305 m) along the Arctic coast of North America, and average ground temperature may be approximately 19°F (−7°C), while further south or in areas such as the Yukon-Kuskokwim Delta and interior Alaska, permafrost is discontinuous or sporadic, with ground temperature warmer than 28°F (−2°C). At a regional scale, climate is the main factor controlling permafrost distribution. At a local scale, permafrost conditions are also related to the local terrain and geological history. The permafrost–terrain relationships in the zones of discontinuous permafrost are generally more complex than those in the continuous zone.[4] Permafrost in the discontinuous zone is also typically warmer and more sensitive to factors such as terrain, vegetation, climate, and site development. The presence of ice-rich or saline permafrost at relatively shallow depths (<50 ft [15 m]) will also affect the overall performance of foundation systems.

2-4.1.6 Submarine Permafrost.

Special attention is required when designing infrastructure or utilities, such as pipelines or subsea cables, at the transitions between onshore and offshore permafrost areas. Historic sea level changes around coastal areas have resulted in nearshore areas where soil salinity may cause unique foundation engineering concerns. In these areas, the permafrost soil may be unbonded because the soil salinity can exceed that of seawater (which freezes at approximately 28.4°F [−2°C]). In these areas, it may be necessary to add additional cooling (such as passive thermosyphons) to foundation systems, especially in transition areas crossed by pipelines and other utilities.

2-4.1.7 Soil Salinity.

Soil salinity is an important material property to define during site investigation because it affects both ice bonding and soil strength. Depending on the depositional history at a site, it may be a significant design consideration, resulting in unfrozen moisture content,

[4] *The Periglacial Environment*, French.

brine pockets, and the presence of soil that behaves as if it is unfrozen. Paragraph 5-3.1 presents an additional discussion of soil salinity and its effect on material properties.

Saline permafrost is found in coastal areas of the Arctic that were submerged during periods of sea level rise and marine sedimentation and in areas, such as around Hudson Bay, that have experienced isostatic uplift. Saline soil is also found in permafrost areas with limited precipitation and relatively dry climates, such as the Tibetan Plateau.[5] For engineering purposes, salinity values are typically reported as concentrations in parts per thousand (ppt), with values greater than 10 to 12 ppt being high enough to influence mechanical behavior. Values up to 30 ppt are not uncommon, but higher concentrations, such as 80 to 100 ppt, also occur and are of particular concern because of the reduction in shear strength and the increased creep rate associated with frozen saline soil (see paragraph 9-5.3.4.2).

2-4.2 Seasonal Frost When Freezing Index Greater than 4,500°F-Days.

2-4.2.1 IBC and SEI/ASCE 32.

Section 1809.5 of the *International Building Code* (IBC) addresses frost protection of shallow foundations and requires, with limited exceptions, that the foundation extend below the frost line; be constructed in accordance with SEI/ASCE 32, *Design and Construction of Frost-Protected Shallow Foundations*; be erected on “solid rock”; or bear on soil that is permanently frozen. However, as noted by SEI/ASCE 32, it “applies to buildings on potentially frost susceptible ground with slab-on-ground or suspended floor foundations” but “does not apply to buildings on permafrost, to areas with mean annual outdoor air temperatures less than 32°F (0°C), or to areas with air-freezing indexes greater than 4,500°F-days (60,000°C-hr).”

The limitation on the applicability of SEI/ASCE 32 precludes its use in most of Alaska and other Arctic and Subarctic areas. The concepts outlined in this guidance can still be applied but require an extension to colder climates, such as in *Frost Protected Shallow Foundations (FPSF) for Interior Alaska Freezing Indices Between 4,000 and 8,000 Degree-Fahrenheit-Days: A Research Report,* by Perreault. In the absence of local building codes or other guidance, the DoR must be familiar with and apply fundamental principles related to permafrost and cold regions ground engineering, and perform thermal analyses when appropriate, to show that the design will not be affected by the freezing of foundation soils.

2-4.2.2 Floor Insulation.

Building foundations often incorporate floor insulation to enhance energy efficiency. Floor insulation in proximity to foundation elements reduces heat flow to the foundation soils, which may increase insulation requirements for shallow frost-protected foundations, even in areas where SEI/ASCE 32 is applicable. Areas with high heat flux, such as vehicle entrances and personnel doors, are especially susceptible to frost

[5] *Geocryology: Characteristics and Use of Frozen Ground and Permafrost Landforms*, Harris et al.

penetration below foundation elements and may require additional thermal analysis. Frost effects on foundations are discussed further in Chapter 7 through Chapter 9.

2-4.3 Topography and Slope Geohazards.

Topography and slope orientation affect permafrost distribution and properties, due mainly to the absorption of solar radiation. In general, the effect will be greater in areas of discontinuous permafrost. For instance, in the discontinuous permafrost zone, frozen ground is more common on north-facing slopes, where absorption of solar radiation is lower; the active layer on north-facing slopes is also generally thinner than on south-facing slopes. Higher levels of solar radiation absorption also occur due to reflection from the walls of buildings.

Slopes in permafrost areas can migrate downslope over time due to the force of gravity and depending on ground ice content, active layer moisture, and ground ice temperature. Some common slope movements that constitute geohazards and associated foundation engineering issues that must be considered when planning a project are discussed in paragraph A-7 and in other publications, such as in Chapter 25 of *Landslides: Investigation and Mitigation,* by Turner and Schuster, and in *National Assessment of Shoreline Change—Historical Shoreline Change Along the North Coast of Alaska, U.S.–Canadian Border to Icy Cape,* by Gibbs and Richmond.

2-4.4 Earthwork (Cut and Fill).

Development in the Arctic and Subarctic changes the local thermal regime in ways that may cause long-term degradation of permafrost or initiate changes in ground conditions that could affect foundation support and site stability. In general, unless engineering measures are implemented to mitigate thawing, earthwork leads to increased permafrost degradation due to changes in the surface energy balance. Earthworks may also modify the flow of surface water in ways that could lead to ponding at the toe of slopes or concentrate drainage along ditches that will enhance permafrost degradation if the drainage crosses ice-rich areas. In addition, cut slopes will expose underlying permafrost due to the removal of protective vegetation, which will lead to thawing and may initiate slope instability.

2-4.5 Surface Water Bodies.

Surface waters are often underlain by thawed zones, especially if they do not annually freeze to the bottom. Foundations and embankments located near lakes can be affected by degrading permafrost around the water body. These thawed zones are most significant when routing linear structures.

2-4.6 Site History.

An understanding of the changes in vegetation that may have occurred or been initiated by events such as wildfires, earthwork, or site development helps engineers determine appropriate foundation types.

2-4.6.1 Wildfire.

Wildfires occurring in areas of permafrost, including on tundra terrain, can trigger permafrost degradation with an increase in the active layer.[6] Primarily a concern during site selection, permafrost in areas that have had wildfires is likely to be different than in surrounding unburned areas. For instance, the insulation properties of burned vegetation are lower than for living vegetation, and, as a result, this change in insulation property can trigger a deepening of the active layer, an increase in permafrost temperature, and the melting of ground ice.

2-4.6.2 Past Development.

Past development and use of a site may affect permafrost conditions and is therefore an important consideration. While development is often easy to identify in the Arctic, in the Subarctic, where vegetation is more abundant, past use may not be evident, even though the past use may have already begun a process of long-term changes in the ground thermal regime.

2-4.6.3 Adjacent Structures.

It is important to consider the location of a facility and the effect it may have on other structures in the area. Adjacent structures in the Arctic and Subarctic can be affected by seemingly minor shading that locally changes environmental conditions and soil temperatures, changes in wind patterns and snow drifting that result in increased thawing, or changes in drainage that affect surface water and groundwater movements. Snow drifting may also affect building egress and increase snow removal requirements.

[6] “The Response (1958–1997) of Permafrost and Near-Ground Temperatures to Forest Fire, Takhini River Valley, Southern Yukon Territory,” Burn.

CHAPTER 3 CLIMATE

3-1 INTRODUCTION.

Climate is a key consideration for Arctic and Subarctic ground engineering projects because temperature, precipitation, and wind regimes can affect the thermal conditions of permafrost and partially frozen ground (see paragraph 2-3). Climate change has the potential to alter existing conditions in ways that may affect foundation design. It is important to understand how future climate projections can be considered for assessments of frozen ground to improve the resilience of foundation designs.

This chapter discusses the potential impacts of climate change on key climate variables associated with foundation engineering and outlines a strategy for using future climate projections to inform designs.

3-2 CLIMATE CHANGE CONSIDERATIONS.

Climate projections may be used to gain valuable insights on the magnitude and uncertainty of projected changes in climate from a range of GCMs and emissions scenarios. General information and a summary of the overall climate projection trends can be found in UFC 3-130-01.

The effects of climate change and site development are especially important considerations that must be addressed in design and construction planning to ensure that designs are resilient and adaptable. The following effects may need to be considered:

- Changes in ground ice temperature due to rising air temperatures.
- Changes in liquefaction potential that may occur due to ground thawing, whether natural or because of site activities.
- Changes in drainage requirements during the life of the facility that may occur due to changes in precipitation associated with changing climate in the Arctic and Subarctic. For example, increased precipitation may require larger-than-normal drainage structures or the incorporation of resilient design features that allow easy adaptation in the future. These changes may include shifts in natural drainages, increased flow, or changes in erosion-control requirements.
- Changes in coastal erosion processes are especially important in areas where changes in sea ice extent are creating longer open water seasons and increased thawing of coastal permafrost.

3-2.1 Global Climate Models.

As of 2024, future climate conditions are typically projected using GCMs that involve the mathematical representation of global land, sea, and atmospheric interactions over a long period of time. These GCMs were developed by various government agencies, but they share a number of common elements described by the Intergovernmental Panel on

Climate Change (IPCC). Climate projection data are available from over 30 GCMs in reports available from the IPCC (see paragraph A-5.1).

3-2.2 Downscaling Climate Data and Sources.

The climate projection resolution of GCMs is generally too coarse for direct use in foundation engineering applications because they do not resolve weather and extreme weather patterns or climatology at local scales. Rather than use GCM output directly, there are different options for analyzing climate projections at a regional scale. Downscaling methodologies incorporate region-specific information in various ways to improve the representation of climate and the temporal and spatial resolution of GCMs. Downscaled climate model outputs are available from a variety of sources, depending on the region being considered. Review available downscaled future climate data sources to select appropriate climate model outputs to inform foundation designs. To estimate climate change effects using downscaled future climate data, compare a long-term average future period, which will vary depending on the type of project and its design life, to a long-term modeled baseline period. See paragraph A-5.2 for data and resources available as of 2024.

3-3 KEY ENVIRONMENTAL PARAMETERS.

The following key parameters, estimated using downscaled GCM output, are used to inform foundation engineering design in a changing climate:

- Air temperature: Increasing air temperature will influence ground temperature. This will result in thawing of permafrost, thereby affecting ground engineering designs that assume frozen ground.
- Precipitation (rain and snow): Precipitation in the form of rain and snow will both remove heat from and insulate the ground. Changes in precipitation patterns and related consequences (such as water ponding or increased drainage) can be important design considerations when evaluating uncertainty in long-term performance.
- Wind: Projected changes in wind speeds affect surface energy balance and are especially important to consider when evaluating the performance of passive thermosyphons when selecting appropriate boundary conditions for thermal models (see paragraph 6-4.2).

Using a multi-model ensemble of climate projections, changes in the key environmental parameters may be estimated across a set of climate models and emissions scenarios to gain an understanding of the magnitude and uncertainty of projected changes from an established modeled baseline period. Paragraphs 3-3.1 through 3-3.3 describe considerations when using climate projections for this set of key environmental parameters.

3-3.1 Air Temperature.

In the Arctic and Subarctic, air temperatures are expected to increase and be more variable, given both observed trends and projections. GCMs tend to have a higher level of agreement (less uncertainty) for air temperature than for other environmental parameters. In addition, it may be necessary to consider uncertainty in air temperature projections for some foundation engineering designs. For example, thermosyphons may need to be sized to take advantage of short periods of colder-than-average temperatures rather than using annual averages that include periods when the thermosyphons may not be effective due to warm air temperatures.

SNAP downscaled climate projections include multiple climate models and emissions scenarios, including representative concentration pathways (RCP)4.5 and RCP6.0 (moderate emissions) and RCP8.5 (high emissions). See paragraph A-5.1 for discussion of RCPs. Using SNAP's set of downscaled climate projections, the mean annual temperature in Fairbanks, Alaska, under RCP4.5 is projected to increase by 4.7°F (2.6°C) in the near term (2030–2039) and by 7.6°F (4.2°C) in the longer term (2090–2099) relative to historical climate conditions under RCP4.5. Under RCP8.5, a mean annual temperature increase of 5.4°F (3.0°C) in the near term and 22.3°F (7.0°C) in the longer term are projected. With a wide range of possible future temperatures, uncertainty may be considered to inform foundation engineering design based on the design lifespan and level of risk involved.

3-3.2 Precipitation (Rain and Snow).

Precipitation changes surface and subsurface water flows related to the drainage and degradation of frozen ground and also insulates the ground when in the form of snow; hence, it is a significant design consideration. While climate models tend to have greater agreement regarding projected changes in temperature, projections of precipitation often involve a greater amount of uncertainty due to the finer spatial and temporal resolutions involved in the physical processes that are being modeled.

Using downscaled climate projections from SNAP, annual total precipitation for Fairbanks, Alaska, is projected to increase by 18% in the near term (2030–2039) and by 25% in the long term (2090–2099) under RCP4.5. Under RCP8.5, an annual total precipitation increase of 18% in the near term and 52% in the long term is projected. With a wide range of future total precipitation amounts (along with mean air temperature), more precipitation may be projected, with a greater portion falling as rain. The timing and magnitude of snow depth may also change, depending on how precipitation and temperature amounts are projected to change seasonally and the uncertainty across climate models and emissions scenarios. These changes in climate may be considered for engineering foundation design because they may affect permafrost depths and the underlying soil thermal properties.

3-3.3 Wind.

Wind affects the surface energy balance and must be considered when evaluating model inputs, such as n-factors, that are used to predict changes in the depth of thaw or in other boundary conditions noted in paragraph 6-4.2. Wind is also a significant factor when evaluating the performance of passive thermosyphons. Wind and related icing also have a significant effect on horizontal loadings and can result in harmonic motions that are accounted for in the IBC and other building codes. Historically, global wind speeds have been decreasing; however, in recent years, wind speeds have begun to increase.[7] Like precipitation, model agreement is typically low for wind speeds due to the finer spatial and temporal resolutions involved in the physical processes that are being modeled.

The community wind tool provided by SNAP provides historical and projected wind speeds for several Arctic communities. For Fairbanks, Alaska, this tool demonstrates that wind events above 7 mph (11.3 kph) may become more common in the future. This is especially true for durations of 12 hours or less and for wind events of 11.5 mph (18.5 kph) or less. More detailed information regarding projected wind speeds can be obtained from downscaled datasets such as the National Aeronautics and Space Administration (NASA) Earth Exchange Global Daily Downscaled Projections (NEX-GDDP). Extreme wind speeds are generally not well represented by climate models.[8] Projected wind speeds may be an important consideration for engineering foundation design because more frequent wind events may increase blowing snow, which can form drifts that insulate the ground and lead to increased thawing and can cover foundation elements that should remain exposed. Conversely, more frequent wind events may increase ground heat loss through convection, which may be beneficial to cooling and to the performance of foundation systems.

3-4 CLIMATE UNCERTAINTY.

3-4.1 Climate Projections.

When using climate projections, it is important to understand the limitations and assumptions built into the models before adopting the data as a basis for design. Because climate models generally provide outputs in a coarsely gridded (greater than 60 mi [100 km] grid resolution) format, differences can be expected when comparing to point observations, especially for climate variables that differ on finer spatial and temporal scales (for example, precipitation and wind). When using climate projections to inform design, use downscaled climate model output to better capture site-level conditions (see paragraph 3-2.2).

3-4.2 Use of Multiple Models.

Due to differences in future climate scenarios (RCP versus shared socioeconomic pathways [SSP], as discussed in paragraph A-5.1), climate model structure, parameterization, and initialization, an ensemble of climate projections must include different representations of both current and future climate for a given location. Because no one model or climate scenario can be viewed as completely accurate, the IPCC recommends that climate change assessments use as many models and climate scenarios as possible, or a “multi-model ensemble” (see page 79, *Climate Change 2013: The Physical Science Basis, Contribution of Working Group I to the Fifth Assessment Report of the Intergovernmental Panel on Climate Change*, edited by Stocker et al.). For this reason, the multi-model ensemble approach is used to delineate

[7] “A Reversal in Global Terrestrial Stilling and Its Implications for Wind Energy Production,” Zeng et al.
[8] “Evaluating Wind Extremes in CMIP5 Climate Models,” Kumar et al.

the probable range of results and better capture the actual outcome (an inherent unknown). Percentiles may be used to express the distribution of future climate projections while also considering each of the models in the multi-model ensemble. The selection of which percentile to use should be based on the balance between the conservatism of the geotechnical engineering inputs used for design and the consequential risks. For example, projections at the 50th percentile represent the median projections, while the projections at the 95th percentile represent an outcome where 95% of the projections are at or below this value.

3-5 CLIMATE AND CONTINUAL IMPROVEMENT.

The *Guide on Climate Change Adaptation for the Mining Sector*, prepared by Golder Associates, provides a stepwise approach to incorporating climate change adaptation into decision-making processes to increase climate change resilience at mine sites. This document is not specific to Canada and can be applied globally. The document provides a three-stage framework for incorporating climate change in decision making:

- Assessing climate risk. This assessment must include use of DoD-specific tools as applicable to the project type.
- Developing adaptation pathways.
- Implementing adaptation pathways.

In this iterative three-stage process, each stage of the cycle should be reevaluated based on the outcomes of previous stages, updates to climate projections, and changes to infrastructure. Reevaluation is based on the results of monitoring and surveilling the adaptation pathways and whether established triggers or thresholds were met. For example, the need for reassessment will arise when there are updates to the climate projections or changes to the infrastructure or operations of the mine component. The reassessment can be included as part of existing continual improvement processes.

CHAPTER 4 SITE INVESTIGATIONS

4-1 GENERAL.

Requirements and guidance regarding site assessment, characterization, and monitoring for Arctic and Subarctic construction are presented in UFC 3-130-02. Additional general site investigation criteria are provided in UFC 3-201-01 and UFC 3-220-01, *Geotechnical Engineering*. See paragraph A-2 for additional resources.

4-2 INVESTIGATION APPROACH.

4-2.1 Scope.

The scope of site investigations in areas characterized by permafrost or by freezing and thawing ground conditions must follow the approach outlined in UFC 3-130-02 and incorporate strategies and investigation techniques discussed in references such as *Cold Regions Pavement Engineering,* by Doré and Zubeck; *Permafrost Engineering Design and Construction,* by Johnston; and *National Standard of Canada CAN/BNQ 2501-500/2017: Geotechnical Site Investigations for Building Foundations in Permafrost Zones*, by Bureau de Normalisation du Quebec. In general, the scope of a field program should progress from broad (low resolution) reconnaissance that defines general conditions to site-specific (high resolution) investigations designed to address issues specific to the design. The actual level of investigation varies depending on the complexity of the project and may include multiple phases of field investigation.

Following initial site investigation, additional investigation may be needed to refine understanding of the subsurface conditions that are most important to foundation design and estimated construction costs, especially when foundation systems or subsurface conditions are complex. As data gaps are filled through investigation, knowledge of the site conditions will move from poor, to fair, to good or excellent, and both the site model and design will be refined.

4-2.2 Multi-phase Investigation.

The design of the Trans-Alaska Pipeline System is one example of a multi-phase investigation program. This very large project spanned many degrees of latitude and various types of permafrost and nonpermafrost terrain. Multiple site investigations were completed, beginning with early scoping and reconnaissance-level investigation, followed by site-specific investigations to generally confirm the conditions along the alignment, and other investigations to address design-specific concerns. The final level of characterization occurred during the construction process, when field design changes were made based on actual site conditions at each foundation. As the pipeline became operational, changes in terrain, drainages, and climate resulted in continuing changes to adapt to these changed conditions.

CHAPTER 5 PROPERTIES OF FROZEN GROUND

5-1 INTRODUCTION.

This chapter provides an overview of testing that may be required to define mechanical properties of frozen and unfrozen ground used in geotechnical analyses for projects in the Arctic and Subarctic. Soil properties may either be measured as part of field investigations and laboratory testing or estimated based on correlations in the literature.

As for conventional foundation design, the level of effort expended to determine the properties of frozen ground will depend on the complexity of the project and the foundation engineering risk to be addressed. Frozen ground properties used in design may differ depending on ground temperature and may change over the life of the facility and duration of load.

5-2 LABORATORY TESTING.

Laboratory testing is an integral part of the overall site characterization processes outlined in Figure 2-1 and a necessary component of the design if site investigations are conducted. General requirements on laboratory testing are provided in UFC 3-201-01 and UFC 3-220-01, and applicable standards for many laboratory tests are published by ASTM. However, when using available data from the literature, it is important to validate the testing conditions to ensure the results are appropriate for use for a given site because, as discussed in MIL-STD-810G, *Department of Defense Test Method Standard: Environmental Engineering Considerations and Laboratory Tests*, test data should be representative of ground conditions at the site.

5-2.1 Index Testing.

Index tests provide important data on the fundamental characteristics of soil and rock materials. Frozen soil classifications must include the Unified Soil Classification System (USCS) symbol (ASTM D2487, *Standard Practice for Classification of Soils for Engineering Purposes [Unified Soil Classification System]*) and a description of the ice in the soil. For engineering purposes, a simplified visual method of characterizing the ice in frozen soil is described in ASTM D4083 and is summarized as a three-step process in Table 5-1. The classifications in ASTM D4083 are based on the size and morphology of ice and on the ice bonding and content as described in *Description and Classification of Frozen Soils,* by Linell and Kaplar, and *Guide to a Field Description of Permafrost for Engineering Purposes,* by Pihlainen and Johnston. The classifications used in ASTM D4083 can also generally be related to water transfer and freezing processes and to ice type, as discussed in *Permafrost Engineering Design and Construction,* by Johnston.

Table 5-1 Frozen Soil Classification Process

Step	Process				
1. Describe soil independent of frozen state	Classify soil by the USCS				
2. Modify soil description by description of frozen soil	***Major Group***		***Subgroup***		
	Description	*Designation*	*Description*		*Designation*
	Segregated ice not visible by eye	N	Poorly bonded or friable		Nf
			Well bonded	No excess ice	Nbn
			Well bonded	Excess ice	Nbe
	Segregated ice visible by eye (ice less than 25 mm thick)	V	Individual ice crystals or inclusions		Vx
			Ice coatings on particles		Vc
			Random or irregularly oriented ice formations		Vr
			Stratified or distinctly oriented ice formations		Vs
			Uniformly distributed ice		Vu
3. Modify soil description by description of substantial ice strata	Ice greater than 25 mm thick	ICE	Ice with soil inclusions		ICE+ soil type
			Ice without soil inclusions		ICE

Source: Adapted from ASTM D4083.

5-2.1.1 Frost Design Classification.

5-2.1.1.1 USACE System.

Table 5-2 presents the USACE frost design soil classification system from *Frost Action Predictive Techniques for Roads and Airfields, A Comprehensive Survey of Research Findings*, by Johnson et al. Frost groups are classified into eight categories, and three types of screening are used to determine frost susceptibility.

1. Soil types are determined based on the USCS, initially in the field.
2. The percentage of soil particles finer than the 8×10^{-4} in. size (0.02 mm) is determined based on measurement in the laboratory (ASTM D7928, *Standard Test Method for Particle-Size Distribution [Gradation] of Fine-Grained Soils Using the Sedimentation [Hydrometer] Analysis*).
3. Laboratory frost heave testing is performed to verify the estimated percentage estimated in step 2 (refer to paragraph 5-2.5 for a discussion of frost heave testing). Frost heave testing may not be performed on every sample and is optional, depending on project requirements.

5-2.1.1.2 Frost Heave.

Frost heave in soils occurs when soils freeze, but the extent of frost heave depends on soil type and the presence of contributing water through capillary rise determined through index testing.[1] For frost heave to occur, there must be what is sometimes referred to as the 3 Ws (water, wicking, and winter). Water must be available to create ice, wicking (capillary action) is required to bring water to the freezing front, and winter (freezing temperatures) is required to convert the water into ice. Reducing one or more of these conditions reduces the magnitude of heave or even prevents it.

5-2.1.1.3 Segregation Potential.

An alternative approach for estimating frost heave potential is to measure the segregation potential of the soil (see “Procedure for Determining the Segregation Potential of Freezing Soils,” by Konrad). See paragraph A-2 for additional resources.

5-2.1.2 Pore Water Salinity.

5-2.1.2.1 Measurement.

For geotechnical engineering purposes, the salinity of pore water in permafrost soil is measured to estimate freezing point depression and unfrozen water content. ASTM D4542, *Standard Test Methods for Pore Water Extraction and Determination of the Soluble Salt Content of Soils by Refractometer*, is used to quickly estimate the soluble salt content of soils. However, electrical conductivity methods have also been widely used. Other methods have been developed for agronomy studies and are not necessarily appropriate for comparison to historical data or application to permafrost engineering problems. It is critical to understand the test method used when comparing test results from different sources.

5-2.1.2.2 Effects.

If saline conditions are identified at a site, the design must account for the behavior of the saline permafrost. Salinity in the pore water causes a freezing point depression, resulting in frozen soil that is weaker than nonsaline soil for a given ground temperature and load duration. Saline soil will also undergo higher levels of creep than nonsaline soil at the same stress level. The presence of pore water salinity may create permafrost that is not ice-bonded because of freezing point depression (the approximate freezing point depression in soil with 10 ppt pore water salinity is 1°F [0.56°C]). Typical sediments deposited in Alaskan offshore marine environments commonly have salinities that vary between 30 to 35 ppt. Salinity at this concentration in soil results in a freezing point depression to 28°F (−2.2°C), with the result that the sediment may be classified as permafrost, but because ice-bonded soil will not form at temperatures above the freezing point depression, the soil behaves as an unfrozen material. Pockets of high salinity can also form onshore and are not uncommon in coastal areas in northern Alaska.

[1] *Frost Susceptibility of Soil: Review of Index Tests*, Chamberlain.

Table 5-2 USACE Frost Design Soil Classification System

Frost Susceptibility[1]	Frost Group	Kind of Soil	Amount Finer than 0.02 mm (% by weight)	Typical Soil Type under USCS
Negligible to low	NFS	a) Gravels	0–1.5	GW, GP
		b) Sands	0–3	SW, SP
Possibly	PFS[2]	a) Gravels	1.5–3	GW, GP
		b) Sands	3–10	SW, SP
Low to medium	S1	Gravels	3–6	GW, GP, GW-GM, GP-GM
Very low to high	S2	Sands	3–6	SW, SP, SW-SM, SP-SM
Very low to high	F1	Gravels	6–10	GM, GW-GM, GP-GM
Medium to high	F2	a) Gravels	10–20	GM, GM-GC, GW-GM, GP-GM
Very low to very high		b) Sands	6–15	SM, SW-SM, SP-SM
Medium to high	F3	a) Gravels	>20	GM, GC
Low to high		b) Sands except very fine silty sands	>15	SM, SC
Very low to very high		c) Clays, PI > 12	--	CL, CH
Low to very high	F4	a) All silts	--	ML, MH
Very low to high		b) Very fine silty sands	>15	SM
Low to very high		c) Clays, PI < 12	--	CL, CL-ML
Very low to very high		d) Varved clays and other fine-grained, banded sediments	--	CL and ML; CL, ML and SM; CL, CH, and ML; CL, CH, ML and SM

G = gravel
H = high plasticity
L = low plasticity
M = silt
NFS = nonfrost-susceptible
P = poorly graded
PFS = possibly frost susceptible
S = sand
USCS = Unified Soil Classification System
W = well graded

5-2.1.3 Bulk Unit Weight.

Bulk unit weight is determined from undisturbed samples (ASTM D7263, *Standard Test Methods for Laboratory Determination of Density and Unit Weight of Soil Specimens*).

In a design context, terms like *ice-rich* and *ice-poor* may be specific to a particular design methodology. For example, permafrost with excess ice is defined as ice-rich,[2] but it also can be described in terms of frozen bulk density,[3] with densities less than about 106 lb/ft^3 (1,700 kg/m^3) exhibiting ice-rich behavior in terms of pile design. Bulk density is also related to the relative compaction and thaw stability of in situ material and engineered fills.[4] Extensive studies of the placement and compaction of frozen soil have shown the difficulty in achieving commonly specified levels of compaction, which are required if there is the potential for the materials to thaw or creep under load.

5-2.2 Thermal Conductivity and Moisture Content.

Thermal conductivity is an important property used in ground thermal analyses. Thermal conductivity values are not constant but, rather, vary with moisture content, temperature, salinity, and soil types. Information on the thermal conductivities of ice-rich permafrost in frozen and thawed states is available in “Thermal Conductivity of Some Ice-Rich Permafrost Soils,” by Slusarchuk and Watson. Thermal conductivity is measured by laboratory testing or calculated based on empirical methods such as those developed in “Thermal Properties of Soils,” by Kersten, or *Thermal Conductivity of Soils,* by Johansen. Kersten’s results are not applicable to ice-rich soils. Generally, the Johansen method gives better results for soil saturation above 10%.[5] Errors have been corrected in the original translation of Johansen’s publication with respect to peat,[6] and this new version offers improvements to the method by accounting for natural and crushed base-course material and mineral composition.

In general, unfrozen water content will decrease as ground temperatures get colder and thermal conductivity increases. Unfrozen water content and thermal conductivity are especially sensitive to changes in low-salinity soil when ground temperatures are between 28°F and 32°F (−2°C and 0°C). As salinity increases in frozen soil, so does the unfrozen moisture content and the range of ground temperatures within which the effect on thermal conductivity is significant. However, unfrozen water content is not accounted for by Kersten. Thus, it is estimated the Kersten equations calculate values for thermal conductivity within ±25% of measured values, which is arguably less variation than the natural variance due to soil inhomogeneity.[7]

5-2.3 Advanced Testing.

Advanced testing is typically used to measure mechanical properties, such as creep, in uniaxial compression (ASTM D5520, *Standard Test Method for Laboratory Determination of Creep Properties of Frozen Soil Samples by Uniaxial Compression*) and shear strength under constant rate of strain (ASTM D7300, *Standard Test Method for Laboratory Determination of Strength Properties of Frozen Soil at a Constant Rate of Strain*). Other tests are used to measure unfrozen moisture content. For a general overview of frozen soils testing, see *Mechanical Properties of Frozen Soils,* by Zubeck and Yang, and Appendix C of *Frozen Ground Engineering,* by Andersland and Ladanyi.

Advanced testing of frozen soil requires specialized test apparatuses and is often conducted in a cold room to better control environmental conditions. Temperature control is an important consideration for advanced testing and may require multiple layers of insulation or circulating baths with precision controls. Samples must be maintained at an appropriate temperature that is representative of temperatures at the site. In addition, future changes in ground temperature may need to be considered in the design of the test procedures. Specialized considerations for handling and shipping frozen samples may be required.[8]

5-2.3.1 Thaw Strain.

5-2.3.1.1 Soil.

Thaw strain tests measure the total deformation that occurs upon thawing. This measurement can be a relatively simple test that provides useful index data indicative of the total settlement that may occur when frozen ground undergoes a phase change from frozen to unfrozen. Values of thaw strain can vary considerably, as shown in “Thaw Strain Data and Thaw Settlement Predictions for Alaskan Soils,” by Nelson et al., who discuss laboratory testing and report thaw strain of between 0% and 80% for a variety of soil types found in Alaska. When comparing reported values from the literature, it is important to understand the actual test setup and procedure used to measure reported values because there is no ASTM standard for this test. Figure 5-1 shows multiple thaw strain tests underway using custom fabricated equipment.

5-2.3.1.2 Rock.

Thaw strain and frost susceptibility in rock masses is related to the presence of frost-susceptible material and water within joints and infillings. If significant ice is present in a fractured rock mass, creep may also occur. Evaluation on a case-by-case basis is required.

[8] “Transportation, Preparation, and Storage of Freezing Soil Samples for Laboratory Testing,” Baker.

Figure 5-1 Thaw Strain Tests

5-2.3.2 Thaw Consolidation.

Thaw consolidation tests incorporate elements of thaw strain testing and measurement of conventional consolidation parameters after the sample has thawed. These tests measure initial strain as the sample thaws and then measure consolidation of the thawed material. For representative values determined during design and construction of the Trans-Alaska Pipeline, see “Thaw Strain Data and Thaw Settlement Predictions for Alaskan Soils,” by Nelson et al.

There is no ASTM standard for this test.[9] Hence, it is important to understand the actual test setup and procedure used to measure reported values.

5-2.4 Creep Tests.

The creep process depends on soil type, ice content, temperature, and pore water salinity; it also depends on loading rate and duration of load application. For testing procedure descriptions, see ASTM D5520 and other sources, including the following:

- *Creep of Frozen Soils*, by Sayles
- “An Engineering Theory of Creep of Frozen Soils,” by Ladanyi

[9] *Mechanical Properties of Frozen Soils*, Zubeck and Yang.

- "Uniaxial Compressive Strength of Frozen Silt Under Constant Deformation Rates," by Yuanlin and Carbee
- "In Situ Creep Properties in Ice-rich Permafrost Soil," by Savigny and Morgenstern
- "The Influence of Cryostructure on the Creep Behavior of Ice-Rich Permafrost," by Bray
- *Creep in Engineering Structures*, by Hult

Creep may occur at low stress levels. When ground temperatures are warm and conditions are ice-rich, the creep potential increases, with the result that creep may govern allowable loads and required embedment depths to limit structural deformation.

5-2.5 Frost Heave Test.

Frost heave testing is commonly conducted to understand changes in ground conditions that may occur along chilled gas pipelines or similar facilities. For structure foundations, it is preferable to mitigate potential frost heave, and this type of testing is generally not conducted. Mitigation of frost heave is discussed further in Chapter 7, Chapter 8, and Chapter 9.

Historically, the susceptibility of soils to weakening due to frost heave and thaw was measured using ASTM D5918, *Standard Test Methods for Frost Heave and Thaw Weakening Susceptibility of Soils*, but this test method is now inactive. Frost heave testing has also been conducted by academic and industry staff using proprietary methods developed to measure specific aspects of frost heave.[10] Frost heave test data must be carefully evaluated when comparing historic data from different sources.

5-3 STRENGTH PROPERTIES AND CREEP.

In general, frozen soil has high shear strength under short-term loads, with maximum strength decreasing as temperatures warm. However, the presence of salinity will reduce the shear strength and creep behavior will affect allowable long-term design loads.

5-3.1 Saline Permafrost.

Salinity in permafrost soil has a significant effect on material properties, including reducing the freezing point (freezing point depression), increasing the unfrozen moisture content, and decreasing shear strength.[11] Creep and creep rate are also affected by saline conditions; hence, it is a very important parameter to define. The strength of frozen saline sand will decrease with increasing salinity and unfrozen water content, as it does in clayey soil.[12]

---

[10] "Frost Heave Predictions for Alaskan Soils," Hazen et al.
[11] "Creep and Strength Testing of Frozen Saline Fine-grained Soils," Nixon and Lem.
[12] Ibid.

Details of the relationship between salinity and unfrozen water content in sand are described in “Shear Strength in the Zone of Freezing in Saline Soils,” by Chamberlain, “Salt Concentration Effects on Strength of Frozen Soils,” by Ogata et al., and “Strength of Frozen Saline Soils,” by Hivon and Sego. Sand strength is generally expected to be greater than the strength of clay for similar loading conditions, temperatures, and salinity. In addition, the freezing extent is also expected to be larger in sandy soil than in clayey soil for the same temperatures because of differences in the thermal conductivity and moisture content of the soil.

5-3.2 Creep in Frozen Soils.

Creep is a highly complex phenomenon that depends on soil type, ice content, temperature, pore water salinity, and the loading rate, magnitude, and duration of load application. However, in practice, creep effects are limited by controlling stress levels along a pile or below a foundation or by decreasing the ground temperature, which reduces the creep rate. Because creep is time, applied-stress, and temperature dependent, it is important to establish the service life and the acceptable total and differential settlement tolerances of structures and anticipated changes in thermal conditions because these will dictate allowable stress levels over time. Creep of footings is discussed further in paragraph 8-5.3.1 and creep for piles is discussed in paragraph 9-5.3.4.

5-4 PROPERTIES FOR ESTIMATING DYNAMIC RESPONSE.

Dynamic material properties are used to estimate the response of a foundation to loads, such as those due to seismic events or vibrations from reciprocating machinery, that may require consideration of small or repetitive strain. Properties can vary at a site and parametric analysis may be required to understand the effect on a foundation system. For example, the difference in the thickness and depth of organic soil across the site, or the presence of unfrozen zones, is a common variable that may warrant a parametric evaluation when evaluating site response. These properties will also vary with ground temperature. Testing may be conducted to estimate these properties, for both frozen and thawed conditions, using methods such as geophysical surveys like those discussed in UFC 3-130-02 or laboratory testing such as bender element tests (ASTM D8295, *Standard Test Method for Determination of Shear Wave Velocity and Initial Shear Modulus in Soil Specimens Using Bender Elements*). For more advanced projects, cyclic testing (such as triaxial, direct simple shear, or even centrifuge testing) can be performed; however, these methods are not typical for frozen soil.

5-4.1 Frozen Soil.

Shear wave velocities are expected to be higher in frozen soil than in thawed. In general, sites with fully frozen and bonded permafrost, and with temperatures colder than 25°F (−4°C), can be considered to have IBC Seismic Site Class B conditions unless shown otherwise by site investigation and testing. Warmer permafrost temperatures will result in lower shear wave velocities. Compressional (*p*) wave and shear (*s*) wave velocities (*Vp* and *Vs*) are measured in the field using seismic refraction survey methods, and variations of the surface wave velocities are determined using the multichannel analysis of surface waves, a seismic method that measures the shear-wave velocity distribution. Downhole methods, including those in ASTM D7400, *Standard Test Methods for Downhole Seismic Testing*, can also be used to measure *Vp* and *Vs*, which can then be used to calculate other properties used in dynamic analysis, such as Poisson's ratio (ν), shear modulus (G_{max}), and the impedance ratio (ζ).

Different methods may be used to measure *Vp* and *Vs*. For example, *Vp* and *Vs* were measured to a depth of 36 ft (11 m) at a site in the North Slope of Alaska[13] using three different seismic methods (such as cross-hole, downhole, and surface wave methods). The soil was well-bonded permafrost and included layers of sand and gravel with variable fines, a layer of organic silt, and a 10 ft (3 m) thick layer of massive ice. The different methods yielded *p*-wave velocities between 4,100 and 4,850 m/s and *s*-wave velocities between 1,800 and 2,200 m/s.

5-4.2 Thawed Active Layer and Underlaying Soil.

Particular attention must be given to the interface between the thawed active layer and the underlying frozen soil, where a large difference or variation in properties exists. The shear wave velocity in the active layer soil is expected to be 10 to 15 times less than the velocity in underlying frozen soil when the active layer soil is thawed. This difference results in a calculated value of G_{max} in thawed soil that is more than 100 times lower than G_{max} in the underlying frozen soil. Also, surface wave velocities in frozen soil have been shown to decrease significantly at temperatures warmer than approximately 30°F (−1°C).[14]

Guidelines for Estimation of Shear Wave Velocity Profiles, by Wair et al., provides a summary and comparison of several methods for estimating shear wave velocity. Additional methods and commentary regarding shear wave velocity estimates and considerations for vertical construction in thawed ground are provided in Section C20.3 of ASCE/SEI 7.

[13] "The Measurement of Compressional and Shear Wave Velocities in Permafrost: A Comparison of Three Seismic Methods," Black et al.

CHAPTER 6 APPLICATION OF NUMERICAL MODELING FOR GROUND THERMAL RESPONSE

6-1 INTRODUCTION.

This chapter discusses the use of numerical modeling and the different approaches available to the designer, including the use of climate inputs discussed in Chapter 3. Geotechnical thermal analysis is a broad topic requiring an understanding of thermodynamic principles, heat flow in soils, climate science, and site conditions. General background can be found in several cold regions engineering textbooks and papers, such as the following:

- *Geotechnical Engineering for Cold Regions*, by Andersland and Anderson
- "Geotechnical Thermal Analysis," by Zarling and Braley
- *Frozen Ground Engineering*, by Andersland and Ladanyi

Thermal modeling is considered fundamental for many projects because it is a useful tool for assessing ground temperature response to site development, such as the change to the depth of freeze and thaw and the potential for permafrost degradation and subsidence. It is also becoming more important due to climate change and its effect on ground temperatures. Numerical thermal modeling can also be complex due to the number of variables, including foundation geometry, climate, material properties, and ground temperature regime, that are included. Thermal modeling must be conducted by experienced practitioners and based on site-specific information and measurements.

6-2 HEAT FLOW.

Complex thermal models using finite element or finite difference methods are based on the first law of thermodynamics, which states that the total energy of a system is conserved unless energy crosses its boundaries. The rate of change in the stored thermal energy must equal the heat flux into the system minus the heat flux out of the system. Changes in thermal energy are associated with sensible heat (changes in temperature), latent heat of fusion (freeze–thaw), and latent heat of vaporization (vaporization and condensation). These parameters can be represented with one-, two- or three-dimensional (1D, 2D, or 3D) analyses in various finite element or finite difference methods like those noted in paragraph 6-3.

6-3 APPLICATIONS.

Ground thermal analyses are facilitated using computer programs. Available programs range from relatively simple programs that can calculate the depth of freeze and thaw using analytical methods to more complex software programs that use finite element or difference methods. There are several commercially available programs (as of 2024) that use finite element methods of analysis, such as TEMP/W by Seequent, RS2 by Rocscience, general programs such as Plaxis from Bentley, and various software products produced by Comsol.

Selecting the appropriate software tool for a given foundation design problem is an important consideration. For complex site conditions or geometry, fully coupled models incorporating seepage or airflow in porous media with thermal analyses may be used to understand ground temperature fluctuations in a dynamic environment. It is important to understand the internal calculations and assumptions inherent to each program and to consider comparing results from more than one software package and against known exact solutions. Sensitivity analysis is required, especially when modeling warm permafrost conditions (such as permafrost with ground temperatures warmer than about 30°F [−1°C]). It is also important to consider the properties of the soils being modeled. In many cases, it is best to focus on the foundation and then expand to a larger soil scenario so the final results portray the real thermal regime. Perform iterations including mesh refinement and time-step reduction to ensure the model results have converged on an acceptable solution. Additionally, some software may offer 3D analysis, which may prove very useful for complex geometries. It is critical that inputs to and results of 3D analysis be confirmed as realistic, which may require comparing them to output from other software products or 2D analyses with known solutions.

6-3.1 Depth of Freeze and Thaw.

For simple 1D scenarios, the active layer, depth of seasonal thaw (permafrost site), or depth of seasonal freeze (seasonal frost site) can be determined from field measurements or estimated using closed form equations such as the modified Berggren equation. The active layer thickness can be calculated by hand following UFC 3-130-05 or using software such as USACE’s Pavement-Transportation Computer Assisted Structural Engineering software (PCASE).

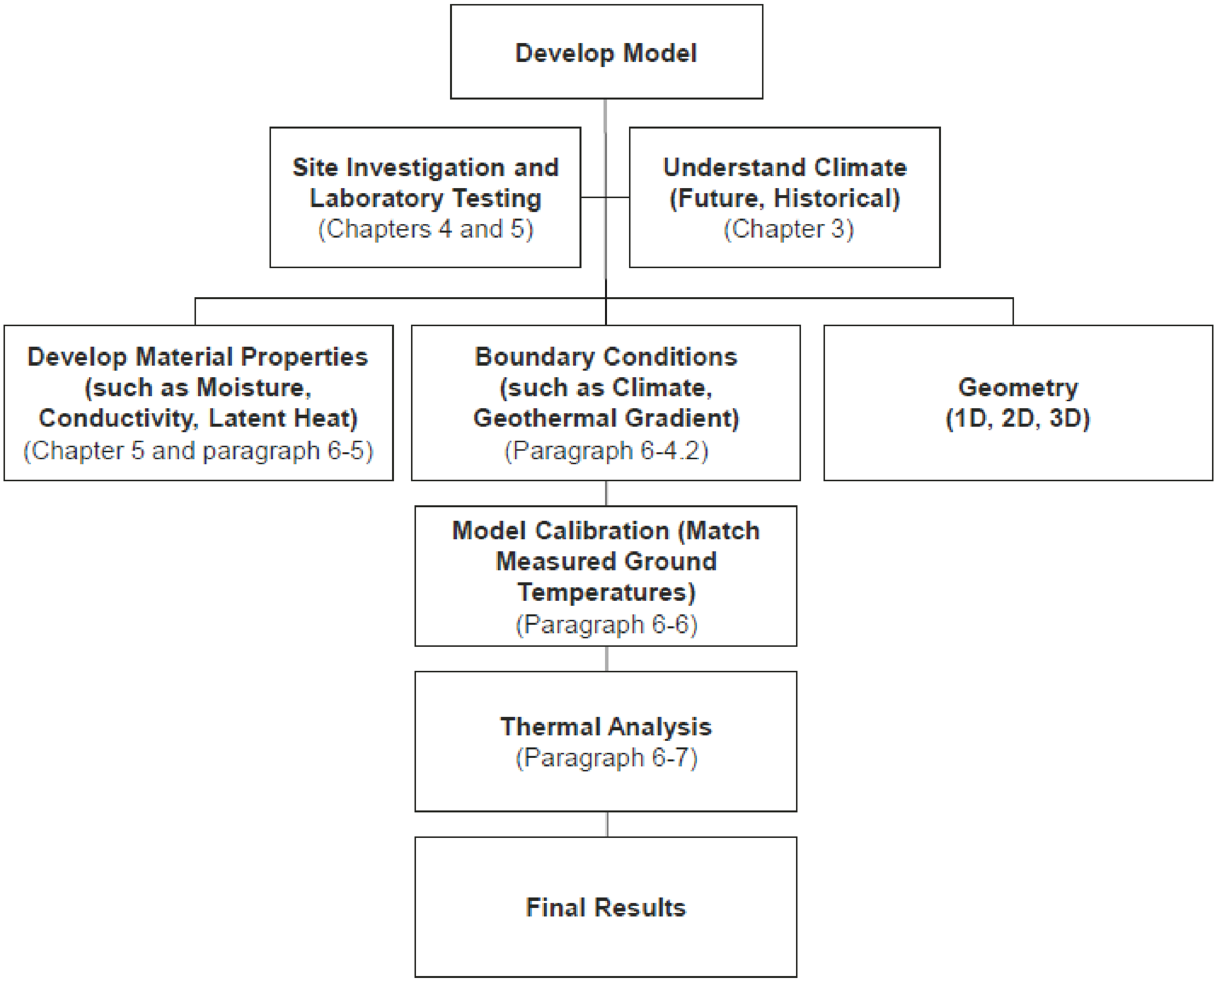
6-3.2 Permafrost Degradation and Subsidence.

Use thermal analyses to assess the effect of site development on ground temperature and the potential for permafrost degradation and subsidence. Methods for estimating potential thaw consolidation are outlined in “Estimating Thaw-Strain Settlement of Frozen Fill,” by Crowther, and “Cold Regions Earthwork,” by Tart. Projects with complex geometry may require the use of finite element analyses.

6-4 THERMAL MODELING PROCESS.

The process for developing an accurate thermal model relies on a comprehensive site investigation with ground temperature measurements, soil samples, subsequent laboratory analysis of the samples (soil type, dry unit weight, and moisture content are the minimum required), and good understanding of the climate. Thermal modeling is typically an iterative process to ensure the model matches site conditions. Figure 6-1 describes the steps of the thermal modeling process.

Figure 6-1 Typical Thermal Modeling Process



6-4.1 Geometry.

One of the first steps in numerical modeling is to define the geometry. Simple problems can be solved with a 1D model, but typical problems require a 2D model laid out with plan, profile, or axisymmetric views. In some instances, 3D analyses may be needed to accurately define foundation geometry. The mesh size must be considered when laying out the geometry. Areas with high temperature gradients require smaller mesh.

Circular structures, such as tanks and isolated piles, can be modeled symmetrically around the axis using 2D analysis to obtain 3D results from the model. This is done by modeling a vertical slice through the center of the tank or pile, including the area outside the structure, and revolving it around this central axis. For other structures, such as rectangular foundations, a vertical slice taken through the center of the foundation footprint, including the area outside the footprint, is the typical approach. The center axis is often a line of symmetry, which allows the modeled geometry to be reduced by one half. The boundary beyond the outside of the tank, pile, or foundation element must be far enough removed so that heat flow is 1D or vertical (zero heat flow normal to the boundary).

6-4.2 Boundary Conditions.

A number of boundary conditions, such as constant or varying temperature, heat flux, convective surfaces, and thermosyphons or other cooling systems, may be included in a typical thermal model. The ground surface boundary condition typically incorporates climatic variables to develop a relationship between air and ground temperatures. The bottom boundary uses a heat flux equivalent to the geothermal gradient at the site. The vertical boundary in a cross-sectional model must be a sufficient distance from the structure so that zero heat flux occurs across the boundary. The centerline of the structure may also be a zero heat flux boundary if the centerline is a line of symmetry. Boundary conditions at the ground surface depend on climate and other inputs that must be processed for use in thermal modeling. Two common approaches used in engineering analyses are highlighted in paragraphs 6-4.2.1 and 6-4.2.2. Thermal model results should be correlated with historical weather data and ground temperatures to calibrate the model before applying future climate projections for the thermal analysis.

6-4.2.1 The n-Factor Approach for Surface Boundary.

The n-factor approach uses a simplified empirical relationship (n-factor) between air and surface temperatures that implicitly includes factors such as net radiation, snow cover, soil thermal conductivity, latent heat, and surface vegetation. It is especially useful when only limited site data are available, but use of n-factors requires considerable judgement when selecting values and must be calibrated with historical ground temperatures.

The freezing and thawing n-factors are the ratio of the surface freezing or thawing index to the air freezing or thawing index, respectively. Tables of typical n-factors for many surfaces can be found in both *Frozen Ground Engineering,* by Andersland and Ladanyi, and *Heat Transfer in Cold Climates,* by Lunardini. Published n-factors can vary by location and orientation, and it is important to consider a range of values during model calibration.

6-4.2.2 Surface Energy Balance Approach.

The surface energy balance approach for establishing surface temperatures considers surface energy inputs and outputs at the ground surface over a given interval of time. The approach can more accurately reflect actual site conditions, but it also requires a higher level of site data than does using n-factors. An example of this approach applied to an elevated building is presented in “Thermal Design Considerations for Raised Structures on Permafrost,” by Oswell and Nixon. Required inputs can include air temperature, wind speed, snow depth and its thermal conductivity, longwave and shortwave radiation, surface albedo, vegetation height, and evaporation data, if appropriate.

6-5 MATERIAL PROPERTIES.

Values for the material properties should be derived from a detailed site investigation and testing. Some material properties commonly required for thermal analyses are listed in Table 6-1 and discussed in Chapter 5. Values used in early analyses may be refined based on the results of the model calibration step or analysis.

Table 6-1 Common Material Properties Used in Thermal Analyses

Material Property	Typical Source
Unit weight	Derived from site investigation following ASTM D7263
Moisture content	Derived from site investigation following ASTM D2216, *Standard Test Methods for Laboratory Determination of Water (Moisture) Content of Soil and Rock by Mass*
Heat capacity (frozen/unfrozen)	Typically estimated from empirical relationships discussed in *Frozen Ground Engineering,* by Andersland and Ladanyi
Thermal conductivity (frozen/unfrozen)	Derived from site investigation following ASTM D5334, *Standard Test Method for Determination of Thermal Conductivity of Soil and Rock by Thermal Needle Probe Procedure*, or estimated using empirical relationships (see paragraph 5-2.2)
Unfrozen water content	Estimated from the empirical relationship proposed, by Tice, Anderson, and Banin, found in *Frozen Ground Engineering,* by Andersland and Ladanyi

6-6 MODEL CALIBRATION—GROUND TEMPERATURE.

During the exploration phase, it is typical to install temperature-measuring strings (such as thermistors or digital temperature sensors) in the boreholes created to log the soil profiles and retrieve soil samples for laboratory analysis. If this drilling and installation is done a year or two before construction, then the temperature profiles retrieved from these strings (whiplash curves) can be used to calibrate the thermal model. Probing for permafrost in early fall provides the depth of the active layer for a permafrost site and can be used to check the accuracy of the model for the area of undisturbed ground.

Thermal models must be developed using historical data and the results compared to the measured ground temperatures. This calibration is a critical step in the thermal modeling process. The input boundary conditions must be reevaluated if the model does not match measured temperature data.

6-7 THERMAL ANALYSIS.

After completing the model calibration, the thermal model can be used to make future predictions. Thermal modeling is an effective tool for understanding the relative difference of conditions. Consider the uncertainty in climate projections when developing thermal models and evaluating the resulting predictions. It can be impractical to run all the climate scenarios, so it is important to look at the range of the results. For example, a normal distribution of climate scenarios can be developed by comparing mean annual air temperature or freezing–thawing indices from each projection. This can be used to provide a range of the anticipated results. It is important to scrutinize results for realism, especially when modeling in warm permafrost zones (where there may be discontinuous permafrost).

CHAPTER 7 FOUNDATION DESIGN APPROACH

7-1 INTRODUCTION.

This chapter presents an overview of the foundation selection and design process for vertical and horizontal structures. Further discussion related to the design of shallow foundations is presented in Chapter 8 and discussion related to pile (deep) foundations is presented in Chapter 9. Examples of various types of foundations that have been used in Arctic and Subarctic areas are in Appendix A.

Selecting the general foundation concept is one of the first steps in the design process, following consideration of the general planning and design requirements and initial site investigation (discussed in Chapter 2 and outlined in Figure 2-1). Subsequent analysis and additional characterization may be required before a final design is selected. Although specific design issues may vary over the life of the facility, the concepts discussed are generally applicable to both new and rehabilitated foundation systems. Prior to finalizing the design, the designer must reconsider the estimated cost and how the design meets the functional requirements of the facility. Additional optimization may be required. For example, a pile design may have been developed for an unusual pile size that is either expensive or difficult to procure within the schedule limitations. Review and optimization could provide an alternate design using a different size or more readily available materials.

7-2 UNIQUE LOAD CONDITIONS AND LOCAL REQUIREMENTS.

Structures in areas characterized by frozen and thawing ground conditions are subject to geotechnical load conditions that are not common in temperate areas. Conditions unique to frozen ground are:

- Frost action
- Downdrag and settlement due to permafrost degradation and thaw subsidence
- Seasonal changes in near-surface materials
- Ice wedges and other massive ice formations

Different approaches to addressing foundation load conditions may be applied, and, in some instances, local practice or code requirements will dictate when a particular approach is required. Therefore, it may be necessary to check the design using different methods to ensure it is adequate. Each of the load conditions highlighted in the preceding list is briefly discussed in the following paragraphs.

7-2.1 Frost Action.

Frost action refers to both the process of (a) water freezing in soil, leading to a total volume increase or the build-up of expansive forces, and (b) subsequent thawing and related compression and reduction in soil strength. Very high loads are applied when ice forms at the freezing front, with varying effects on structures (see paragraphs 7-5 and 7-6).

7-2.2 Permafrost Degradation, Thaw Subsidence, and Downdrag.

7-2.2.1 Ground Thaw.

The thawing of frozen ground is another type of impact on foundation stability. The thawing of soil that has excess amounts of ground ice is of particular concern because it will cause settlement of shallow foundations and downdrag on deep foundations; therefore, it must be considered in the design. Permafrost degradation may be caused by multiple factors (see paragraphs 2-3.2 and 6-3.2), including construction activities that result in modification of the site thermal regime, normal facility operations, and naturally occurring climate change. Heat loss through the floor of a structure is an example of a cause of permafrost degradation that can affect the foundation to the extent that the structure is no longer sound and requires partial or full reconstruction. In other cases, where ground temperature in the permafrost is near freezing (for example, warmer than about 30°F [approximately −1°C]) or where saline conditions are found, site grading and development alone may raise ground temperatures enough to cause permafrost degradation.

7-2.2.2 Estimating Thaw Subsidence.

Estimate potential thaw subsidence using data from literature such as "Estimating Thaw-Strain Settlement of Frozen Fill," by Crowther, "Permafrost Thaw and Ground Settlement Considering Long-Term Climate Impact in Northern Alaska," by Yang et al., and "Frost Heave and Thaw Settlement Estimation of a Frozen Ground," by Sinnathamby et al., preferably with correlation to site-specific index properties and laboratory testing, such as the thaw strain and thaw consolidation testing discussed in Chapter 5. If practical, field testing is an excellent method for estimating thaw consolidation and developing site-specific correlations for earthen structures. The test sections and monitoring incorporated into the design of the Inuvik Tuktoyaktuk Highway in the Northwest Territories, Canada, are examples of field testing and are discussed in "Monitored Thermal Performance of Varying Embankment Thickness on Permafrost Foundations," by De Guzman et al.

7-2.3 Seasonal Changes in Near-Surface Materials.

Foundation designs must be evaluated for both winter and summer load and soil strength conditions. Freezing air temperatures cause a seasonally frozen and thawed zone (an active layer) to form near the ground surface. These changes may result in frost heave or loss of soil strength. In addition, as soil freezes and thaws, material properties, such as elastic modulus and its ability to resist loads, also change. For example, piles resisting lateral loads from seismic events or wind forces will have different soil structure responses in summer and winter.[1] Moreover, thermal expansion

[1] "Analysis of Laterally Loaded Piles in Frozen Soils," Yang et al.

and contraction of bracing induces opposing strain loads in summer and winter that need to be considered in structural design.

7-2.4 Ice Wedges and Other Ground Ice Formations.

Massive ice formations, such as ice wedges, are common and generally ubiquitous on permanently frozen terrain. For examples of the types of ground ice found in northern Alaska and along the Beaufort Sea coast, see "Permafrost of Northern Alaska" and "Ground Ice in the Upper Permafrost of the Beaufort Sea Coast of Alaska," both by Kanevskiy et al. The presence of these massive ground ice features must be addressed in design documents. For example, pile design criteria commonly allow for some amount of massive ice, with provisions for increasing the depth of piles if more ice is encountered than was already accounted for. Footings or slab foundations underlain by massive ice formations must be designed to prevent thawing the underlying soil and may require the use of insulation[2] and ground cooling (see paragraphs 8-5.5.2 through 8-5.5.4). In cases where the ice formation is extensive, such as due to buried glacial ice or ice wedges, relocating facilities may be required[3] or the ice may need to be removed as part of a ground improvement program.

7-3 FOUNDATION DESIGN APPROACH.

Design, construction, and maintenance of foundations on permafrost and freezing or thawing ground conditions must satisfy certain material, environmental, and logistical challenges, as discussed in Chapter 2 and outlined here:

- Special properties and behaviors of soils, rocks, and building materials at low temperatures and under cyclic freeze–thaw action
- Permafrost that is subject to thawing and subsidence during and after construction
- Seasonal freezing and thawing of ground associated with frost heave, thaw settlement, and other effects
- Difficulty of excavating and handling frozen ground
- Limited availability of natural construction materials and support facilities
- Adverse conditions of temperature, wind, precipitation, distance, accessibility, working seasons, and cost

For general design approaches for permafrost areas, see *Design and Construction of Foundations in Areas of Deep Seasonal Frost and Permafrost,* by Linell and Lobacz, and *Frozen Ground Engineering,* by Andersland and Ladanyi. Both are based on the thaw stability of the site and include examples of different foundation types for facilities of varying design life. These general approaches for permafrost areas are outlined in

---

[2] "Design, Construction and Operation of an Insulated Ice Drilling Pad, North Slope, Alaska," Hazen et al.
[3] "Structure and Properties of Ice-rich Permafrost Near Anchorage, Alaska," Kanevskiy et al.; "ARRC Rail Alignment Improvements Birchwood, Alaska Railroad Design—Construction in Marginally Frozen Relic Ice and Soil," Krzewinski et al.

Figure 7-1 and discussed in paragraphs 7-4.1 through 7-4.4. In areas with deep seasonal frost that affects foundations, designing a stable foundation still requires considering how the foundation soil changes and affects foundations as ground temperatures and properties of the soil change seasonally.

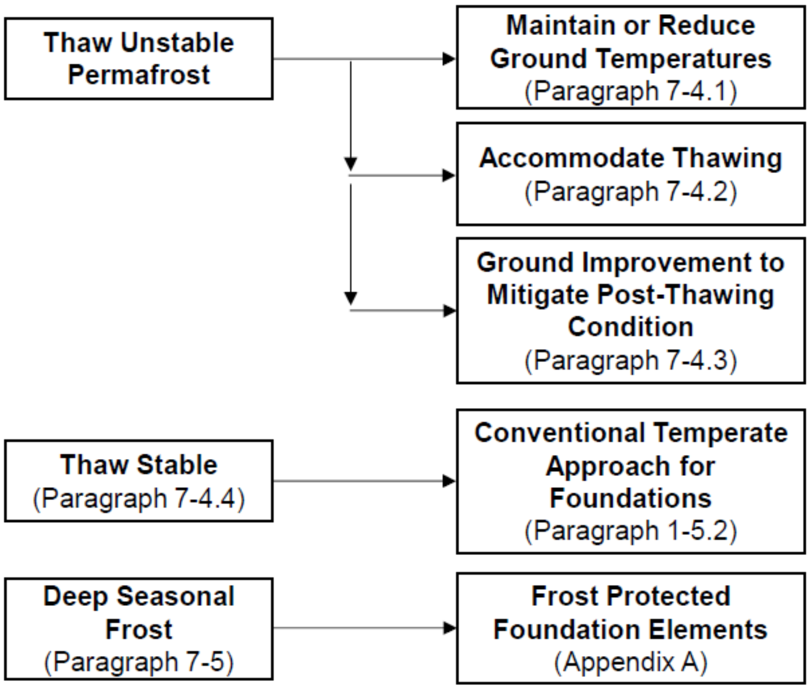
7-3.1 Maintain or Reduce Permafrost Ground Temperature.

The existing thermal regime must be maintained when foundations are resting on or within thaw-unstable permafrost because of the excess settlement and loss of bearing that occurs when ice-rich soil thaws. This approach is used in regions of both continuous and discontinuous permafrost and is typically accomplished for permanent structures by elevating the structure to decouple it from the underlying soil or by using a combination of insulation and cooling to control heat flow from the structure into the ground. Strategies to maintain ground temperatures in areas of deep seasonal frost may include insulation of the foundation perimeter (as for shallow frost-protected foundations), modification of site conditions, or, in the case of structures with internal temperatures that are below freezing (such as liquified natural gas tanks or refrigerated warehouses), a combination of insulation and heat loops can be designed to keep foundation soils thawed. Different approaches to meeting these objectives are described in paragraph 7-5.

7-3.2 Accommodate Thawing (Accept Thermal Regime Changes).

Foundations can be designed to accommodate changes in ground conditions when permafrost thaws. These conditions occur when facility development results in degradation of permafrost or when permafrost degradation is expected to occur naturally due to environmental changes. Common examples of site activities that can induce changes in the underlying permafrost include placement of granular soil over undisturbed permafrost to create an at-grade work pad for construction staging (which allows heat flow into the underlying soil) and activities that modify drainage or disturb surficial organic soil and vegetation. Even if a granular pad is thick enough to insulate the underlying permafrost from thawing, settlement may be induced along the perimeter of the fill area due to changes in surface drainage and a decrease in pad thickness in those areas. An example of this design approach is described in “Marginal Permafrost, a Foundation Material in Transition,” by Musial and Wyman, for pile foundations installed for a transmission line in Alaska. In the case of horizontal structures, allowing for thawing must include annual costs for releveling the embankment surface and patching the surface pavement. Most often, this annual maintenance is more cost-effective than constructing an embankment that is resistant to thawing.

Figure 7-1 General Design Approaches



Source: Adapted from *Design and Construction of Foundations in Areas of Deep Seasonal Frost and Permafrost,* by Linell and Lobacz, and *Frozen Ground Engineering,* by Andersland and Ladanyi.

Foundations that allow some thawing of thaw-unstable permafrost are generally applicable for temporary facilities, facilities in support of military operations with a design life of five years or less, lighter structures, and horizontal structures (such as roadways and airfields), or when the thaw-unstable permafrost is underlain by relatively dense, thaw-stable materials. For lighter structures, this approach can involve limiting the heat input into the soil by thermally decoupling the structure from the permafrost using a raised foundation. This reduces settlement of the structure during its design life while also allowing access for releveling if required. This method is used for single-family housing and can be an effective foundation when costs are a limiting factor. Provisions for releveling are typically incorporated into the design.[4]

7-3.3 Ground Improvement to Mitigate Post-thawing Conditions.

Foundation soils may need to be modified or improved in all types of permafrost terrain, depending on expected conditions after a project is built. This approach entails either thawing and consolidating the frozen soil or over-excavating the soil and replacing it with soil that is not susceptible to frost. Thawing is accomplished using electrodes, heating mats, or steam, and the amount of energy applied depends on the ice content and the heat of fusion of the soil. The drainage characteristics of the thawed soils must be considered to allow the excess water to drain or be pumped and to improve stability by compacting the thawed soils to an appropriate density. The thaw-unstable soils must

[4] "Adjustable Foundation Design Development in Arctic Engineering," Borjesson and Clarke.

be relatively thin and NFS material readily available to make excavation and replacement a viable option. Once the ground conditions have been improved, conventional temperate foundation options are available for design and construction.

Soils that have been thawed may be in a weak or loose condition unless further modification or replacement is performed. If the thawed soils within an excavation are not drained and adequately compacted before winter weather sets in, they can refreeze and heave upon refreezing. If the refrozen soil subsequently thaws after placement of fill or completion of foundations, thaw-induced settlement may occur.

7-3.4 Thaw-Stable Permafrost.

When thaw-stable conditions are present at a site, such as sites underlain by ice-poor granular soil, foundations can be designed using the conventional foundation engineering practice outlined in the documents referenced in paragraph 1-5.2.

7-4 PROTECTION FROM FROST ACTION.

Protecting the foundation from seasonal frost action must be a consideration for each foundation design alternative. Frost action involves the harmful process of frost heave resulting from the formation of segregated ice lenses at the freezing front in soil during the freezing period, followed by thaw weakening or the loss of bearing strength when the seasonally frozen soil thaws. Heave forces may occur due to the formation of these ice lenses below the foundation or when frozen soil bonds to the foundation through adfreeze and lifts it as the surrounding soil freezes. Methods to protect a foundation from frost action involve using NFS foundation materials within the depth of frost, providing adequate drainage away from the foundation, maintaining a thawed condition around the foundation, resisting the potential frost heave forces, or isolating the foundation so it is not affected by the frost heave forces.

Design frost depths are developed using the thermal analysis methods described in Chapter 6. Results are heavily influenced by assumed climatic conditions (air freezing index), ground surface conditions (n-factors), and soil thermal properties. References for freeze and thaw depth determination are noted in Chapter 6 and more general discussion is included in several references, such as *Frozen Ground Engineering,* by Andersland and Ladanyi.

For frost heave to occur, the soil must be frost susceptible, a source of water must be available, and freezing temperatures must take place. If one or more of these conditions is prevented or eliminated, frost heave will not occur. See paragraph 5-2.1.1.2 for additional information.

7-4.1 Frost Susceptibility.

Frost susceptibility must be considered when designing foundations in Arctic and Subarctic areas. The frost susceptibility of a soil is generally defined by the content of material finer than the 0.02 mm size, as summarized in Table 5-2 and outlined in UFC 3-220-10. However, frost susceptibility is also related to the plasticity of fine-grained soil and the permeability of the foundation materials. Coarse-grained soil (such as sand and gravel) with trace to no fines is generally considered to have low frost susceptibility, whereas a silty or clayey soil is typically highly susceptible to frost. Generally, NFS material is specified, but in some instances where material sources are limited or facilities have a design life of less than five years, material with a low frost susceptibility may be appropriate and may satisfy design criteria. Additional testing may be required to justify the use of low-frost-susceptible material.

The percent passing the No. 200 sieve size is sometimes used to assess frost susceptibility, but this approach is typically used in areas where local experience and knowledge of material quality and performance is understood. Basing acceptance of materials during construction on the No. 200 result also will be beneficial during construction because the test can be more quickly performed than the hydrometer test needed to determine the 0.02 mm particle size.

7-4.2 Drainage.

Drainage is a very important consideration when trying to protect foundations against frost heave. Providing positive drainage away from the structure and the foundation subgrade through surface grading and buried drainage pipes limits the potential for ice lenses to form in the foundation materials. See Chapter 11 for requirements and paragraph 5-2.1.1.2 for information regarding the importance of groundwater on frost action.

The percent passing the No. 200 sieve size is sometimes used to assess frost susceptibility, but this approach is typically used in areas where local experience and knowledge of material quality and performance is understood. Basing acceptance of materials during construction on the No. 200 result also will be beneficial during construction because the test can be more quickly performed than the hydrometer test needed to determine the 0.02 mm particle size.

7-4.3 Maintain Thawed Conditions.

Maintaining the thawed condition around a foundation is usually accomplished for slab-on-grade buildings by insulating the perimeter as is done for frost-protected shallow foundations (see SEI/ASCE 32). The methods described by SEI/ASCE 32 are not directly applicable when the freezing-degree days exceed 4,500°F-days. However, the approach can be modified for colder temperatures like those found around Fairbanks, Alaska, as outlined in *Frost Protected Shallow Foundations (FPSF) for Interior Alaska Freezing Indices Between 4,000 and 8,000 Degree-Fahrenheit-Days: A Research Report,* by Perreault. At minimum, foundation insulation must consist of vertical insulation on the outside of footings. It is preferable to include insulation boards placed horizontally outside of the building perimeter, but this may be modified by local practice. The width and thickness of the insulation used depends on climatic conditions at the site. In addition to preventing freezing of soil beneath the foundations, the insulation helps with building energy efficiency.

Using floor insulation to improve the energy efficiency of a building is becoming more common. This is an important consideration when designing perimeter insulation because the reduction in heat loss through the floor increases the requirements for foundation insulation.

7-4.4 Resist Frost Heave Forces.

Frost heave can affect both deep and shallow foundations. Deep foundations are designed to provide sufficient embedment to resist the uplift loads applied to the perimeter of the foundation. Shallow foundations can be anchored or can incorporate structural elements such as lateral extensions to increase uplift resistance. Where practical, shallow foundations should extend to below the depth of frost to eliminate potential basal heave. Frost heave forces also may be resisted by increasing the weight of the structure, which is usually not cost effective.

Frost heave forces can be significant but varies with material type, as discussed in paragraph 9-7 and in other sources ("Russia and North American Approaches of Pile Design in Relation to Frost Action," by Nidowicz and Shur; *Design and Construction of Foundations in Areas of Deep Seasonal Frost and Permafrost,* by Linell and Lobacz).

7-4.5 Isolate from Frost Heave Forces.

Isolating foundations from frost heave forces is accomplished in various ways, depending on if the foundation is deep or shallow. Insulation, which can include polystyrene, wood chips, or added soil fill, can be used to control freezing around the foundation. For piles, the portion of the pile in the active layer subject to uplift can be covered with a low-friction material to limit or prevent soil and ice from bonding to the pile. Materials used for this include soil-oil-wax mixtures, plastic, coal tar, Teflon, multiple layers of polyethylene sheeting, or similar nonadhering surface materials. For shallow foundations, it is common practice to place the footing below the depth of the active layer or to replace frost-susceptible soil in the subgrade with NFS material that extends below the anticipated depth of frost.

Compressible inclusions are another type of structural element that can be included in the foundation design to control frost heave on the base of footings or structural slabs.[5] This type of frost heave control involves limiting water movement in the soil and reducing the effect of ice expansion, versus the use of NFS materials. It can include low-strength expanded polystyrene (EPS) or extruded polystyrene (XPS) boards and blocks, rubber or plastic materials, or other collapsible materials analogous to those used to control foundation loads in areas with expansive soil. The success or failure of the approach depends on specific site conditions and good quality assurance and quality control during construction; hence, design should proceed carefully and include an evaluation of the elastic characteristics of each type of material used and its compatibility with applied loads, design life, and site conditions.

[5] "Foundation Design for Frost Heave," Widianto et al.; "The Compressible Inclusion Function of EPS Geofoam," Horvath.

7-5 DYNAMIC RESPONSE TO LOADING.

Dynamic loading is typically a result of seismic ground shaking or rotating machinery. The foundation response to each is different.

7-5.1 Seismic Ground Shaking.

Frozen ground is very stiff compared to unfrozen ground. For planning purposes, continuous permafrost regions that have a thin (on the order of a few feet) active layer can initially be characterized as Site Class B (as defined in the IBC) pending direct measurement of shear wave velocities and further site investigation. In regions of discontinuous permafrost, site classes will vary depending on the depth to permafrost, thickness of the permafrost, and designed long-term condition of the facility. Other aspects of seismicity to consider are seasonal changes in near-surface soils from frozen to unfrozen and how the depth of permafrost over time may increase due to site development and changes in climate. Deep seasonal frost affects site responses[6] and must be considered during design.

7-5.2 Liquefaction and Seismically Induced Settlement.

Frozen ground is not considered to be liquefiable, but liquefaction and seismically induced settlement become design considerations when permafrost is expected to thaw over the life of a facility or if the site was previously frozen in recent times. Recently thawed soils may be in a normally consolidated state or, more likely, an unconsolidated condition. Analyses must be conducted considering both the immediate and long-term thermal state of the foundation soils and the presence of layers of frozen and unfrozen material that may develop over time.

The site response of facilities is influenced by the presence of permafrost. Of particular concern is the change in response as subsurface conditions change from frozen to thawed, either seasonally or due to construction or climate change. For example, relatively deep thawing was predicted due to construction and facility operations at a site with warm permafrost on Eielson Air Force Base near Fairbanks, Alaska. This change in site conditions would have caused an increased risk of liquefaction due to regional seismicity; therefore, a mitigation program (consisting of thawing and ground improvement) was conducted to reduce the potential impacts from both thawing permafrost settlement and potential liquefaction-induced damages that may have occurred because of an earthquake after the ground thawed. Other common options to improve ground conditions and reduce liquefaction potential and seismically induced settlement are deep dynamic compaction and vibrocompaction.

7-5.3 Cyclic Machine Loading.

Rotating machinery, such as turbines, compressors, and generators, may induce cyclic loads that are sustained or continuous over the project life. Cyclic loads due to rotating machinery are different from those imposed by earthquakes and other transient state

[6] "Frozen and Unfrozen Shear Wave Velocity Seismic Site Classification of Fairbanks, Alaska," Cox et al.; "Effects of Seasonally Frozen Soil on the Seismic Behavior of Bridges," Xiong and Yang.

design forces, which typically have varying frequency, amplitude, and duration. Usually, the cyclic loads have well-defined operational amplitude and frequency domains that can be dampened structurally so that loads imposed on foundations are minimized. If the thermal state of foundation soils is expected to change over the life of a structure, additional analysis will be required to check the foundation's response to differing thermal states. Engineering judgment is required to determine the most suitable means and measures for addressing the effect of cyclical loads on pile foundations. Paragraph 9-11 presents further discussion regarding the effect of cyclical loads on adfreeze piles.

7-6 INSULATION AND CONTROL OF HEAT FLOW.

Structures are often elevated above the ground surface to decouple heat flow from the building into the ground in areas underlain by permafrost. Insulation is also commonly incorporated into the design of foundations to control heat flow and is an integral part of both structural foundation systems discussed in Chapter 9 and within fills used for horizontal structures (see Chapter 10).

For vertical and horizontal structures, insulation in foundations is typically either EPS or XPS. Cellular glass and other materials, such as urethane foam, are also used in specific applications. The insulation must have strength and strain characteristics compatible with applied dead and live loads and environmental conditions. Consider cellular glass products when heavy loads like those beneath liquefied natural gas tanks, aircraft ramps and tarmacs, or rotating radars are present; when little or no compression under load is a design requirement; when high fire resistance is needed; or when resistance to petroleum and solvents is a design requirement.

7-6.1 Insulation for Structural Foundations.

In general, XPS and EPS insulation beneath structural foundations should have a minimum compressive strength of 60 psi (414 kPa) measured at 5% strain. In addition, geomembranes must be placed over insulation installed beneath foundations to protect the insulation from degradation due to spills of hydrocarbons or other solvents that will degrade the material.

Polystyrene insulation is degraded by petroleum products and solvents, and it should be protected by a membrane liner when used in a foundation application, such as a flat loop thermosyphon (see paragraph 8-5.5), or in other situations where degradation by exposure to petroleum products and hydrocarbons will adversely affect its intended function.

7-6.2 Insulation for Horizontal Structures.

For horizontal structures, consider XPS or EPS insulation with a minimum compressive strength of 40 psi (276 kPa) measured at 5% strain. The most severe loading conditions in horizontal structures may occur during construction. It is imperative that the insulation material characteristics be matched to applicable design and performance criteria, and it must be recognized that constructability considerations may control the selection of materials in horizontal structures.

7-7 FACTOR OF SAFETY.

7-7.1 Working Stress Design.

Much of the design practice for foundations in frozen and freezing ground conditions was developed based on working stress design principles and use of a single global factor of safety (FS). The appropriate global FS for a given working stress design analysis may vary, depending on factors such as the criticality of a structure, uncertainty of conditions, or uncertainty in potential climate impacts. FS values for DoD projects are provided in UFC 3-220-01 and additional discussion is presented in Chapter 8 and Chapter 9 of this UFC.

7-7.2 Limit State Design.

Geotechnical engineering practice in temperate conditions increasingly is applying limit state design, including consideration of serviceability limit state and ultimate limit state principles or using limit state design based on load resistance factor design, but these are not widely applied in frozen ground situations. These general concepts and an approach to bridging the gap in working stress design and limit state design concepts in unfrozen conditions is presented in the *Canadian Foundation Engineering Manual* by the Canadian Geotechnical Society and in “Eighteenth Canadian Geotechnical Colloquium: Limit States Design for Foundations,” Parts I (“An Overview of the Foundation Design Process and Limit States Design for Foundations”) and II (“Development for the National Building Code of Canada”), both by Becker.

Consideration of limit states is an implicit part of codes. There are many national and local codes and standards that may need to be considered during design that may or may not have specific code requirements for foundation design in Arctic and Subarctic regions, especially when permafrost is present. Some of these national and local codes can be found as follows:

- In the U.S., consult the American Petroleum Institute, IBC, and Uniform Building Code.
- In Canada, consult the National Research Council Canada, National Standard of Canada, and Canadian Standards Association.
- In Europe, consult the Eurocode.

In the absence of specific requirements, it will be necessary to consider site conditions and recommendations found in the professional literature, including this and other UFCs in the series, texts such as *Frozen Ground Engineering,* by Andersland and Ladanyi, and supplemental resources like those listed in Appendix C.

CHAPTER 8 SHALLOW FOUNDATION DESIGN

8-1 INTRODUCTION.

Shallow foundations may be used in areas of freezing and thawing soil, including those underlain by permafrost, provided that both the thermal impacts of structures and the overall behavior of foundation materials discussed in previous chapters are considered. Shallow foundations may be placed on granular pads and may incorporate insulation or, where the granular pad is underlain by permafrost, systems to maintain or cool the foundation soils. The timing of construction is an important consideration in permafrost areas to avoid thawing foundation soils that will support shallow foundations.

Design of the foundation system generally involves conventional bearing capacity and settlement calculations, whereas design of the granular pad subsystem involves thermal analyses like those discussed in Chapter 6. Calculating settlement involves conventional techniques for consolidation potential if permafrost will be allowed to thaw and evaluation of creep of frozen soil. Establishing these design criteria requires good site data, including information about ice content and its extent, ground temperature, and subsurface stratigraphy and material type. Consideration also must be given to the duration and magnitude of applied loads. For example, even relatively low ground pressures applied for the duration of the project life may result in significant creep in ice-rich soil, while relatively high ground pressures may be carried with little deformation if the load is only applied for a short period of time. Refer to Appendix A for representative examples of foundation configurations.

8-2 SHALLOW FOUNDATIONS ON THAW-STABLE PERMAFROST.

Shallow foundations on thaw-stable permafrost, such as coarse granular soil and rock without excess ice, should be designed according to conventional temperate zone methods that consider bearing capacity and settlement. For coarse granular soil, the friction angle may be estimated from information, such as drilling action or blow counts, collected during the geotechnical investigation. Similar to the way these data are affected when sampling coarse gravel and cobbles, blow count data from methods such as split spoon sampling (ASTM D1586, *Standard Test Method for Standard Penetration Test and Split-Barrel Sampling of Soils*) may be exaggerated in frozen ground. Thus, blow count data in frozen ground must be considered a relative measure of consistency between sample locations at the time of the investigation and should not be used with standard correlations between blow count and material property used in temperate conditions.

One case where correlations between field parameters and material properties may be useful is for estimating soil strength in ice-poor material. Soil strength may be conservatively estimated by assuming a saturated unfrozen soil at the same frozen dry density as in situ material and using correlations such as those found in UFC 3-220-10.

8-3 SHALLOW FOOTING WITH GROUND IMPROVEMENT.

Shallow footings and ground improvement are often used by USACE, Alaska District, in areas of discontinuous permafrost. Most commonly, pockets of discontinuous permafrost are thawed. The thawed soil may require densification to reduce settlement potential and potential for liquefaction (see paragraph 12-3.5). Foundations are designed to provide frost action protection that is appropriate for the area.

Permafrost may be prethawed beneath heated buildings using techniques such as electric probe thawing, cold or warm water injection thawing, steam thawing, or heating mats. However, if the near-surface permafrost to be thawed is thaw-unstable and ice-rich, it must have thaw-stable and ice-poor permafrost underneath to provide stability. If there is sufficient time in a project schedule, clearing a site of vegetation can be a cost-effective method for thawing ground, especially in areas of discontinuous permafrost; however, years may be required to accomplish this, depending on the depth of thaw desired and other local conditions. After the permafrost has been thawed, conventional temperate zone ground improvement techniques, such as preconsolidation of deep dynamic compaction, may be needed to further stabilize the site. Design shallow spread footings according to conventional temperate zone methods that consider bearing capacity, settlement, and seasonal frost. Additional ground truthing activities, such as soil borings, cone penetration tests, or compaction testing, are generally required to verify that conditions meet the design expectations after the area has been thawed and consolidated.

8-4 SHALLOW FOOTINGS ON GROUND SURFACE.

Shallow foundations bearing on the ground surface or at shallow depth can be used when they are supported on NFS fill and when no excessive long-term settlement is anticipated due to changes in the thermal regime of the foundation soil. Surface footings can also be used to accommodate anticipated settlement or heave.

Buildings supported on surface footings often incorporate a rigid base or space frame structure to maintain the building’s integrity in the event of differential movement and to span footings that may lose support until the system can be re-leveled. Space frames are rigid structural systems that are laterally connected to the vertical supporting elements. These systems can be releveled while the structural system serves to maintain the integrity of the superstructure by limiting differential movement between the structural elements, such as doors and framing, while also limiting horizontal displacement of the supporting elements during vertical displacement and dynamic (such as seismic) loading. Typically, these systems are built on a granular pad, but they can also be placed on natural ground that has suitable bearing capacity. The benefits for lighter structures are ease and rapid construction with provision for releveling as needed.

8-5 SHALLOW FOOTINGS ON IN SITU PERMAFROST.

This foundation method involves installing footings below the maximum anticipated depth of permafrost thaw over the life of the foundation (See *Permafrost Engineering*

Design and Construction, by Johnston). Typically, the footings are set on a bed of NFS granular fill or within an embankment, as shown in the typical sections in Appendix A. This foundation method is applicable for temporary facilities, facilities in support of military operations with a design life of five years or less, lighter structures, horizontal structures (such as roadways and airfields), and for cold permafrost soils that have minimal potential for thaw strain or long-term degradation of the thermal regime. Thermal analysis or site monitoring is used to estimate the active layer depth in the backfilled pits, which will likely be deeper than baseline conditions due to the backfill material and disturbance of the ground surface. Insulation placed near the ground surface may often further reduce the active layer depth and may be combined with other methods of ground cooling to maintain ground temperatures.

Elevate heated structures to provide ventilation to minimize heat transfer from the structure into the ground. A rigid framework and an adjustable leveling system may also be considered for lightweight structures to mitigate potential differential settlements.

8-5.1 Foundation Design Process.

The foundation design for shallow footings on in situ permafrost requires checking the bearing capacity, displacement under load, and settlement that may occur due to creep. Thermal analysis is required to estimate long-term changes in ground temperature and the potential for thawing due to construction and must recognize potential climate impacts during the design life. Depending on the structure, frost-protected shallow foundations like those described in paragraph 7-5.3 may be appropriate, provided thermal effects and differences in heated and unheated structures are considered. The general procedure for designing shallow foundations in permafrost is outlined here:

1. Select footing depth based on the expected deepest thaw and required lateral support.
2. Estimate the warmest ground temperature, including temperatures beneath the structure, using appropriate material properties.
3. Select footing based on bearing capacity theory and the desired FS.
4. Modify footing size as appropriate.
5. Check settlement during design life.

8-5.2 Bearing Capacity.

The ultimate bearing capacity, q_u, follows the general form taken from conventional bearing capacity theory and includes conventional terms (N values) for cohesion, surcharge, and self-weight and factors (F) for shape, depth, load inclination, base, and ground inclination. Refer to *Frozen Ground Engineering,* by Andersland and Ladanyi, section 7.2, for the equation, definition of terms, and details on application. Analyses to estimate ultimate bearing capacity must be performed in terms of total stress. The effects of ground temperature, time of loading, and ice content of the soil must be considered when estimating values of cohesion and friction angle. In addition, the friction angle used to estimate N values should correspond to an unconsolidated-undrained value for a given frozen soil density. (See pages 171–179 in *Frozen Ground Engineering,* by Andersland and Ladanyi, for details on application.) In general, for short-term loads and cold ground temperatures, the bearing capacity of frozen soil can be relatively high. As time and load increases, creep and changes in ground temperature become a consideration. Refer to paragraph 7-8 for a discussion of FS.

Strength testing under temperature-controlled conditions must be considered if relying on the long-term bearing capacity of ice-rich material. Strength testing also must be used to verify long-term creep behavior (see paragraph 8-5.3.1).

8-5.3 Settlement.

Footing size is generally controlled by considering settlement rather than by the bearing capacity of frozen ground. Both short-term and long-term settlement occurs when loads are applied to frozen soil. Five types of deformation occur when loading frozen ground:

- Instantaneous-elastic (soil may rebound partially)
- Instantaneous-plastic (irreversible, bearing failure)
- Viscoelastic (reversible)
- Consolidation (irreversible)
- Creep or viscoplastic (irreversible)[1]

Of the five types of deformation in frozen soil, instantaneous-plastic, consolidation, and creep are the most significant. Creep and consolidation of frozen soil require special attention. Instantaneous-plastic deformation is determined using conventional soil mechanics and accounting for the temperature dependency of short-term cohesion in frozen soil. Creep and consolidation of frozen soil are time dependent and are discussed in paragraphs 8-5.3.1 and 8-5.3.2.

8-5.3.1 Creep Settlement of Footings.

Creep settlement of footings can be substantial at low stresses if the soil has a high ice content, temperatures warmer than 23°F (−5°C), or both. Low ice content soils with low stress conditions will have lower rates of creep; however, creep must still be considered in design. Additional discussion of creep and guidelines for pile foundations are presented in paragraph 9-5.3.4.

Design and Construction of Foundations in Areas of Deep Seasonal Frost and Permafrost, by Linell and Lobacz, outlines methods for estimating the creep of footings. However, cavity expansion theory has also been shown to give good results for ice-rich homogeneous frozen soil[2] and other soil types. Creep parameters may be estimated from published data, provided the materials and site conditions associated with the published data are appropriate for use in the analysis. Alternatively, creep rates can be

[1] *Frozen Ground Engineering*, Andersland and Ladanyi; *Rheological Properties and Bearing Capacity of Frozen Soils,* Vailov.
[2] “Creep of a Strip Footing on Ice-rich Permafrost,” Sayles.

measured for specific soil types, ground temperatures, and loading rates in the laboratory (see paragraph 5-2.4).

8-5.3.2 Consolidation.

The consolidation behavior of frozen soil is poorly understood. Initial evaluations must consider consolidation to be a design consideration when ground temperatures are warmer than between 31.5°F (−0.3°C) in silty sand and 29°F (−1.7°C) in clay. When ground temperatures are colder than the threshold values, consolidation is expected to be very slow and thus not a design consideration.[3]

Upon thawing, total potential thaw settlement under a footing can be approximated based on the total volume of ground ice within a unit of soil within approximately 6.5 ft (2 m) of the footing. Using this approximation for deeper depths overestimates potential thaw settlement at deeper depths due to bridging of underconsolidated soils. Consolidation will also occur once the soil is thawed and can be estimated using soil mechanics principles for unfrozen soil. Perform laboratory testing to determine total thaw strain. Consolidation after thawing must be considered for some soil types, but it requires specialized testing, as noted in Chapter 5 and discussed in UFC 3-130-02.

8-5.4 Frost Heave Forces.

Shallow foundations may be subjected to frost heave forces along the base of footings. This can result from the refreezing of seasonally thawed soil or the refreezing of sites where the thermal regime was disturbed during construction. Analysis methods for estimating frost heave forces are outlined in *Frozen Ground Engineering,* by Andersland and Ladanyi. Alternatively, frost heave tests can be conducted to measure uplift forces in the laboratory or in the field.

8-5.5 Shallow Foundation Configurations on Permafrost.

Shallow foundations may be configured in various ways in permafrost areas, depending on site conditions and specific design requirements. Common practice is to elevate a heated structure when practical to provide ventilation and minimize heat transfer to limit thawing beneath the building. However, this is not always a practical solution, and other options, like those discussed in the following paragraphs, may need to be considered. See Figures A-6 through A-14 for example foundation configurations. Additional examples can be found in the following:

- *Design and Construction of Foundations in Areas of Deep Seasonal Frost and Permafrost*, by Linell and Lobacz
- *Permafrost Engineering Design and Construction*, by Johnston
- *Cold Region Structural Engineering*, by Eranti and Lee

[3] *Handbook for the Design of Bases and Foundations of Buildings and Other Structures on Permafrost*, Vyalov and Porkhaev.

- *Construction in Cold Regions, A Guide for Planners, Engineers, Contractors, and Managers*, by McFadden and Bennett
- *Frozen Ground Engineering*, by Andersland and Ladanyi
- *Review of Thermosyphon Applications*, by Wagner

8-5.5.1 Shallow Footings on or Below Granular Pads.

8-5.5.1.1 Granular Pads.

Footings may be placed on or within granular pads or embedded beneath the pad. The footing depth depends on the depth of thawing anticipated over the life of the foundation. Granular pads provide insulation that protects the underlying permafrost from thawing and a working surface around the structure. Preferably, the fill will be thick enough that the active layer remains within the pad and above frozen soils that could potentially thaw and cause settlement. Penetrations of building foundations for drains or other utilities can be a source of unanticipated thawing and settlement due to leakage of fluids or other heat sources. Extra attention should be given to the details of penetrations and quality control around them during construction.

Thermal analysis is required to estimate the granular pad thickness needed to prevent thawing to the level of footing foundations. If the active layer extends below the footing elevation into underlying thaw-unstable soils during the design life, excess settlement of footings may result, and frost heave may occur when refreezing the following winter. Settlement due to creep also must be considered. Bearing capacity and settlement are calculated according to the methods described in paragraphs 8-5.2 and 8-5.3.

8-5.5.1.2 Post and Pad Foundations.

Post and pad foundations are another type of foundation that is often used for temporary facilities, facilities in support of military operations with a design life of five years or less, lighter structures, and horizontal structures (such as roadways and airfields). The footing in this case may be supported on a granular pad or below the depth of anticipated thawing. This type of foundation is illustrated in Figures A-7 through A-9. The support, or post, rising from the footing is often adjustable to accommodate potential settlement, especially when the footings are shallow and might be within the depth of potential thawing or subject to long-term creep settlement.

8-5.5.2 Shallow Footings on Insulated Granular Pad.

This foundation method is designed using techniques like those for a shallow foundation on a granular pad, except insulation is used to decrease the required pad thickness or enhance thermal isolation of the footing. Insulation is often placed near the bottom of granular fill, based on consideration of constructability and to minimize potential damage during construction. The location and extent of insulation beyond the edge of a structure needs to be checked to avoid thawing under the edges. It is good practice to include some depth of granular soil beneath the insulation to accommodate the potential for thaw penetration into the underlying soils. The amount of granular soil beneath the insulation and the location within the granular pad will depend on variation in the natural ground surface, design requirements, climate, and local experience.

Insulation alone will not generally be sufficient to prevent the thawing of frozen ground below continuously heated structures unless the insulation layer is very thick, which is typically not economical. Thermal analysis must be conducted to show that the underlying permafrost will not be degraded during the life of continuously heated structures. For temporary construction, insulated rig mats have been used to preserve underlying pads of snow and ice and allow operations over multiple seasons.[4] Ground thermal analyses must be conducted to support the design of these types of temporary facilities, facilities in support of military operations with a design life of five years or less, lighter structures, and horizontal structures (such as roadways and airfields), which may also be applied to gravel pads.

8-5.5.3 Shallow Footings on Ventilated Granular Pad.

Ventilated granular pads are cooled by natural or forced ventilation through ducts that have commonly been metal pipes but could be other materials, provided they can sustain the applied loads and provide the desired ventilation performance. An example of this type of system is shown in Figure A-10.

The ventilation ducts within the pad are opened during the freezing season and closed in the spring when air temperatures approach 32°F (0°C). As discussed in “Active Freezing Techniques,” by Mageau and Nixon, in warm permafrost regions, natural ventilation may be feasible for a small building in the range of 33 ft (10 m) in the lateral dimension (width), and has been shown to be effective in cold permafrost regions to widths of 100 to 150 ft (30 to 45 m). However, Mageau and Nixon indicate that forced-air systems are likely needed to achieve the required airflow for larger structures. In general, use has decreased due to both operational challenges and as flat loop thermosyphon systems have improved. The performance of air-ducted foundations over a 50-year period was reviewed in “Air-Ducted Hangar Foundations at Thule, Greenland,” by Bjella, who noted that drainage effects of the design must also be considered.

8-5.5.3.1 Ventilated Pad Design Method.

An overview of active freezing design methods using air ducts and other methods is presented in “Active Freezing Techniques,” by Mageau and Nixon. They note that for larger structures, an airflow rate of 0.32 ft^3/s (0.009 m^3/s) would be required for each 10 ft^2 (1 m^2) of heated floor area for a 70°F (21°C) structure having up to 10 in. (254 mm) of insulation. They also provide insulation and gravel pad thickness requirements for different ground surface temperatures. Forced air ducts are normally 1 ft to 2.5 ft (0.3 to 0.8 m) in diameter, with center-to-center spacing of three to four diameters, which are then sometimes connected to buried or aboveground manifolds in groups of four to six.

[4] “Design, Construction and Operation of an Insulated Ice Drilling Pad, North Slope, Alaska,” Hazen et al.

8-5.5.3.2 General Design Considerations.

Pad design considerations include winter prevailing wind direction and snow drifting, airflow rate, duct spacing, duct length, thermal properties of the pad and duct system, and pad thickness. Due to the uncertain nature of wind velocities that will occur in the ducts, base designs on natural convection circulation induced using dissimilar height duct plenums. This intake and outlet stack differential is designed to provide minimum design airflow at zero wind conditions. Increased airflow due to changes in wind velocity is assumed to be greater than the natural convection circulation and enhance cooling. Designing natural ventilation systems requires extensive data on year-round average air velocities in ducts, high safety factors, or a high tolerance to insufficient heat removal and resulting settlements. Forced ventilation systems using fans require maintenance but allow for design using predetermined air velocities. Use differential temperature controllers to control fan and damper operation, and establish ground temperature monitoring within the granular pad. Changes in drainage must also be considered and provided for in the design to ensure the ducts do not become flooded or blocked by icing.

8-5.5.3.3 Maintenance Considerations.

Ventilated pads have a history of failure when maintenance and monitoring is not performed. The ducts tend to fill with snow and other wind-blown debris, effectively eliminating the airflow needed to cool the soil. In addition, warm air circulation can increase the thaw rate of the underlying permafrost if duct dampers are left open or are opened by wind during the summer.

Cooling effects can be enhanced by placing insulation on the ground surface beneath and around structures in the summer to limit heat gain and by removing this insulation in winter to enhance cooling. For raised structures with passive refrigeration, care needs to be taken to prevent snow accumulation and storage of materials in the raised space. Planning for long-term seasonal maintenance of these systems is critical to their successful application, as is understanding snow drifting and wind direction. Snow fences may be required to mitigate snow drifting, but there are also long-term issues to consider with degradation of permafrost where snow accumulates due to snow fences.

8-5.5.4 Shallow Foundations on Refrigerated Granular Pad.

8-5.5.4.1 Refrigerated Granular Pads.

Refrigerated granular pads are composed of an insulated granular pad that is cooled by a refrigeration system (for example, piping) placed within the pad, as shown schematically in Figure A-12. These foundation systems are usually used for slab foundations on permafrost with excess ice that is susceptible to unacceptable displacements if thawed. These systems are used in bulk fuel storage tanks, heated warehouses, industrial process facilities, and high-floor-load facilities such as hangars and vehicle maintenance facilities. Refrigeration systems may be passive (meaning they do not require external energy sources) or active (meaning they require external power to operate).

8-5.5.4.1.1 Passive Refrigeration.

Refrigeration of granular pads is commonly accomplished using passive two-phase thermosyphons configured with flat loop evaporators within the fill beneath a building. This and other applications of thermosyphons for refrigeration are described in *Review of Thermosyphon Applications*, by Wagner; “Thermosyphon Applications in Cold Climates,” by Zarling; and “Some Considerations Regarding the Design of Two-Phase Liquid/Vapor Convection Type Passive Refrigeration Systems” and “Recent Developments in Thermosyphon Technology,” both by Yarmak and Long. Passive thermosyphons use natural convection and have no external power requirements. Include accommodation for ground temperature measurement beneath the structure in the design, and allowance must be made for periodic monitoring and maintenance as part of integrity management and life-cycle planning.

8-5.5.4.1.2 Active Refrigeration.

Active refrigeration systems or refrigeration systems that rely on a mechanical method to remove heat include chilled-liquid systems, forced-air convection systems, and direct-expansion systems. Their advantage is year-round cooling. Mechanical cooling can be added to a two-phase thermosyphon to create a hybrid thermosyphon,[5] or mechanical cooling can be used alone to achieve rapid cooling using a cold fluid such as brine. Active systems require active management of operation, ongoing maintenance, and a source of power. Long-term operations and maintenance costs must be considered when planning the use of mechanical systems of refrigeration.

8-5.5.4.2 Design.

Design of a slab-on-grade structure with two-phase passive thermosyphons is described in “Passive Techniques for Ground Temperature Control,” by Long and Zarling, but thermal analyses can readily be accomplished using commercial 2D analysis software such as TEMP/W. Thermosyphon technology continues to improve the performance of horizontal thermosyphons (flat-loop systems), which allows for thinner pad construction, more space between aboveground finned condenser sections, and reduced costs. Design methodology requires that the NFS pad placed below the building floor and insulation containing the thermosyphon evaporators does not thaw to its base prior to the onset of the next winter’s freezing season because thermosyphon systems only work when air temperatures are colder than ground temperatures. Important design variables include air temperature, wind speed and direction, building temperature (boundary condition), and details regarding embankments used to support the facility, such as insulation type and thickness, thickness of NFS fill, soil thermal properties, and thermosyphon conductance and spacing.

8-5.5.5 Complex Foundation Configurations.

Complex foundation configurations may be required for some facilities involving different types of foundations for the same structure. This type of combined and complex

[5] *Demonstration of an Artificial Frozen Barrier*, by Wagner and Yarmak.

foundation requires thorough site investigation and analysis such that bearing capacity and settlement remains uniform and acceptable across the entire structure.

8-5.5.6 Structure Location on Granular Pad Overlying Permafrost.

When siting buildings on granular pads, it is important to locate footings back from the edge of the pad so they will not be affected by thawing during the life of the structure. The depth of thaw tends to be deeper at the edge of pads, which can result in more cracking and settlement in these areas. The deeper thaw is a function of snow drifting, solar radiation, and water ponding near the toe of the slope that frequently develop when gravel pads are placed on permafrost.

General practice has been to increase the setback from the edge of granular pads built on permafrost as climate has changed. In the absence of other data or site-specific ground thermal modeling, structures should be set back from the crest of embankment slopes a minimum of 12 to 16 ft (4 to 5 m) or 1.5 times the pad thickness, whichever is greater. Using insulation or construction techniques such as air convection embankments (ACE) and changes in the design life may warrant reducing the setback requirement. For example, embankments for facilities that will be operational for short periods, such as a year or two, will be less sensitive to the effects of thawing at the edges of pads than those in place for longer periods of time.

CHAPTER 9 PILE FOUNDATION DESIGN

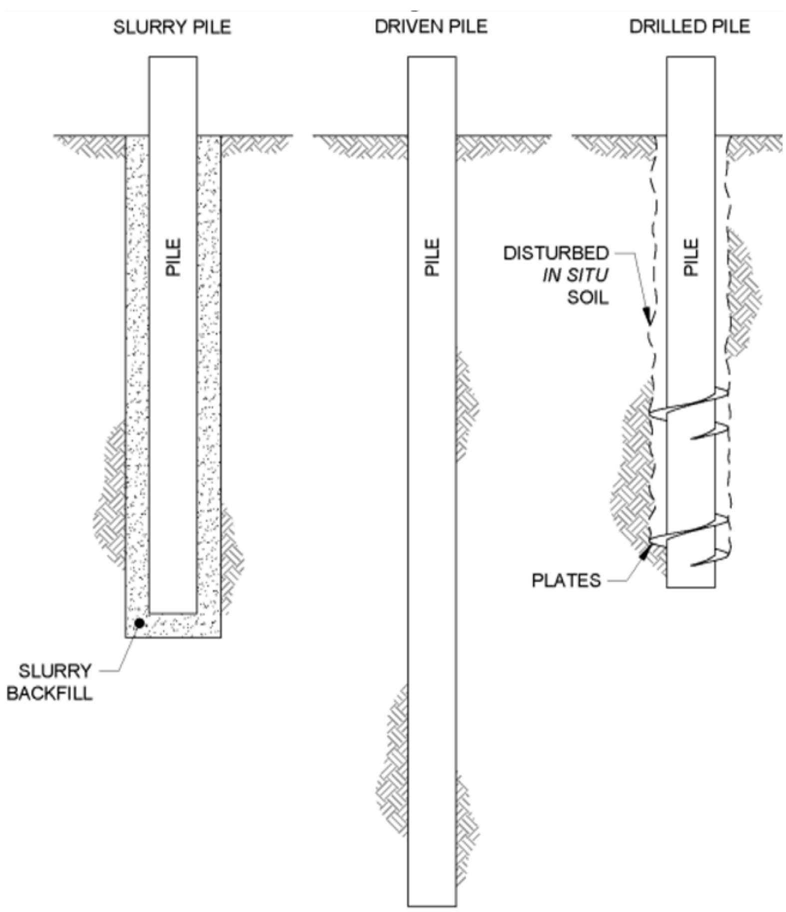
9-1 INTRODUCTION.

Piles are a common type of deep foundation used in Arctic areas of North America. The installation of pile foundations causes changes to the ground and requires varying design methods for different types of deep foundations. Piles are readily available, adaptable to a variety of conditions, and have a long history of successful installation. For general design principles for piles in permafrost and a discussion of frozen soil properties, see Chapter 8 of *Pile Foundations in Engineering Practice,* by Prakash and Sharma. Photographs of pile installations are included in Figures A-15 through A-19.

9-2 GENERAL PILE TYPES.

Pile types may be broadly classified by installation method. Several different types of piles commonly used in North America are shown conceptually in Figure 9-1. Pile material and structural sections will vary, and their selection must consider local practice and availability.

Figure 9-1 Typical Pile Types for Permafrost Areas



9-2.1 Slurry Piles.

Slurry piles are installed by drilling an oversized hole and setting either an open or closed end pile into place. The annular space between the pile and borehole wall is backfilled with slurry, as described in paragraph 9-2.1.5, that freezes after a few days to weeks. The hole diameter should be a minimum of 2 in. (50 mm) larger than the outside diameter of the pile, but providing a 3 to 4 in. (76 to 100 mm) annular space with a larger diameter hole is not uncommon and may facilitate densification. The oversized hole allows for very accurate positioning of the pile but may also require specialized drilling equipment like that shown in Figure A-16. Slurry is densified by vibrating the pile or using concrete vibrators. For piles longer than 30 to 40 ft (9 to 12 m), the entire pile should be vibrated, and more care must be given to specification and control of the gradation of the slurry.

9-2.1.1 Slurry Adfreeze.

Slurry piles gain support from the bond between the pile and frozen slurry, which is termed adfreeze strength and is discussed further in paragraph 9-5. The adfreeze strength can be greatly reduced by the presence of pockets of saline groundwater or the inflow of surface water from the active layer in summer. Saline groundwater may be encountered during drilling and will reduce the adfreeze capacity and potentially lead to increased creep if allowed to mix with the slurry. Tip resistance is commonly not included in North American practice because the vertical displacement that occurs due to adfreeze bond creep is usually less than the vertical displacement required to engage the tip resistance.

Pile capacity is controlled by the adfreeze bond between the slurry and pile. The pile–slurry bond can be increased by roughening the pile surface or incorporating measures such as shear studs or other deformations on the pile. The strength gained through roughening the pile surface may increase pile capacity on the order of three to seven times, based on testing of deformed bars and relatively small-diameter piles.[1] Adding helical shear plates greatly increases capacity and reduces creep deformation by shifting the location of the shear plane into the slurry. An example of a helically wrapped pile is shown in Figure A-17.

9-2.1.2 Ground Temperature Sensitivity.

Ground temperature is one of the most important criteria for the design of piles, influencing both strength and creep behavior. The sensitivity of pile capacity to ground temperature is especially important in warm permafrost, which is permafrost with ground temperatures warmer than about 30°F (−1°C). For example, a pile in permafrost at 30°F (−1°C) will have twice the sustained adfreeze capacity as a pile at 31°F (−0.56°C) and four times the capacity of a pile at 31.5°F (−0.28°C). Hence, refrigeration systems are commonly employed in combination with ground insulation to maintain or reduce the ground temperature and are frequently part of foundations for critical structures.

[1] “Thread Bar Pile for Permafrost,” Holubec.

9-2.1.3 Helical Shear Piles.

A helical shear pile is a specialized type of pipe pile that has a narrow (typically 2- to 4-in. wide [50 to 100 mm]) helical wrap (flight) around the circumference of the pile. The helix can be installed on pipe piles to increase capacity and reduce creep. Helix shear piles are especially effective at improving load resistance in areas with warm or saline permafrost because the helix moves the critical shear plane away from the surface of the pile into the slurry or slurry–permafrost boundary. A typical use is to provide added resistance to frost heave or uplift so that pile length can be minimized.

9-2.1.4 Slurry Shear Piles.

Shear piles are like helical shear piles, but instead of a continuous helical wrap, individual rings are welded onto the pile. Their use is not common in the U.S. (in 2024) but may have application, depending on local resources.

9-2.1.5 Slurry Mixtures.

Slurry mixtures typically consist of water and either sand, silt, or a mixture of the two, but they may include cement additives for some conditions (see paragraph 9-2.1.6). Sand–water mixtures result in an adfreeze capacity that is about 50% greater than silt slurry. Also, the sand–water mixture will have a lower moisture content than when mixed with silt, so the latent heat of fusion is less and, consequently, the freezeback time is faster. To develop dense backfill, the slurry must be fully thawed when placed, but the slurry temperature must also be kept near freezing to reduce freezeback times. Mixing water with frozen sand generally results in a slurry with high ice content, which should be avoided. If the piles do not include a refrigeration system, the time for freezeback of the slurry can be slow if the ground temperatures are warm or saline conditions are present. In this case, the slurry around open pipe piles can be frozen quickly by blowing cold winter air through a duct to the bottom of the pile, allowing it to return up the annulus. Mechanical refrigeration has also been incorporated within piles to enhance freezeback.

A typical sand–water slurry specification has 93% to 100% passing the U.S. No. 4 sieve size and 0% to 17% passing the U.S. No. 200 sieve size, mixed to a 6-in. (150 mm) slump that is mixed with clean water so the temperature is no warmer than 40°F (4.4°C).[2]Slurry specifications will vary, depending on local practice and the availability of material. Frozen material should not be included in slurry mixtures. Proper mixing of slurry materials is critical, especially if cuttings are used, and the ability to do so may dictate the slurry materials used.

9-2.1.6 Cement Slurry Piles.

9-2.1.6.1 Standard Cement Slurry Piles.

Cement slurry consists of a mixture of cement, sand, and water in the annular space between the pile and permafrost. Depending on the grout mix design and water-to-

[2] *Permafrost Engineering Design and Construction*, Johnston; *Frozen Ground Engineering*, Phukan.

cement ratio, cement slurry can provide very high bond strength between the pile and slurry, especially in saline soil conditions. If very high bond strength is developed, the capacity of the pile will be controlled by shearing at the permafrost–slurry interface instead of at the pile–slurry interface.

Attention must be given to the grout mix design to ensure the grout sets before freezing and does not shrink or crack. Cement must be formulated for use in cold temperatures, but with proper mix design, cement slurry can be used effectively at ground temperatures as cold as 14°F (−10°C). Load testing to confirm the permafrost–adfreeze slurry bond strength is required when relying on the cement content of the slurry to increase capacity if conditions vary from previous installations. For further description of the use of cement slurry for piles, see "Laboratory and Field Performance of High Alumina Cement-Based Grout for Piling in Permafrost," by Biggar et al., and paragraph 9-5.3.3.

9-2.1.6.2 Grouted Micropiles.

Grouted micropiles are a special type of cement slurry pile. Micropiles use a small-diameter (typically <4 in. [100 mm]) steel bar, such as those manufactured by Dywidag or Williams, that is installed in a grout-filled hole. They are best suited to use as anchors when they can be installed in bedrock or thaw-stable ground, although micropiles can also be used to carry vertical and horizontal loads in other types of material when used in conjunction with surface casings. The capacity of micropiles is very sensitive to installation methods and ground conditions. Testing has shown that they may not develop significant capacity when bonded in ice-rich permafrost;[3] therefore, they should be used cautiously in this type of material, in combination with a load test program during design and a proof testing program during construction to verify that capacities are being achieved.

9-2.2 Driven Piles.

Piles can be driven in frozen ground using a conventional impact hammer or vibratory hammers, often in combination with thermal modification. However, soil type and ground temperature must be considered because these factors affect drivability. Pile installation methods depend on the soil type, subsurface temperatures, and pile type. Local experience and equipment availability are often important factors affecting how successfully piles are installed, especially in remote areas. The presence of ice lenses or cobbles frozen in the soil matrix may inhibit pile driving or result in stress concentrations associated with damaged piles. For general background on pile installation in frozen ground, see *Frozen Ground Engineering,* by Andersland and Ladanyi; *Design and Construction of Foundations in Areas of Deep Seasonal Frost and Permafrost,* by Linell and Lobacz; and *Driven Piles in Permafrost, State of the Art*, by Nottingham and Christopherson. Driving steel H-sections and open-end-pipe piles into frozen ground can be accomplished using a wide range of impact-driving equipment, including vibratory hammers[4] and hydraulic rock-breaker-type hammers. Reinforced pile

[3] "Field Tests of Grouted Rod Anchors in Permafrost," Johnston and Ladanyi.
[4] "The Adfreeze Strength Characteristics of Vibratory Driven Piles," Mayrberger et al.

tips must be included with the design to reduce the potential for damaging piles during installation.

9-2.2.1 Predrilling or Thermal Modification (Prethawing).

Direct driving may not be possible, depending on several factors, including ground temperature, soil type, and the presence of saline soil. In general, piles are easier to advance when ground temperatures are warmer and in finer-grained soils. In colder ground with significant gravel content, pile driving may require predrilling and, in some cases, thermally modifying (prethawing) a small volume of soil around the predrilled hole. Prethawing can be accomplished by adding warm water to the predrilled hole or inserting a steam probe. The temperature of the water and amount of time for prethawing must be monitored, especially if steam thawing is used, to control the volume of soil thawed.

The ratio of the predrilled hole size to the pile diameter may vary, but it is typically on the order of 80% to 90% unless the soil is thermally modified. For criteria on minimum hole diameter for thermal modification, see “Pile Construction Practices in Arctic Regions State-of-the-Art,” by Nottingham et al. A predrilled hole that is not prethawed can promote stress concentrations at the pile tip during installation, which can lead to localized buckling. Local practice and equipment must be considered when developing specifications, or installation of test piles must be planned for during design to verify means and methods. Refer to “Pile Construction Practices in Arctic Regions State-of-the-Art” for further discussion of this approach to facilitate pile installation.

9-2.2.2 Pile Testing.

When driving piles in unfrozen ground, it is standard practice to perform high strain dynamic load testing using a pile driving analyzer to estimate capacity and monitor pile performance during driving. Testing driven piles with a pile driving analyzer in frozen ground may provide some information regarding pile stresses, but the data are not a reliable indicator of final capacity in permafrost areas due to the way in which load capacity in permafrost is developed. Measuring penetration resistance under an impact hammer or penetration rate under a vibratory hammer provides qualitative data but should not be used as a basis for determining the axial capacity. Use conventional static pile load tests performed according to ASTM procedures instead of impact testing for piles installed in permafrost. Special consideration is needed for long-term testing to measure creep rate because of the time required to hold loads and the potential for seasonal changes in ground temperature to affect results.

9-2.3 Helical (Drilled) Piles.

Helical (drilled) piles are used in permafrost areas of Alaska and Canada, but, depending on ground conditions, predrilling may be required to facilitate installation. For example, installations in coarse-grained materials such as those around Deadhorse, Alaska, may require both predrilling and thermal modification. Helical piles have one or more spiral plates welded at specific locations along the shaft. The shaft width typically varies from 1.5 to 36 in. (40 to 910 mm) in diameter, with helices that can vary from 6 to

48 in. (150 to 1220 mm) in diameter. The diameter of the top shaft section may be increased to provide greater lateral capacity to allow for retrofitting or because of anticipated thaw degradation and reduction of soil strength.

Helical piles are installed by drilling each pile into the ground using hydraulic drill equipment. The rate of advancement must be carefully matched to the rotation so soil disturbance is minimized, and the pile is essentially drilled into the soil. Their use is limited by the torque capabilities of the equipment, but they have been used in areas with degrading permafrost or high salinity soil conditions. Perform load testing to validate the design, but production installation is commonly monitored based on applied torque.

Helical (drilled) piles are commonly used for projects that require higher pull-out capacity (anchors) or where frost jacking forces control the design loads. Other benefits include rapid installation, little installation noise or vibration, no casing or dewatering requirement, lightweight installation equipment, the ability to be loaded immediately after installation, and their ability to be removed and reused (temporary facilities or facilities in support of military operations with a design life of five years or less).

9-2.4 Structural Materials.

Pile materials should be selected based on local practice, availability, and structural requirements, but steel, concrete, and timber piles have historically been widely used. In northern Alaska, steel pipe and H-piles are the most common types used in permafrost (in 2024); this is due to their drivability, high vertical and lateral load capacity, and ease of modification through welding. Pile design must consider corrosion potential, which will vary with location, and may include consideration of saline pore water (for example, in Utqiagvik, Alaska) and external environmental conditions such as salt spray or flooding salt water. Concrete piles are rarely used in the Arctic areas of North America but are more common in other parts of the world, where they are installed in permafrost using predrilling and slurry backfill methods. Concrete piles are typically precast and pretensioned to resist tensile loads due to frost heave forces. Timber piles may also be used, provided they have sufficient capacity and are protected from decay and deterioration in the active layer.[5]

9-3 PILE SYSTEMS WITH ADDITIONAL GROUND COOLING.

Ground cooling systems may be used with each general pile type, in combination with insulation, to enhance or maintain the capacity of piles by controlling ground temperature.[6] Cooling systems in common use in North America include passive thermosyphons installed within or adjacent to adfreeze piles, piles built as passive thermosyphons, and active ground freezing systems used to stabilize excavations. Air or liquid cooling can also be used to enhance freezeback or maintain ground

---

[5] *Design and Construction of Foundations in Areas of Deep Seasonal Frost and Permafrost*, Linell and Lobacz.
[6] *Review of Thermosyphon Applications*, Wagner.

temperature, but these methods are less common for permanent installations in North America at this time (2024) given the availability of thermosyphon systems.

The purpose of incorporating cooling with pile systems is to reduce ground temperature so the piles can be designed for higher adfreeze and reduced creep, or to maintain ground temperature over the life of the structure. Additional cooling is generally required when ground temperatures are warmer than 30°F (−1°C), as they often are in western Alaska, or because ground temperatures are expected to warm over the life of the facility. They may be integral to the pile or installed adjacent to the foundation or structure.

9-4 END-BEARING PILES.

End-bearing piles are best suited to conditions where stable, dense sand, gravel, or bedrock is present. Conventional design procedures for temperate conditions can be applied to estimate capacity.

End-bearing capacity of deeper piles (such as slurry piles) is typically ignored in permafrost unless the tip is seated on undisturbed, ice-poor, dense sand, gravel, or bedrock materials that will not creep more than design tolerances over the life of the foundation. Studies of pile performance in ice-rich permafrost have shown that the end-bearing resistance of the pile on undisturbed frozen soil or ice is low until the pile has settled about 30% of the base diameter, assuming constant ground temperature. Given common design settlement rates of about 1 mm/year, the end-bearing resistance mobilized over the life of the foundation will generally be very low and is neglected in practice.

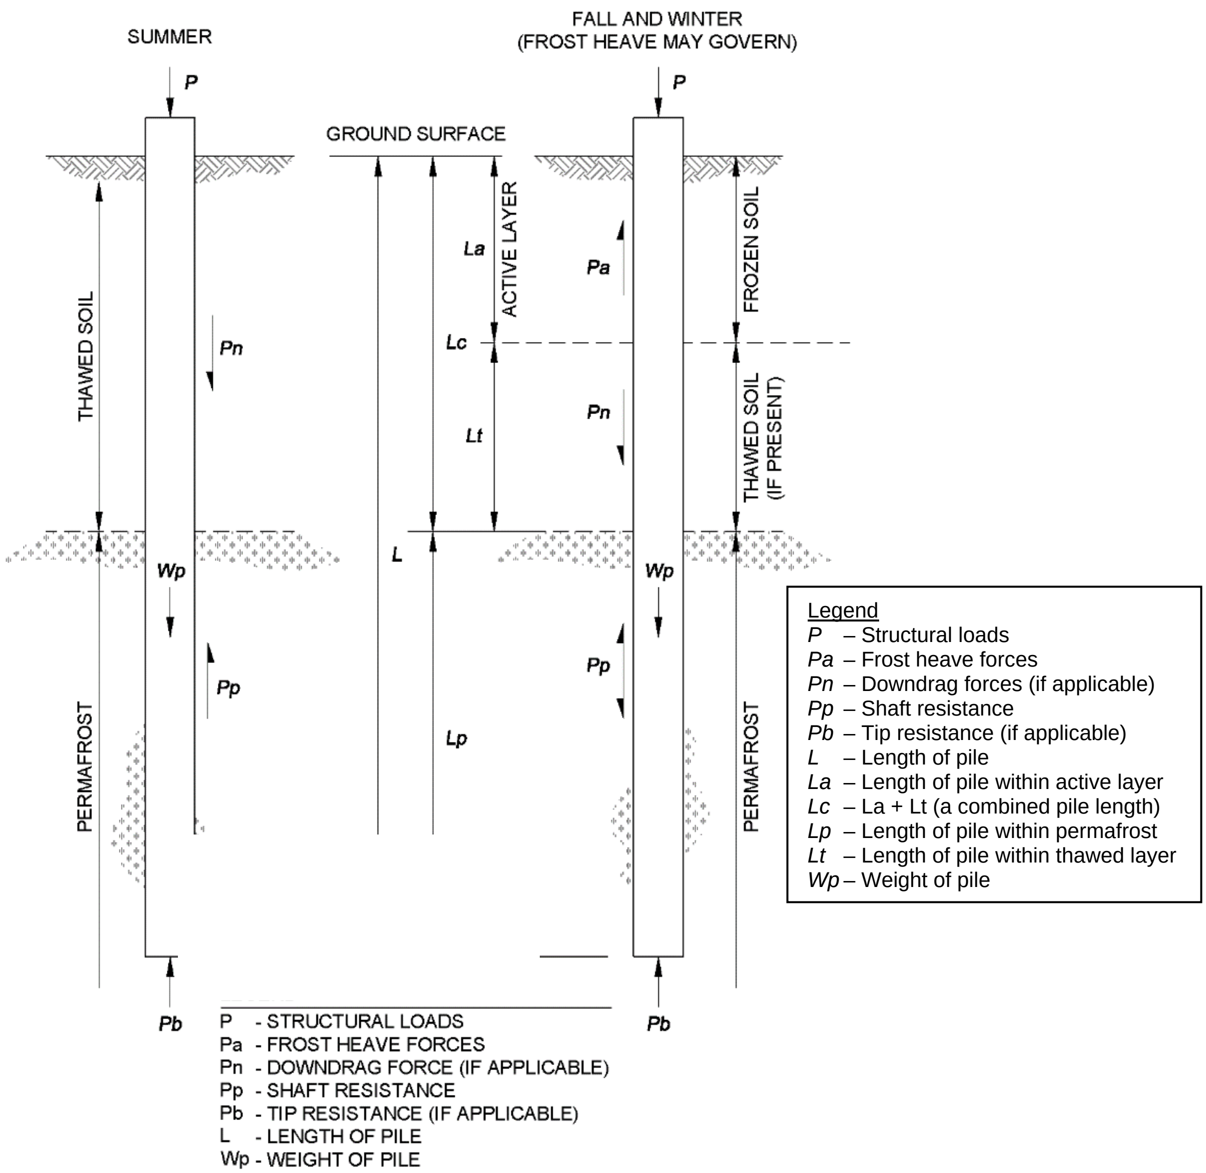
9-5 ADFREEZE PILES.

Piles installed in permafrost can provide long-term support for heavy loads if the design considers the mechanics and changeable nature of permafrost. The pile capacity, in compression or tension, will be significantly influenced by site conditions, such as ice content, thermal condition, and soil salinity, and by the nature and duration of the load application, pile type, and installation method. Therefore, a thorough understanding of both the thermal regime throughout the intended structure's service life and the soil properties is needed to determine the optimal pile design and allowable pile capacity. Considerations in the design of adfreeze piles are presented in the following paragraphs.

9-5.1 Pile Capacity—Seasonal Change in Resistance.

The capacity of piles in permafrost will vary from winter to summer due to changes in the ground temperature and corresponding changes in the mechanical properties of the permafrost (see Figure 9-2). In the later part of the summer season, the active layer will become fully thawed (see Figure 2-5). As winter cooling begins, the active layer begins to refreeze, with attendant development of seasonal frost heave forces along that portion of the pile within the active layer. However, adfreeze shear strength (shaft resistance) will increase as the permafrost temperatures oscillate toward the cold side of the trumpet curve.

Figure 9-2 Seasonal Load and Resistance



9-5.2 General Relationships.

The geotechnical pile capacity is determined by integrating the shaft and tip resistance over the respective pile areas and including an appropriate FS for both adfreeze and creep-controlled conditions, as indicated in Equation 9-1. The effect of potential downdrag must also be considered and is discussed further in paragraph 9-9. The general relationship for pile capacity expressed in Equation 9-1 is applicable to both adfreeze and creep-controlled conditions, provided appropriate values are used for each of the parameters.

Equation 9-1. General Form of Equation for Vertical Pile Capacity

$$Q_a = \frac{1}{FS}(Q_s + Q_p)$$

Where:
Q_a = allowable pile capacity for a given load condition
Q_s = adfreeze capacity based on allowable adfreeze strength for given ground temperature and design creep rate
Q_p = pile capacity mobilized at the tip when ground conditions are appropriate (Tip capacity may be ignored for ice-rich conditions because the strain needed to mobilize the tip resistance typically exceeds allowable strain along the shaft.)
FS = factor of safety, which will vary with load case (Refer to paragraph 7-8 and UFC 3-220-01 for additional requirements.)

9-5.3 Adfreeze (Shaft Resistance).

The term adfreeze refers to the tangential shear strength developed along the interface of a pile and the surrounding in situ soil or engineered slurry. Adfreeze strength is a function of ground temperature, salinity, soil-slurry type, moisture content (including ice content), pile material and roughness, and installation method (typically either a slurry or driven pile). The pile shaft condition and presence of adfreeze reduction agents, such as paints, oil, and mill slag, can also affect the adfreeze strength. The ultimate resistance to compression or tension loads on the pile can be estimated by summing the unit resistance over the surface area of the pile that is exposed to soil or slurry within the permafrost.

9-5.3.1 Common Values of Adfreeze.

Commonly applied values of adfreeze strength are presented in the following references.

9-5.3.1.1 Linell and Lobacz.

In *Design and Construction of Foundations in Areas of Deep Seasonal Frost and Permafrost,* Linell and Lobacz developed recommended adfreeze strengths based on an analysis of specific dimensioned steel and timber test piles embedded approximately 10 ft (3 m) in permafrost at ground temperatures between 32°F and −27°F (0°C and −33°C) with gradual incremental loading. Their recommendations are in terms of average sustainable adfreeze for both in-place soil and engineered silt or granular slurry. The creep displacement associated with the sustainable adfreeze strength is implied to be less than 1 in. (25 mm) over a 20-year service life. They also note that hard, sound freshwater ice shows a lower rate of creep deformation (and higher adfreeze strength) than frozen slurry at some temperatures.

9-5.3.1.2 Weaver and Morgenstern.

“Pile Design in Permafrost,” by Weaver and Morgenstern, presents recommendations for the adfreeze strength of ice and soil at ground temperatures between 30°F and 23°F (−1°F and −5°C) in terms of the long-term cohesive strength of the frozen soil and an empirical roughness coefficient given by the factor, *m*, as shown in Equation 9-2.

Equation 9-2. Long-Term Shear Strength

$$\tau_{lt} = mc_{lt}$$

Where:
τ_{lt} = long-term shear strength
m = an empirical roughness parameter
c_{lt} = long-term cohesive strength of the soil

Suggested values for *m* in Equation 9-2 from “Pile Design in Permafrost,” by Weaver and Morgenstern, were 0.6 for steel piles, 0.7 for concrete piles, and 1.0 for corrugated steel pipe piles. Equation 9-2 is based on a review and analysis of published pile test data, with the caution that piles supported in permafrost at temperatures warmer than 30°F (−1°C) may require special precautions, such as the addition of (artificial) cooling, to develop axial capacity.

9-5.3.1.3 Continued Research.

Research continues on the capacity of piles in frozen ground, and specific research may develop alternate values for the empirical roughness parameter or the form of Equation 9-2. For example, research on the adfreeze strength of a steel pile installed in Leda clay under varying ground temperature and normal stress indicated that a higher roughness coefficient, *m*, may be appropriate for the testing conditions and that the strength equation should include an additional frictional factor.[7] These results demonstrate the evolving nature of frozen ground engineering and the value of test programs for assessing design variables.

9-5.3.2 Roughness.

Adfreeze values in the literature generally do not consider differences in pile roughness, other than the roughness inherent in different pile materials (such as steel, concrete, timber). For steel piles, surface conditions have been shown to have a significant effect on pile capacity. In “Effect of Backfill Properties and Surface Treatment on the Capacity of Adfreeze Pipe Piles,” by Sego and Smith, sandblasting a steel pile was shown to double the adfreeze strength at the pile–slurry interface, relative to untreated mill-finished steel pipe piles.

[7] “Interface Shear Strength Characteristics of Steel Piles in Frozen Clay Under Varying Exposure Temperature,” Aldaeef and Rayhani.

9-5.3.3 Cement Slurry (Shaft Resistance).

Cement grout is a type of slurry that is considered separately from the conventional sand–water slurry discussed in paragraph 9-2.1.5 because of the considerable strength gain that can be achieved. In “Laboratory and Field Performance of High Alumina Cement-Based Grout for Piling in Permafrost,” Biggar et al. show that using cement grout doubled the pile load carrying capacity for a given displacement rate when the native soil had salinity up to 30 ppt, which is not an uncommon value (see paragraph 2-4.1.7). Although grout backfill will likely be more expensive than sand–water slurry, it may be preferable because of a lack of suitable material or because of the salinity in the soil.

The use of cement grout will likely move the critical shear plane from the pile–slurry interface to the interface between the soil and slurry for properly prepared steel pile surfaces. By shifting the critical shearing surface, the overall pile capacity increases because the surface area where shearing occurs is increased. However, in ice-bonded permafrost, the grout–in situ soil interface adfreeze bond should be reduced from the steel pile–grout interface adfreeze strength due to the material property differences between the steel and in situ soils. The reduction factors depend on the in situ soil material at the ground interface, with well-graded, clean sands and gravels having greater strength then high-plasticity clays for similar environmental conditions.

9-5.3.4 Creep Settlement.

Piles in permafrost will creep when installed in both ice-rich and ice-poor conditions, but consideration of creep becomes especially important when soils are ice-rich or have a high saline content because of the higher creep potential associated with these materials. In ice-poor soil or bedrock, piles can be designed for end bearing, provided frost jacking and uplift forces do not control the design.

Although creep is a highly complex phenomenon (see paragraph 5-3.2), in practice, creep effects are limited by controlling stress levels along the pile or by decreasing the ground temperature, which reduces the creep rate. Because creep is time and temperature dependent, it becomes important to establish the service life and the acceptable total and differential settlement tolerances of structures because these will dictate allowable stress levels over time. A common design standard is to design structure foundations for a creep rate of 1 in. in 100 years.

9-5.3.4.1 Creep Criteria.

If there is no slip between the pile and the soil, the pile settlement is equal to the cumulative shear deformation of frozen soil in contact with the pile. Equation 9-3, based on Equation 7.3-15 in *Frozen Ground Engineering,* by Andersland and Ladanyi, expresses the settlement (S) from primary creep using the International System of Units, as shown here:

Equation 9-3. Creep Criteria

$$s = \frac{3^{(n+1)/2}}{n-1} * a * \left(\frac{\dot{\varepsilon}_c}{b}\right)^b * \left(\frac{\tau_a}{\sigma_{c\theta}}\right)^n * t^b$$

Where:
a = pile radius (m)
τ_a = average shear stress along the pile–soil interface (MPa)
$\dot{\varepsilon}_c$ = creep strain rate (m/t)
t = time (hours)
$\sigma_{c\theta}$ = reference stress = $\sigma_{c0} * (1 + \theta/\theta_c)^w$ (Mpa)
σ_{c0}, n, b, w = experimentally determined values based on soil type
θ = soil temperature, −T(°C) or absolute value
θ_c = reference temperature, arbitrarily 1°C

Representative creep parameters that may be used in Equation 9-3 were compiled in *Frozen Ground Engineering*, by Andersland and Ladanyi, from a variety of source documents. Considerable judgement is required when using creep parameters, and designers must be familiar with the source documents and properties of the materials tested to confirm they are representative of the material being analyzed. Use field or laboratory testing like that described in *Creep of Frozen Soils*, by Sayles, to confirm the applicability of the values chosen for the design when warranted by project complexity.

Because creep of ice and ice-rich materials is poorly defined at temperatures warmer than 30°F (−1°C), piles in warm ice-rich permafrost must be refrigerated (see paragraph 9-6). Lowering ground temperature reduces the creep rate. However, it might take multiple winters to cool the soil to less than 30°F (−1°C) when using thermosyphons in warm permafrost areas. In addition, horizontal insulation may be required to assure stable ground temperatures are maintained.

9-5.3.4.2 Soil Salinity Effects.

Soil salinity in permafrost is an important parameter that must be characterized during site investigation and laboratory testing (see paragraph 5-3.1). The effect of salinity on creep was investigated in “Design of Vertical and Laterally Loaded Piles in Saline Permafrost,” by Nixon and Neukirchner, and in “Time-Dependent Displacement Behaviour of Model Adfreeze and Grouted Piles in Saline Frozen Soils,” by Biggar and Sego, who provide a design approach for saline soils. They show that soil salinity may increase the creep displacement of vertically and horizontally loaded piles by as much as 10 to 100 times that of nonsaline frozen soil.

9-5.3.4.3 Ground Temperature Effects.

Creep rate increases with increasing ground temperature. The creep of ice and ice-rich materials is poorly defined at temperatures warmer than 30°F (−1°C); therefore, piles in warm, ice-rich permafrost should be refrigerated, either passively or through mechanical means, to maintain or reduce the creep rate. In addition, horizontal insulation may be required to ensure stable ground temperatures are maintained. If ice-poor soils or bedrock are present in areas with warm, saline permafrost, piles should be designed as end bearing in these materials.

9-5.3.5 Allowable Adfreeze Shear Stress.

Creep is considered in the design of adfreeze piles by determining an allowable adfreeze shear stress. The allowable shear stress depends on several factors, including time of loading, ground temperature, and allowable displacement over the design life. Estimated values of adfreeze shear stress are established based on an understanding of site conditions, published data from the literature, and site-specific testing. Design values are selected from the developed relationships by either reducing the allowable shear stress for a given time of loading by a factor or selecting an allowable value for an increased time of loading.

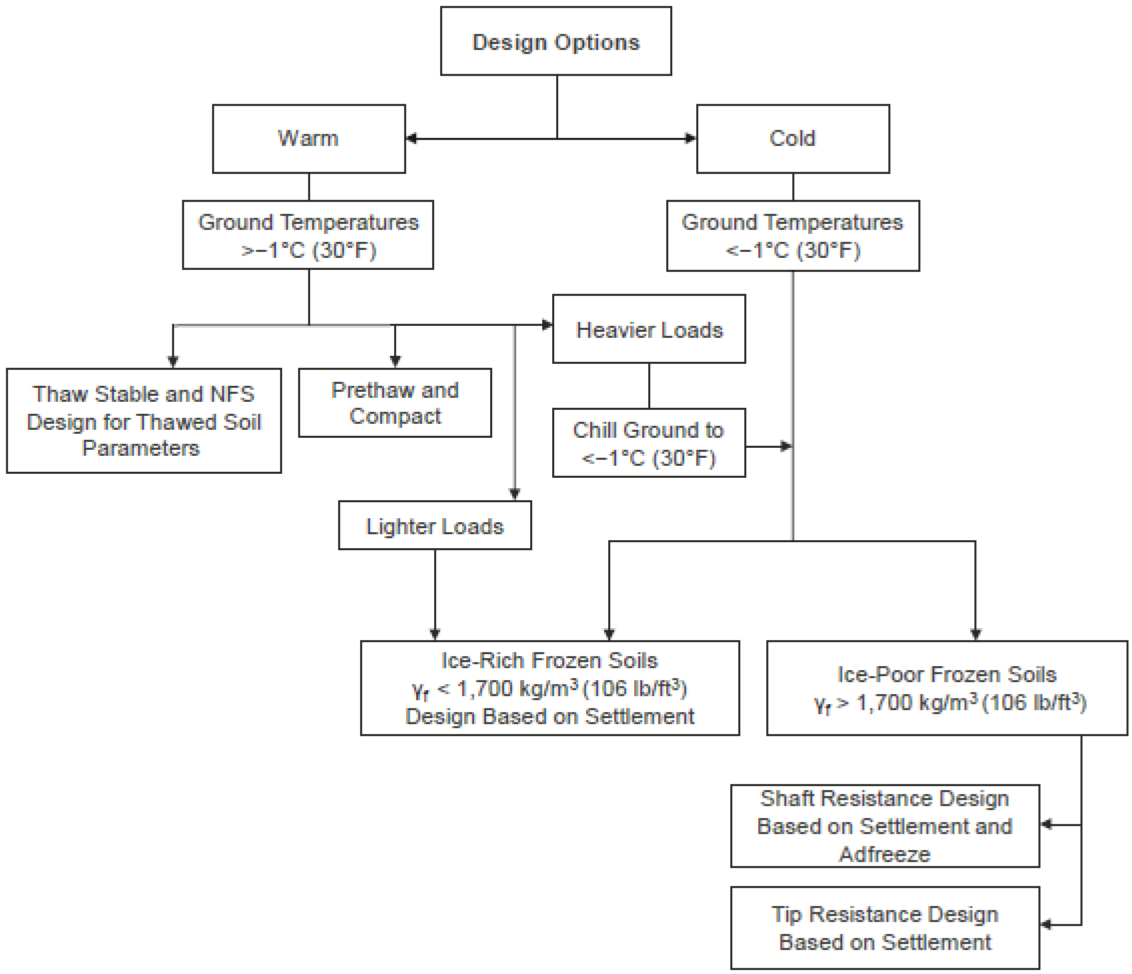
9-6 ADFREEZE PILE DESIGN PROCESS.

General design procedures for adfreeze piles, including charts for estimating adfreeze bond strengths and creep parameters, are presented in *Design and Construction of Foundations in Areas of Deep Seasonal Frost and Permafrost,* by Linell and Lobacz; “Pile Design in Permafrost,” by Weaver and Morgenstern; *Pile Foundations in Engineering Practice,* by Prakash and Sharma, and *Frozen Ground Engineering,* by Andersland and Ladanyi. Recent updates to engineering practice must also be considered and include issues such as the following:

- The projected warmest or average permafrost temperature of the site for design and how this will be established. Ground thermal modeling may be required to predict changes in ground temperature.
- The tangential adfreeze bond strength along the pile length in permafrost as a function of temperature in ice-poor permafrost.
- The allowable shear strength associated with the design pile displacement for piles in ice-rich or saline permafrost.
- The embedment depth in permafrost to support the structural loads and resist downdrag and upward frost heave forces.
- The pile material, size, shape, and method of installation.
- Complete freezeback to the design temperature before loading, which is typically monitored using thermistor strings.

One approach to the design of piles in permafrost proposed in “Pile Design in Permafrost,” by Weaver and Morgenstern, is based on maximum ground temperature and the performance of piles, depending on their installation in ice-rich or ice-poor permafrost (see Figure 9-3). However, Figure 9-3 should be applied cautiously at sites where the permafrost is warmer than 30°F (−1°C) and creep effects or potential site changes over time may control the design.

Figure 9-3 Adfreeze Pile Design Process in Permafrost



9-7 TANGENTIAL ADFREEZE (FROST HEAVE).

The magnitude of frost heave forces is related to many factors, including soil and ground ice type and heterogeneity, variation of soil temperature with time and depth, rate of freezing, availability of water, foundation surface type, overburden pressure, pile load, and pile type. The following variables are especially significant when determining the minimum pile length necessary to resist frost heave:

- Pile loads and duration of loading
- Active layer thickness
- Tangential adfreeze bond strength in the active layer
- Pile shaft resistance below the active layer
- Serviceability limit state or failure criteria (pile vertical or lateral displacement at which maintenance must be done)

Design values of tangential adfreeze used in North American practice commonly are on the order of 30 psi (~200 kPa) to 60 psi (~400 kPa), depending on the standards being used (Table 9-1). However, 40 psi (275 kPa) is a very commonly applied value in North America for silty, frost-susceptible soil in the absence of other data.

Table 9-1 Published Values of Tangential Adfreeze in Absence of Other Data or Specification

Soil Type	Tangential Adfreeze
Silty frost-susceptible soil (commonly applied in North America)	40 psi (275 kPa)
Organic soil	10 psi (70 kPa)
Silty granular soil	20 psi (140 kPa)

Source: Adapted from "Foundations in Cold Regions," by Phukan.

9-7.1 Minimum Pile Embedment and Frost Heave.

The minimum embedment needed to resist frost heave must be considered in every design. Pile heave due to frost action cannot occur unless the uplift force, *Pa*, exceeds the resistance provided by the length of pile embedded below the active layer, *Pp*, and the applied load on the pile (pile weight plus normally applied dead and live loads), as illustrated in Figure 9-2. The uplift force depends on the active layer thickness, the adfreeze bond strength in the active layer, the supply of water to the freezing plane, and the ability of the material to transmit water to the freeze plane. The pile uplift resistance depends on the embedded length of the pile below the active layer and the integration of shaft resistance along that length.

9-7.2 Engineering Measures to Mitigate Frost Heave.

Three conditions are required for frost heave and the development of the resulting tangential heave load:

- Freezing temperatures that change water in unfrozen soil to ice when the soil freezes
- Availability of water that moves to the freezing front due to capillary forces
- Frost-susceptible soils that can wick the available water to the freezing front

If one of these necessary conditions are eliminated, frost heave should not occur. Examples of engineering measures used to control and mitigate frost effects are discussed in paragraph 7-2.1 and paragraph A-8.

9-8 LATERAL LOADS.

Piles embedded in permafrost to sufficient depth to resist uplift forces and structural loading generally have high resistance to lateral loads during short-term loading, such as due to wind. If these same piles are subjected to sustained lateral loads, the capacity must be reduced due to creep that will occur. For methods for estimating the p-y (load-deformation) response of laterally loaded piles in permafrost for various load durations, see "Analysis of Laterally Loaded Piles Embedded in Layered Frozen Soil" and "Lateral Pile Analysis Frozen Strength Criteria," both by Crowther, and "Analysis of Laterally Loaded Piles in Frozen Soils," by Yang et al. *Frozen Ground Engineering,* by Andersland and Ladanyi, reports that long-term lateral loads on piles installed in ice-rich frozen ground, whether slurry or drilled, can rotate about the length of the pile over time, virtually eliminating the depth of fixity.

9-9 DOWNDRAG.

Downdrag will develop on a pile installed in frozen ground for several reasons, including thawing and settlement of ice-rich permafrost along the length of the pile and seasonal heave and thaw of frost-susceptible soil at the ground surface. In areas of significant seismic risk, liquefaction of soils that have thawed is another significant cause of downdrag that requires mitigation through ground improvement. As noted in paragraph 9-5.2, downdrag effects should be considered during design, and, if they are found to be a significant design issue, measures to mitigate the downdrag must be incorporated into the design. These mitigation measures include isolation of the pile from shallow frost heave and settlement effects, use of insulation or cooling to prevent a decrease in the depth of permafrost or thawing of ice-rich material along the length of the pile, changes in the pile geometry to provide greater resistance to anticipated load conditions, and ground improvement after thawing.

9-10 TENSION LOADS.

Design pile resistance to applied uplift or tension loads using appropriate adfreeze values for the design conditions and appropriate reduction for uplift, like that applied in the design of foundations in temperate regions using standards discussed in paragraph 1-5.2.

9-11 CYCLIC LOADS.

9-11.1 Machine Loads.

The behavior of adfreeze piles subjected to cyclical loads from machine loads such as from generators and other vibrating equipment is a special case (see paragraph 7-6.3) that requires careful analysis because the effects of these loads on adfreeze are not well defined. Model testing and monitoring indicate that cyclic loads increase the displacement rate of adfreeze piles relative to static-only axial loads for similar engineering and geologic conditions.[8] The magnitude of the increase is related to the

[8] "Displacement of Piles Under Dynamic Loads in Frozen Soils," Parameswaran; *Vibration Amplitudes in the Inuvik Powerhouse*, Pernica et al.; "Dynamic Load Effect on Settlement of Model Piles in Frozen Sand," Stelzer and Andersland; "Adfreeze Strength of Model Piles in Frozen Soil Under Dynamic Loads," Zhang et al.; "The Settlement of Model Piles in Frozen Soil Under Dynamic Loading," Zhang et al.

amplitude of the load, pile roughness, foundation rigidity, and other factors influencing creep in permafrost.

9-11.2 Sustained Axial Loads.

Adfreeze piles subjected to sustained axial cyclic loads require careful evaluation during the site assessment and engineering design phases. Site evaluation is particularly important if pore water salinity is present along or near pile embedment depths in the planned development area. Depending on geotechnical conditions and structural loadings, a comprehensive site and project analysis may be required for adfreeze pile design, including pile load testing. General adfreeze pile design recommendations are described below.

9-11.2.1 Structural Methods.

Structural methods to eliminate or reduce the cyclic loads to the adfreeze piles must be evaluated early in the design process and are the preferred approach to mitigating the effects of dynamic loads on adfreeze piles. Structural methods may include base isolation and dampening for machine-induced cyclic loads. If structural methods will not eliminate cyclical loading on adfreeze piles, engineering methods to permanently decrease the ground temperatures around cyclically loaded piles must be implemented because this will reduce the creep rate. Ground cooling is particularly important for sites with warm permafrost or elevated pore water salinity. Engineering methods may include the use of rigid insulation within pad fill, passive subgrade cooling, and active refrigeration.

9-11.2.2 Slurry.

For slurry adfreeze piles, dense slurry consisting of saturated, well-graded sand and gravel is recommended. Potable water is recommended for the slurry to reduce weakening by salt or other contaminants. Grout can be used in lieu of slurry in specific applications, although it should be designed for the expected ground temperatures and tremie placed.

9-11.2.3 Pile Surface Texture.

Steel and concrete adfreeze pile surfaces planned for slurry backfill should either be roughened by sand blasting to remove coatings, corrosion, and expose bare metal or lugs, helix wraps, or other structural protrusions that extend into the slurry or grout backfill should be installed around the piles. Structural protrusions should also be considered for timber adfreeze piles.

9-11.3 Creep.

Testing results showed that small cyclical loads will accelerate the creep of adfreeze piles in frozen sand by a factor of about 2 for alternating stresses of as little as 3% to

5% of the static stress.[9] Therefore, a 50% reduction from the allowable static adfreeze strength is sometimes considered as an initial estimate for design. For critical facilities, pile load tests should be conducted to determine or confirm a site-specific creep rate due to applied dynamic loads.

9-12 ADDITIONAL CONSIDERATIONS.

9-12.1 Pile Load Testing.

Pile load tests are used to verify design assumptions and optimize pile design. The results may provide insights on site conditions and foundation responses that cannot be captured by field investigation and laboratory testing alone. Pile load tests should be conducted on up to approximately 10% of the piles installed, but the actual number tested will depend on the scale of the project, uncertainty of soil conditions, confidence in the soil property characterization, and confidence in the installation method. Procedures for load tests are found in ASTM D5780, *Standard Test Methods for Individual Piles in Permafrost Under Static Axial Compressive Load*.

In selecting the number of piles to be tested, the uncertainty of soil conditions and confidence in the soil properties and thermal regime should be considered. For example, when the length of helical piles installed within the active layer is designed to carry a portion of the load, soil and moisture content variation across the site may have a higher potential to affect pile capacity. In comparison to slurry piles, which can be closely monitored and controlled, approximately 10% of helical piles should be tested, while fewer slurry piles can be tested. Design of pile load tests conducted in freezing air temperatures, or under long-term sustained loads, requires specific measures, such as providing shelter for test equipment or load cells that are susceptible to freezing. Significant time and effort are required when conducting long-term load tests in the Arctic and Subarctic. Examples of longer-term load tests in permafrost conditions are presented in "The Adfreeze Strength Characteristics of Vibratory Driven Piles," by Mayrberger et al., and in general references such as *Frozen Ground Engineering,* by Andersland and Ladanyi.

9-12.2 Utility Connections to Buildings.

Incorporate flexible utility connections into the design to accommodate potential differential movements between the building and surrounding ground surfaces that occur due to seasonal frost action. For example, properly designed pile-supported structures will have little long-term settlement, but the surrounding ground surface may continue to settle because of thermal changes caused by site development or longer-term environmental changes at the site. If only vertical displacement is anticipated, the utility connections can be made with slip interfaces to facilitate movement between the structure and the underlying soils. See UFC 3-130-05 for further discussion.

[9] "Displacement of Piles Under Dynamic Loads in Frozen Soils," Parameswaran; *Effect of Dynamic Loads on Piles in Frozen Soils*, Parameswaran.

9-12.3 Monitor Drilling for Slurry Piles and Predrilled Holes.

Design criteria commonly assume a certain amount of massive ice will be present along the length of the pile, which needs to be confirmed through logging cuttings produced during installation to confirm that conditions are as expected or that specific geologic units, such as a bearing layer, have been encountered. Therefore, drilling operations must be monitored and logged by personnel who are experienced with logging frozen soil and familiar with the anticipated subsurface conditions assumed in the design. If necessary, additional confirmation of subsurface materials can be accomplished using a downhole camera or lights to illuminate the borehole sidewalls and allow direct observation of conditions. When the amount of massive ice exceeds the design criteria, it is common to extend the pile an additional foot per foot of excess massive ice. Changes in pile length may require field splicing, which will affect the production of pile installation and schedule, especially if sufficient material is not on hand, which is often the case if the site is in a remote location.

A percentage of slurry piles should include installation of small-diameter casings to allow for installation of thermistor strings, which will in turn allow for measurement of ground temperatures to confirm that slurry has frozen back. The actual number of thermistors installed will depend on the number and configuration of the slurry piles.

CHAPTER 10 HORIZONTAL STRUCTURE DESIGN

10-1 SITE INVESTIGATION CONSIDERATIONS FOR HORIZONTAL STRUCTURES.

In general, the site investigations for horizontal structures (such as road and airfield embankments, pipelines, and other long linear infrastructure) must follow the criteria referenced in UFC 3-130-02, UFC 3-220-01, UFC 3-250-01, *Pavement Design for Roads and Parking Areas*, EM 1110-1-1804, and Chapter 7 of this UFC. Other general discussion is found in technical literature, such as the following:

- *Roads and Airfields Constructed on Permafrost, A Synthesis of Practice*, by Connor et al.
- *Thaw Stabilization of Roadway Embankments Constructed Over Permafrost Areas*, by Zarling and Braley
- *Guidelines for Development and Management of Transportation Infrastructure in Permafrost Regions*, by the Transportation Association of Canada

Foundations for horizontal structures will cross or span varying terrain or permafrost conditions and must consider not only the stability within the specific terrain unit and the transitions between terrain units, but also water features and mitigation of thermal erosion due to water. Foundations for horizontal structures may affect the subsurface conditions over time, and those effects need to be considered for the design life of the structure. The site investigation results will allow for evaluating and selecting appropriate foundation types for the project alignment and structure.

10-2 SELECTION OF FOUNDATION TYPE.

Foundation selection depends on the conditions of the existing terrain. In areas of seasonal frost, embankments and other horizontal structures should be constructed when the ground is thawed, using methods described in UFC 3-250-01, where several methods to protect the embankment section from seasonal frost effects are described in detail.

There are several different foundation options for permafrost regions. These options generally require active methods that provide thermal protection of the underlying soil, achieved either through thickened embankment fill or a combination of insulation such as rigid XPS or EPS insulation and embankment fill. Other methods may also be utilized, including air-convective embankments, air-convective shoulder treatments, or passively cooled embankments using open ducting or thermosyphons. In some cases, if the underlying permafrost is relatively thaw-stable, passive methods (such as allowing the permafrost to thaw) may be used. Additional details and considerations can be found in documents such as the following:

- *Embankment Design and Construction in Cold Regions*, by Johnson
- *Cold Regions Utilities Monograph*, by Smith

- *Frozen Ground Engineering*, by Andersland and Ladanyi

10-3 CONTROL OF HEAT TRANSFER AND DEGRADATION OF PERMAFROST.

Heat transfer from horizontal structures can be costly to control, and total prevention of the thawing of the underlying embankment and natural soil is often impractical. A cost analysis may dictate allowing for thaw with intervals of maintenance or patching prior to developing excessive differential settlement. Allowing for thawing must include annual costs for releveling the embankment surface or patching the surface pavement. Most often, this annual maintenance is more cost-effective than constructing an embankment that is resistant to thawing.

When insulation is used, material properties must be appropriate to provide sufficient strength and performance over time. For example, EPS, commonly used as lightweight fill, requires a more robust structural section above it to withstand repetitive loads than higher density materials with better strength in combination with low strain would require. Both EPS and XPS may be appropriate for a given application, but material properties must be carefully considered to attain proper performance. Insulation must also have a shear strength sufficient to resist applied loads and loads anticipated during construction, which may be higher than the structural loads.

10-3.1 Site Selection.

Terrain unit analysis and site investigations that characterize changes in near-surface conditions are critical to selecting the best route or alignment for horizontal structures, especially in permafrost environments where thaw-unstable terrain may be avoided by careful site selection. Passive methods may be utilized in terrain units classified as thaw stable. In areas that are thaw unstable (such as ice-rich polygonal ground), active methods may be employed; however, these are costly in long structures such as roadways. Route or alignment selection must consider the potential effects of thaw-unstable terrain and related geohazards on the project. A combination of desktop, remote sensing, and field methods can be effectively employed to characterize sites and monitor their performance over time.

10-3.2 Removal—Excavate and Replace.

This method is typically used where thaw-unstable permafrost conditions exist. A variety of excavation methods are available for frozen ground, depending on soil type, moisture (ice) content, and planned excavation depth. Typical frozen ground excavation equipment consists of single-tooth rippers, cutters, hydraulic impact breakers, and conventional bucket excavators with frost teeth. Drilling and blasting may be cost effective if large volumes of material must be moved. For options and additional details, see Chapter 9 of *Frozen Ground Engineering,* by Andersland and Ladanyi.

10-3.3 Stability of Slopes during Thaw.

The thermal effects and subsequent stability of embankment side slopes can be substantial. Embankments over frozen ground typically must be designed to be wider and to have flatter side slopes than those in temperate climates. Embankments wider than those used in temperate areas, along with flattened side slopes, can be used to provide sacrificial slopes that can deform while having little significant effect on the working embankment.[1] A recent study, “Thermal Stabilization of Embankments Built on Thaw-Sensitive Permafrost,” by Kong and Doré, used very shallow shoulder slopes, most prominently on the downwind side of the embankment, that allowed for wind scouring of the snow and prevented snow piling and drifting in the ditch areas, preventing warming due to increased winter insulation from snow. Thermal analysis and a review of studies such as *Embankment Design and Construction in Cold Regions,* by Johnson, and Chapters 9 and 11 of *Frozen Ground Engineering,* by Andersland and Ladanyi, provide additional information.

10-4 PAVEMENT STRUCTURES.

Horizontal structures, or embankments, are designed to support concrete and asphalt airfields, roads, parking areas, and other linear structures (including unsurfaced, or gravel, roads). Embankment and pavement design must follow UFC 3-260-02, *Pavement Design for Airfields*, for airfields and UFC 3-250-01 for roads and parking areas. Additional considerations for embankment and pavement structures in cold regions can be found in *Cold Regions Pavement Engineering,* by Doré and Zubeck.

Construction of embankments often changes the natural thermal regime of the ground, creating the potential for thaw settlement, frost heave, and consolidation. Thaw settlement often occurs at ice-rich locations, such as those with wedge ice. The subsequent free water produced during thawing will then freeze the following winter season, creating frost heave. Frost heave can occur just as readily at nonthaw-settled locations in cases where there are frost-susceptible soils, water, and freezing temperatures, which can create ice lenses within the embankment. The formation of these ice lenses can result in differential surface movement during freezing and significant loss of strength during thaw. Embankments constructed of NFS material perform well but can still undergo destructive deformation and settlement if constructed over thaw-unstable subgrades.

10-5 DRAINAGE STRUCTURES.

Effective drainage is critical for the long-term performance of horizontal structures. Improper design or construction, in combination with thermal degradation, can affect the stability and functionality of these structures. Retention and storage requirements may be different than those in temperate areas due to impermeable freezing ground. Appurtenances must also be sized to accommodate changes in precipitation due to climate and vegetation changes during the life of the structure. Drainage structures, including culverts, are addressed in Chapter 11.

Horizontal structures have the potential to affect surface water and groundwater flow across a site, such as by altering runoff patterns or blocking drainages. These changes,

---

[1] *Guidelines for Development and Management of Transportation Infrastructure in Permafrost Regions,* Transportation Association of Canada.

including cross-embankment flow, may alter the permafrost depth, inducing catastrophic thawing of thaw-unstable materials in the drainage pathway. Careful consideration of both the number of drainage structures and their potential to affect the thermal conditions at a site (such as ponding water, ditches, and culverts) must be considered. It is critical that embankments that become impoundments during periods of high runoff are sufficiently impervious and incorporate measures to prevent seepage pathways from developing along culverts that may penetrate the embankment.

CHAPTER 11 DRAINAGE AND DRAINAGE STRUCTURES

11-1 INTRODUCTION.

General guidelines for drainage and groundwater are covered in UFC 3-130-01. Surface water and groundwater can have very detrimental effects in permafrost areas and require special consideration for every project. Proper drainage is necessary to maintain the thermal stability of the structure and reduce the need for future maintenance. When possible, avoid construction of foundations in areas where natural groundwater and surface water flow exists. In most cases, this is impossible; therefore, additional drainage pathways are required to ensure water is conveyed through the embankment in a nondestructive manner. Permafrost features, such as ice wedges or other types of massive ground ice, are especially sensitive to thawing, and these areas should be avoided when possible.

11-2 VERTICAL STRUCTURES.

Positive drainage must be developed to drain water away from the foundations of vertical structures to prevent ponding and degradation of frozen ground conditions. When embankments or pads are used over permafrost terrain, the physical limits of the pads must include room for setbacks and insulation that may be required. This allows for sacrificial slope edges that can fail due to permafrost degradation related to the effects of ditching, ponding water, and thawing related to seasonal snow drifting, without damaging the embankment.

11-3 HORIZONTAL STRUCTURES.

Several surface water and groundwater mechanisms can negatively affect horizontal structures by enhancing permafrost degradation and erosion along ditches and drainage along the toe of embankments, forming aufeis when natural drainage is blocked, building up ice, and causing cross-drainage thawing of permafrost below the structure. Adverse drainage effects can be avoided by rerouting the alignment around or away from natural drainage features or can be mitigated by drainage improvements. Drainage improvements can be challenging, and it is difficult to ensure flow moves through the designed structures. Examples of aufeis mitigation can be found in “Aufeis Formation and Remediation,” by Zufelt and Daly, and “Aufeis Formation and Prevention,” by Slaughter.

The highway between Inuvik and Tuktoyaktuk in Northwest Territories, Canada, is an all-weather road that traverses varied permafrost terrain and opened in 2017. The highway construction incorporated innovative test sections with minimal fill thickness in select areas that are being monitored to support research into the performance and are focused on (1) assessing performance of the highway, (2) providing advance alerts to potential problems, and (3) building expertise for future application. Recent updates on insights gained from the Inuvik Tuktoyaktuk Highway should be considered for relevance to planned project activities.

11-3.1 Surface Water Control—Culverts.

Culverts are generally required to ensure control of water movement across horizontal structures. Culverts have a history of poor performance in cold regions due to the thawing of frozen materials adjacent to and under the drainage structure, ice buildup due to impeded flow, inadequate installation, and thermal effects on the underlying soil. In addition, buried piping and culverts frequently heave or settle, due to the previously mentioned errant flows, creating irregularities in the surface that may require long-term maintenance. Carefully consider the frequency of placement and the sizing of these structures. Often, the number of drainage structures specified during design is inadequate to ensure no cross-embankment flow occurs. In general, overdesign culverts with respect to the number of cross-embankment appurtenances, strategically placed for effective water conveyance, oversized to accommodate seasonal icing, and properly constructed. Inlets and outlets may heave or become filled with ice; this may warrant installation of heat trace or steam pipes to keep culverts from being blocked by ice in winter. Inclinations on both the shoulder slope and the cut slope, as well as the drainage ditch inclinations, will change as permafrost degrades under the side slopes and ditches. This creates areas where water ponds and fails to reach drainage structures. Also, thawing at the location of a drainage structure will increase the height required for the water to pond before running through the drainage structure, resulting in stranded culverts many feet above the elevation of the ditch line.

Consider phasing culvert installation during construction. Installing culverts during embankment construction often leads to better long-term performance than installing culverts after embankment construction. Careful consideration of location is required. When possible, systematically place culverts at specific locations that are identified as drainage pathways during spring thaw, thereby avoiding ponding related to the embankment construction. It is common practice to install culverts at two elevations at critical water crossings. This ensures water can flow in the spring when the lower culvert is iced up and covered in snow and also provides a second flow path in the event of a storm surge. Compaction must be controlled to ensure the long-term performance of the culvert and the embankment. Additional information can be found in *Cold Regions Hydrology and Hydraulics: An American Society of Civil Engineers Monograph,* by Ryan and Crissman, and *Frozen Ground Engineering,* by Andersland and Ladanyi.

11-3.2 Surface Water Control—Storage.

The design of surface water storage used for stormwater or snowmelt management systems must be carefully considered. In regions with seasonally frozen ground, these considerations must include the effects of early winter shallow freezing on drainage pathways versus the deep frost late into the spring, when snowmelt runoff storage must be accommodated. In permafrost regions, the impoundment of surface water often causes thermal alterations to the underlying permafrost, with unintended consequences such as thermal erosion and talik development or subsidence.

11-3.3 Subsurface Water Control.

Subsurface groundwater is generally present both above and below permafrost. The subpermafrost groundwater can have enough hydrostatic pressure to cause artesian flow when wells are constructed through the frozen mantle and the hydraulic potential is much greater in elevation. These types of artesian conditions can also be found in regions with high-salinity soils, where zones of hyper-saline permafrost may have high hydrostatic pressure and behave in a thawed manner. Wells with unintended artesian conditions will cause thawing of the immediately surrounding permafrost, which can affect the stability of the well and adjacent structures. Ground freezing has been used to reverse the thermal erosion and reduce adverse effects.

A gravel pit in the Fairbanks area, adjacent to a local hillside, was advanced in permafrost terrain. The thickness of the frozen zone of gravel was approximately 100 ft (30 m). A groundwater well was installed in the pit to measure water depth. Due to the artesian conditions, unintended flow through the installed well occurred, and the gravel pit quickly filled with water and had to be abandoned until the well could be refrozen in place using active freezing methods. Once the well was refrozen, the pit was dewatered, and gravel mining commenced.

This Page Intentionally Left Blank

CHAPTER 12 CONSTRUCTION CONSIDERATIONS

12-1 INTRODUCTION.

Construction in the Arctic and Subarctic often occurs at self-contained work sites that are remote and have long supply chains and limited logistical support. The challenges of working at remote sites are compounded by weather extremes that affect equipment and the productivity of personnel, as well as potentially limiting sea-ice access during sealift operations. The cold regions environment is also sensitive to construction impacts that can greatly modify site conditions, as well as permitting issues and other limitations on operations discussed in Chapter 2. This chapter discusses general considerations relative to construction planning and logistics, site development and ground improvement, and other development activities. Additional discussion regarding construction issues in the Arctic and Subarctic can be found in many sources, such as the following:

- *Design and Construction of Foundations in Areas of Deep Seasonal Frost and Permafrost*, by Linell and Lobacz
- *Permafrost Engineering Design and Construction*, by Johnston
- *Cold Region Structural Engineering*, by Eranti and Lee
- *Embankment Design and Construction in Cold Regions*, by Johnson
- *Thermal Analysis, Construction, and Monitoring Methods for Frozen Ground*, by Esch
- *Construction in Cold Regions, A Guide for Planners, Engineers, Contractors, and Managers*, by McFadden and Bennett

12-2 PLANNING AND LOGISTICS.

Prior planning and consideration of supply chain and logistical limitations are critical for successful implementation of work in the Arctic and Subarctic. Often, years of preparation and preliminary site work are needed prior to development of a new facility at a remote site. For example, it may be necessary to first establish temporary facilities or facilities in support of military operations using soft-sided structures (such as tents) for fuel, power, water, sanitation, and communications to facilitate primary site development and permanent structure construction. Depending on mission and schedule requirements, site development must include planning for work during winter conditions. Airport and dock construction may also be part of the site development work, requiring careful planning for material logistics and delivery schedules. For terrestrial logistics, seasonal ice roads may be needed to allow overland access (see UFC 3-130-01), and these activities generally will require completion of multiple environmental studies to secure permits, access (see UFC 3-130-01), and withdrawal of water from lakes or rivers.

12-3 SITE DEVELOPMENT.

Site development typically will include construction of a work pad that is graded to provide a level working surface. The extent of grading and fill placement at a facility depends on the number and size of embankments needed to support the full build-out of vertical and horizontal structures and the intended life of the site. For example, temporary facilities or facilities in support of military operations with a design life of five years or less may perform adequately with less fill than is required to support pavements and activities that are expected to occur over decades. To facilitate rapid construction, special considerations are required when constructing an embankment in the Arctic, particularly when construction occurs during winter months (see UFC 3-130-01). Challenges include compacting and engineering testing of the granular fill placed during freezing weather.[1] Also, the potential for thaw settlement is high if portions of the winter-constructed embankment thaw in summer and require recompaction of structural material to achieve proper stiffness.[2]

12-3.1 Protection of Natural Ground Surface.

Minimize disturbance of natural tundra overlying frozen ground because this will increase thaw degradation and potentially affect the functionality and stability of facilities.

12-3.2 Construction Constraints.

The use of granular pad foundation subsystems will be limited by the subgrade conditions. In areas where seasonal subgrade thawing will result in difficult construction, granular pad foundation subsystems are typically constructed in the winter to mitigate summer construction problems. These summer construction problems may include instability of the thawed surface soils and thawing of permafrost in excavations or where surface organics are disturbed. Water entering excavations through the active layer may also complicate summer construction. However, construction of granular pads in the winter presents its own set of problems that must be considered. The soil in granular pads constructed in the winter tends to bind together, making compaction difficult and resulting in fill that is looser than desired. Measures such as using thawed aggregate or reworking materials in the summer may be required depending on design criteria, which may affect construction schedules or design selection. Similarly, providing good drainage at the edges of pads is an important consideration (see Chapter 11).

Use select granular materials for best results, which may be a limitation in some areas where high-quality fill is not available. The granular materials must be relatively dry and free of frozen clods to allow proper placement and compaction during freezing conditions. Granular materials must also have low frost susceptibility.

[1] “Construction—Wintertime Compaction and LNG Facilities in Fairbanks, Alaska,” Prusak et al.
[2] “Estimating Thaw-Strain Settlement of Frozen Fill,” Crowther; “Cold Regions Earthwork,” Tart.

12-3.3 Compaction During Periods of Freezing Air Temperatures.

Proper placement and compaction of structural fill can be conducted in temperatures below freezing. Careful planning and selection of the embankment material is required. Fill can be placed to an appropriate density in freezing weather with little to no detrimental effects upon thawing. This is especially important at sites where there is a limited window of time, either when air temperatures are above freezing (such as in Antarctica and Greenland) or due to other schedule constraints. The limiting temperature will depend on the material properties and method used to keep fill material in a thawed or near-frozen state. However, in “Construction—Wintertime Compaction and LNG Facilities in Fairbanks, Alaska,” Prusak et al. showed the limiting air temperature to be approximately 15°F (−10°C). At air temperatures below that value, it became difficult to achieve the desired fill density.

Around-the-clock construction monitoring (engineering controls) is especially important for placement of compacted fill in freezing conditions to ensure the site is free of snow and prepared in accordance with the specifications before placing additional lifts. Around-the-clock inspection also allows for the density of the lift to be measured immediately after placement, but prior to freeze.

An alternate method for establishing compaction criteria is to use a test fill that is built to establish compaction criteria and verify that desired compaction is being achieved using the available equipment at a site. It is important to establish correlations between in-place density and number of passes from specific compaction equipment supplemented by laboratory testing. Test fills are most applicable when the materials used do not exhibit a normal moisture density relationship, which may be the case for coarse crushed rock. A testing plan is required to establish the geometry of the test fill, testing and measurement methods, and acceptance criteria. The testing plan should include laboratory testing to develop compaction curves and establishing moisture–density relationships on the test fill material as a reality check on the field-generated data, whenever possible.

12-3.3.1 Winter Fill Placement.

12-3.3.1.1 General Use.

Winter construction and placement of frozen fill for roads and work pads may be required due to rapid construction schedules, improved mobility during the winter, and the need to meet permit restrictions aimed at minimizing environmental impacts and disturbance of the tundra. Placement of fill in freezing weather requires careful planning and control to ensure performance is as intended. Roads are often constructed according to standards that differ from those applied to embankments supporting building foundations. For example, fill that is supporting structures may need to be kept in a thawed condition so the fill can be compacted before it freezes. Frozen fill may be suitable for roads so long as provision is made in the schedule to recompact the fill as it thaws in the summer.

12-3.3.1.2 North Slope.

Winter construction and placement of frozen fill for roads and pads is a common practice on Alaska's North Slope. Winter construction offers improved mobility and the ability to meet permit limitations on operations aimed at minimizing environmental impacts and tundra disturbance. This process generally requires a two-season operation. Sand and gravel used for roads and pads are mined in the winter and placed frozen, typically with 10% to 20% overbuild to allow for the thawing and settlement that occurs in the summer, when the material is reworked and compacted. Winter-placed gravel must be reworked to thaw and drain excess moisture before being compacted. Other factors to consider include breaking frozen clods of soil and preparation of the site to remove surficial snow and ice that may thaw and result in an unstable fill upon thawing.

12-3.3.1.3 Permanent Structures.

A different approach is applied for pads supporting permanent structures, such as those discussed by Prusak et al. in "Construction—Wintertime Compaction and LNG Facilities in Fairbanks, Alaska." In this instance, fill materials were pre-thawed and placement was closely monitored to ensure compaction could be achieved before the material began to freeze. Compaction was successful to temperatures of 20°F (−6.7°C).

12-3.3.2 Seasonal Considerations for Incorporating Insulation.

When insulation is incorporated into embankment design, the schedule for construction must be considered. If fill material is placed late in the season, the insulation has the effect of limiting winter cooling. In general, it is preferable to place insulation early in the construction season to help maintain the colder ground temperatures while site work is completed. If schedule constraints dictate that insulation must be placed in late summer or fall, when ground temperatures are at their warmest, it is prudent to review design assumptions and implement mitigations, such as adding extra cooling capacity to foundations where thermosyphons are being installed.

12-3.4 Site Improvement Methods.

Site improvement methods such as those described in the paragraphs that follow may be required if there is long-term potential for thawing at permafrost sites that can lead to a reduction of bearing capacity and an increase in liquefaction potential. The extent of ground improvement will depend on site history, design life, and anticipated changes in ground conditions over the life of the facility. These activities may add one or more years to project schedules, especially when there are seasonal access constraints, which are often associated with remote sites.

12-3.4.1 Ground Thawing.

12-3.4.1.1 General.

Ground thawing is used when post-construction conditions are expected to degrade over time due to high ice content, such as when permafrost areas thaw over the life of a facility. Ground thawing is often used in conjunction with other ground improvement techniques, such as deep dynamic compaction or vibrocompaction, because thawed ground will likely be loose and saturated. Application of another ground improvement technique is especially important in seismic areas to reduce the liquefaction potential of thawed areas.

12-3.4.1.2 Forced Ground Thawing.

Several methods are used to force ground thawing, including thaw points driven into the ground, thaw pipes placed in drilled holes, or heating mats placed on the ground surface. Construction planning must include consideration of dewatering that may be needed when the ground is thawed, as well as the potential for encountering site contamination. Clearing vegetation is also an effective method for thawing permafrost, but it may require several years before the site is thawed to sufficient depth for construction. This approach is limited to the Subarctic, where the air and permafrost temperatures are relatively warm.

12-3.4.1.3 Heating Probes.

Two F-35A aircraft hangar-facility projects designed and constructed by USACE at Eielson Air Force Base, Alaska, required initial ground thawing to mitigate potential differential settlement from discontinuous permafrost underlying the project sites. Ground thawing was accomplished using electric heating probes (0.75 in. diameter [19 mm]), wired to a 220 volt single-phase generator and installed within a 1.25 in. (32 mm) casing drilled to a final depth of 25 ft (7.6 m). The heating probes were placed on a 10 ft (3 m) grid pattern across the treatment area, with one thermistor string installed for every 12 heating probes to monitor the progress of permafrost thawing. In this case, electric heating probes (700°F [371°C] heating elements) were used instead of steam points to facilitate faster thawing and to avoid the introduction of water into the subgrade, which would complicate further site development. Well points were installed to extract thaw water and facilitate the circulation of heated water and thawing effect within the permafrost. The projects are in an area of high seismicity, with underlying soil strata that include thawed permafrost subject to seismic-induced liquefaction settlement. Accordingly, the sites were further improved by means of deep dynamic compaction (DDC).

12-3.4.2 Excavation and Replacement.

Excavation and replacement of thaw-susceptible soil ensures compaction and the long-term performance of the site. The availability of appropriate materials and suitable construction equipment will affect the economics and dictate the feasibility of this ground improvement method. Excavate in the spring when the ground is still frozen; however, depending on ground conditions, excavations may be difficult to perform or may require blasting. If excavations extend into summer, they must be dewatered so water does not pond in the excavation prior to backfilling. Well-trained quality assurance is needed to ensure excavation has reached the ice-poor to ice-free limits.

12-3.4.3 Thermosyphons.

12-3.4.3.1 Passive Cooling.

Passively cooled thermosyphons are used to maintain or reduce ground temperatures without the need for mechanical refrigeration systems.[3] Installations must be designed to provide adequate cooling capacity for site conditions, including understanding ground temperature and wind speeds at the site. Additional considerations are discussed in paragraph 8-5.5.4 and examples of thermosyphon installations are shown in paragraph A-10. Performance is related mainly to wind speed and finned condenser area, and it is important to place passively cooled thermosyphons to maximize their effectiveness and to group them in areas around a structure to avoid damage to the thermosyphons from snow removal or other maintenance activities. Include periodic monitoring and maintenance as part of integrity management and life-cycle planning.

Control of seepage and use of NFS materials is especially important when passive refrigeration, such as that discussed in paragraph 8-5.5.4, is installed as part of the foundation design to limit the potential for heave of the foundation elements as the ground refreezes. Ponded water should not be allowed to accumulate in excavations needed to install flat loop thermosyphon systems because this may result in excessive heaving beneath foundations.

12-3.4.3.2 Hybrid Systems.

There are also hybrid systems that incorporate an attachment that allows for use of a vapor compression refrigeration system to cool the condenser enough to activate the thermosyphon during every season. Further details can be obtained from the only licensed manufacturers in North America (in 2024): Arctic Foundations or Arctic Foundations Canada.

12-3.4.4 Active (Mechanical) Ground Freezing.

Active or mechanical ground freezing may be an option for some sites. This method is adaptable to many situations, provides relatively strong soil structures within a matter of months, and is easily reversible by applying heat. However, these systems have high energy requirements because they use circulating coolants that must be maintained at temperatures between −20°F (−29°C) and about −75°F (−59°C). For design and construction considerations, see Chapter 6 of *Frozen Ground Engineering,* by Andersland and Ladanyi. A case study, “Construction Ground Freezing—A Look at Modeled versus Measured Performance,” by Daggett et al., compares modeled to measured performance of mechanical ground freezing.

Another relatively simple approach to construction ground freezing involves blowing cold air into open pipe piles or along the face of excavations. This approach has been effective for enhancing freezeback around piles and temporarily cutting off the seepage of saline groundwater into open excavations during construction of utilidors in Utqiagvik.

[3] *Review of Thermosyphon Applications,* Wagner.

12-3.5 Methods of Site Improvement After Thawing.

Frozen ground that has been thawed will require site improvement using the same techniques as applied in temperate areas. These methods could include vibrocompaction, deep dynamic compaction (see paragraph 12-3.4.1) or other methods, such as wick drains or stone columns, to enhance consolidation. In seismically active areas such as Alaska, ground improvement may be required to provide stable foundation conditions for both permanent dead loads and earthquake-induced loads, to improve bearing capacity, to mitigate excess settlement that may occur, and to reduce the liquefaction potential. These ground improvement techniques are often proprietary to specialty contractors and may require an extra level of design analysis and specification development. Post improvement testing is required to demonstrate that the desired level of ground improvement has been achieved.

Two F-35A aircraft hangar-facility projects designed and constructed by USACE at Eielson Air Force Base, Alaska, required ground improvement by DDC after initial thawing of underlying discontinuous permafrost. DDC was performed to mitigate potential seismic-induced liquefaction settlement of the subgrade soils. The complete sequence of ground improvement consisted of (1) over-excavating near-surface soils subject to seasonal freeze and thaw; (2) thawing permafrost using electric heating probes; (3) preparing a stable excavation surface with several feet of classified fill; (4) performing DDC across the treatment area, extending 25 ft (7.6 m) beyond structural limits; and (5) after DDC, proof rolling the area with a large vibratory roller, with the addition of classified fill compacted in 12 in. (305 mm) lifts to 95% density per ASTM D1557, *Standard Test Methods for Laboratory Compaction Characteristics of Soil Using Modified Effort (56,000 ft-lbf/ft^3 (2,700 kN-m/m^3))*. DDC was accomplished using a 16 ton (14.5 metric ton) tamper dropped from a height of 50 ft (15 m), producing 4 ft (1.2 m) craters on a 10 ft (3 m) grid pattern. Each DDC point was subject to four to eight drops, with some areas needing a second pass to achieve the required degree of improvement. Ground improvement was verified by performing pre-DDC and post-DDC geotechnical borings, measuring the level of soil densification through the increase in standard penetration blow counts (modified ASTM D1586 using the large diameter split spoon sampler). The required level of ground improvement was achieved to the maximum target depth of 40 ft (12 m). Alternative ground improvement methods (such as vibrocompaction and permeation grouts) and deep foundations (driven piles) were considered during the design phase. DDC combined with ground thawing was selected as the best approach, with respect to cost, local experience, and suitability, for the specific ground conditions.

12-4 CONCRETE AND GROUT UNDER FREEZING CONDITIONS.

Concrete or grout can be used for anchors and foundation elements. However, poured concrete requires careful mix design so the concrete has sufficient time to cure before freezing and because the concrete may include admixtures. The foundation may need to be protected from cold air temperatures or placed inside a tented structure during curing. For footings in remote locations, prefabricated footings that can be placed on a vessel for transport are often used instead of poured footings.

For further information on mix design and placement of concrete under freezing conditions, see the following publications:

- ACI 306R
- *Creep Behavior of Shallow Anchors in Ice-Rich Silt,* by Zhang et al.
- “Development of Innovative Antifreeze Grout Mortar for Anchor Applications in Cold Regions,” by Lin et al.
- *Design and Construction of Foundations in Areas of Deep Seasonal Frost and Permafrost,* by Linell and Lobacz
- *Cold Region Structural Engineering,* by Eranti and Lee
- *Construction in Cold Regions, A Guide for Planners, Engineers, Contractors, and Managers,* by McFadden and Bennett

Refer to UFC 3-130-01 for requirements on placing concrete.

CHAPTER 13 PERFORMANCE MONITORING AND MAINTENANCE

13-1 GENERAL.

Well-designed and -implemented performance monitoring programs are used to inform decisions about maintenance activities that are necessary for preserving the original capital investment and performance of structures. Monitoring includes measuring ground temperatures in permafrost areas, measuring deformation for critical foundation components, and visual inspection, and is linked to baseline measurements, established performance criteria, and clear data recording standards.

Management of geotechnical monitoring data is an evolving area or practice without specific guidance used to help optimize operations and maintenance. It has most commonly been applied to linear infrastructure and can be relatively simple (such as documenting end-of-construction conditions and periodic monitoring) or can involve more extensive data acquisition and monitoring linked to risk and cost–benefit analyses. Detailed guidance related to geotechnical asset management for transportation projects can be found in *Geotechnical Asset Management for Transportation Agencies*, by the National Cooperative Highway Research Program, or a library of online resources found on the Ohio Department of Transportation website (https://www.transportation.ohio.gov/working/engineering/geotechnical/asset-management/asset-management#page=1).

13-1.1 Ground Temperature.

Ground temperature is one of the most important and commonly measured parameters for assessing the capacity and performance of foundation systems where frozen ground is present. A ground temperature monitoring system, consisting of temperature sensors installed at various locations and depths, provides early warning to managers and engineers about changing conditions that risk foundation damage.[1] Ground temperature in North America is typically measured using thermistor strings or digital temperature cables with known calibrations of output to temperature. Other methods of measuring ground temperature, such as thermocouples, may also be appropriate; consult with the geotechnical engineer of record for additional guidance. Ground temperature monitoring systems can be coupled with data loggers and installed at many locations. For remote installations, solar-powered systems with satellite uplinks may be used to provide real-time monitoring and analysis of data. Other techniques for measuring ground temperature are discussed in Chapter 3 of *Thermal Analysis, Construction, and Monitoring Methods for Frozen Ground,* by Esch.

Ground temperature measurement is especially important for flat loop thermosyphon systems or active refrigeration systems, like those used in mainline refrigeration units along the Trans-Alaska Pipeline System. Because these systems are difficult or impossible to access, instrumentation must be installed at the time of construction and

[1] *Improving Design Methodologies and Assessment Tools for Building on Permafrost in a Warming Climate,* Bjella et al.

include redundant sensors. Regularly calibrate sensors because the data from many of the sensors on the market today will drift over time.

13-1.2 Settlement, Tilt, and Lateral Movement.

Settlement, tilt, and lateral movement of structural foundation elements are common measures of foundation performance. Settlement and tilt are determined by conventional optical survey measurements, although there are tilt meters and crack monitoring gauges that allow continuous measurement of these parameters. Gauges are used in temperate climates and are deployable for cold climate applications, provided they are also winterized.

Settlement can also be monitored using drone-based or ground-based lidar surveys and high-resolution remote sensing data, such as interferometric synthetic aperture radar, for large or remote sites. However, the accuracy of these surveys, especially those involving remote sensing, must be checked. Survey control may be needed to improve accuracy, and survey monuments will need to be designed to resist frost movement. Features included in these types of monuments are illustrated in Figure 5.1 of *Design and Construction of Foundations in Areas of Deep Seasonal Frost and Permafrost,* by Linell and Lobacz. They require a casing around the survey marker that is filled with a media such as silicone oil or a wax-oil mixture. The marker must be anchored into permafrost deeper than the estimated depth of thawing anticipated over the life of the marker.

13-1.3 Groundwater.

Groundwater can be a significant factor in the stability of embankments or foundation systems. Conventional systems (such as open standpipes or pressure transducers) provide simple and effective measurements in areas of seasonal frost or below the base of permafrost. However, both systems will freeze, and pressure transducers are not well suited to long-term measurements in freezing conditions unless the system is winterized. Geophysical surveys like those discussed in UFC 3-130-02 are also commonly used to identify thawed areas and unfrozen zones within permafrost.

13-1.4 Visual Inspection.

Specific observations and the frequency of inspections will vary depending on the structure, but examples include noting the condition of thermosyphons, blocked airflow below elevated structures, fluids leaking from elevated structures, and out-of-level doors, windows, and floors. Other features worthy of notice during a visual inspection include cracks developing within structures and pavements; changes in grade, areas of subsidence, and tension cracks in the ground external to structures; differential movement and disturbance of utilities entering buildings; and evidence of site modifications that may pose future facility instability issues, such as removal of vegetation, which will increase the risk of thaw degradation.

13-2 MAINTENANCE OPERATIONS.

Well-planned and -implemented monitoring programs provide indications of developing stability problems before they affect the structure. Catastrophic acute foundation failures are rare, but chronic problems can occur in the Arctic and Subarctic due to inappropriate engineering or unforeseen site conditions in design and construction. Chronic problems related to thawing permafrost may not become apparent until well after construction, but ground temperature monitoring like that discussed in paragraph 13-1.1 can help prevent disastrous outcomes. Examples of this monitoring include identifying areas where ground temperatures are higher than desired due to heat inputs from the structure, identifying areas of the site with high local ground-ice contents, measuring lateral translation, and measuring settlement (either locally or area-wide) to make sure it is not excessive.

13-2.1 Operational Impacts to Consider.

Normal day-to-day facility activities can affect the thermal regime and the support capacity of foundations. Plowing snow away from structures maintains colder permafrost temperatures, avoids thawing of ground ice, and prevents the resulting localized thaw settlement and structure damage. If snow drifts are not cleared or if plowed snow is stockpiled, the insulating effect will change the local thermal regime and can warm up the underlying permafrost soils and, over time, trigger permafrost degradation that can affect the structure performance. Similarly, blowing snow into ditches adds insulation in these areas and contributes to ponding near the toe of embankments. Preparing an operations manual will provide guidance to the maintenance team over the long term, thus improving the performance of foundations.

13-2.2 Mitigation Measures.

Develop appropriate mitigation measures to address observed movement or foundation distress based on an understanding of the cold regions design principles and criteria provided in previous paragraphs. Examples of mitigation measures include the following:

- Adding additional ground cooling capacity to a facility.
- Redirecting drainage to eliminate the added heat loss and associated permafrost degradation caused by flowing water.
- Incorporating adjustable foundation elements.
- Changing the surface energy balance by managing vegetation.

This Page Intentionally Left Blank

APPENDIX A BEST PRACTICES

A-1 INTRODUCTION.

The Best Practices Appendix is considered to be guidance and not requirements. Its main purpose is to communicate proven facility solutions, systems, and lessons learned but may not be the only solution to meet the requirement. It identifies additional background information and practices for accomplishing the design of foundations for freezing and thawing conditions. The DoR is expected to review and interpret this guidance and apply the information according to the needs of the project. If a Best Practices document has guidelines or requirements that are not discussed in the Unified Facilities Guide Specifications (UFGS) or UFC, the DoR must submit a list of the guidelines or requirements being used for the project, with sufficient documentation, to the Government Project Manager for review and approval prior to incorporation within the design.

A-2 CANADIAN EXPERIENCE.

Various guides and national standards have been developed for use in Canada, including some by the government of the Northwest Territories. These guides and standards contain performance guidelines, design data, preferred materials and methods, and logistical considerations developed from decades of experience with the design and construction of foundations in the Canadian north. Over time, certain products and approaches to constructing foundations have proven successful and have been adopted by design consultants and builders working in the Canadian north. These guidelines and standards should be reviewed as they document both failures and successes in foundation construction and durability in cold regions. Publications relevant to foundations in cold regions include the following:

- *National Standard of Canada CAN/BNQ 2501-500/2017: Geotechnical Site Investigations for Building Foundations in Permafrost Zones*, by the Bureau de Normalisation du Quebec
- Chapter 13 of the *Canadian Foundation Engineering Manual*, by the Canadian Geotechnical Society, for an alternative approach for estimating frost heave potential is to measure the segregation potential of the soil

A-3 OTHER CODES AND STANDARDS.

The effects of these various codes and standards will vary, as will the way specific requirements may need to be handled on a project. Extensive literature is published by sources in the U.S. (such as the American Petroleum Institute, International Code Council, International Conference of Building Officials) and by the National Research Council Canada and the European Union, but there is no prescriptive code requirement for foundation design in permafrost regions. Russia, however, has developed an extensive body of regulatory documents, which include a series of national building codes, standards, territorial building codes, and guiding regulations with specific design criteria for permafrost areas. Resident professionals who are familiar with the specific requirements in the project area are a valuable resource to consult during project planning to confirm local practice and avoid delays in project design approval and construction.

A-4 PLANNING AND DESIGN CONSIDERATIONS.

Military installations in cold regions may be self-contained or connected to existing public or industrial infrastructure. Where public or private infrastructure exists, specific standards and practices for construction may need to be followed. Other installations own, operate, and maintain their own facilities. For those installations, direction from the installation staff, often in the form of installation facilities standards (IFS), should be solicited and followed. New installations may benefit from the guidance used at existing military installations or local municipalities. Revegetation after construction should follow applicable IFS guidance and local requirements. IFSs are available on the WBDG at https://www.wbdg.org/airforce/ifs.

Modular construction, where an entire facility or a major component of a facility is preassembled and shipped via barge or sled to the point of use, has been used at oil field developments on the northern coast of Alaska. It is advantageous in these locations because the construction season is short and labor costs are relatively high. Barges can usually begin to arrive in Utqiagvik, Alaska, and the eastern Arctic around the first of September. This means the nonmodular construction materials must be shipped a year in advance and stockpiled for the next construction season. Facilities may also be built on-site using basic structural materials, or significant components (such as mechanical assemblies) may be preassembled at the point of manufacture. The approach adopted depends on logistical limitations specific to each site, and the use of modular construction needs to be discussed with the design team on a case-by-case basis. Prefabrication of foundation assemblies has been shown to be cost-effective in remote locations and locations with a high cost of labor.

A-5 CLIMATE CHANGE CONSIDERATIONS.

A-5.1 Intergovernmental Panel on Climate Change.

The IPCC provides a common source of information relating to emission scenarios, provides third-party reviews of models, and recommends approaches to documenting future climate projections. Periodically, the IPCC issues assessment reports summarizing the current state of climate science. The most current complete synthesis of information regarding climate change must be used in climate analyses. The IPCC does not run the models but acts as a clearinghouse for the distribution and sharing of the model forecasts.

In the IPCC Fifth Assessment Report (AR5), which consists of Working Group Reports and a Synthesis Report, potential scenarios for future climate are designated as RCPs, while in the IPCC Sixth Assessment Report (AR6), SSPs are used. Both sets of scenarios include a suffix that specifies the radiative forcing projected to occur by 2100. For example, SSP2-4.5 denotes a pathway that is characterized by climate change mitigation and adaptation options of SSP2, which would result in 4.5 watts per square meter of radiative forcing by 2100 (like RCP4.5). Compared to AR5, a wider range of scenarios are provided in AR6, covering an updated set of pathways by which future climate may unfold. The RCP and SSP scenarios for similar radiative forcing values provide comparable trajectories of future climate. For example, both SSP1-2.6 and RCP2.6 are characterized by sustainable development proceeding at a reasonably high pace. Similarly, both SSP5-8.5 and RCP8.5, which are commonly considered for work in Arctic areas, are characterized by high greenhouse gas emissions.

A-5.1.1 IPCC Fifth Assessment Report (AR5).

Documents from the AR5:

- *Climate Change 2013: The Physical Science Basis, Contribution of Working Group I to the Fifth Assessment Report of the Intergovernmental Panel on Climate Change*, Stocker et al.
- *Climate Change 2014: Impacts, Adaptation, and Vulnerability. Part A: Global and Sectoral Aspects, Contribution of Working Group II to the Fifth Assessment Report of the Intergovernmental Panel on Climate Change*, Field et al.
- *Climate Change 2014: Impacts, Adaptation, and Vulnerability, Part B: Regional Aspects, Contribution of Working Group II to the Fifth Assessment Report of the Intergovernmental Panel on Climate Change*, Barros et al.

A-5.2 Downscaling Climate Data and Sources.

A-5.2.1 Scenarios Network for Alaska + Arctic Planning (SNAP).

Downscaled climate data for the Arctic and Subarctic is available through the SNAP project at University of Alaska Fairbanks. The SNAP website (https://uaf-snap.org/climate-tools/) includes a collection of tools that use downscaled climate data to estimate projected changes in a variety of different climate variables and scenarios, such as those noted in paragraph A-5.1. The tools that follow can be found at the SNAP website:

- Community Climate Charts
- Precipitation Projections for Alaska Infrastructure
- Community Wind Data
- Arctic Environmental and Engineering Data + Design Support System (Arctic-EDS)

A-5.2.2 Climate Data Portals.

Climate data portals can provide climate projections that are readily accessible and provide regional or global coverage. Examples include the following:

- IPCC Interactive Atlas (https://interactive-atlas.ipcc.ch/)
- World Bank Climate Change Knowledge Portal (https://climateknowledgeportal.worldbank.org/)

These portals provide information for both AR5 and AR6. However, they may not provide enough information for design applications, which require higher resolution climate data (see paragraph A-5.2.3). The projections available from these portals can be used to understand how downscaled climate projections compare to regional or global projections and how downscaled projections from AR5 compare to projections from AR6. Climate data portals are often updated much faster than daily downscaled data and provide good summaries of the most recent projections.

A-5.2.3 Daily Downscaled Climate Data.

Daily downscaled climate projections can be downloaded from SNAP and from a variety of other sources at a daily resolution. One example is NASA's NEX-GDDP, which provides projections of total precipitation, wind speed, relative humidity, solar radiation, and mean, minimum, and maximum temperature for an ensemble of climate models and emissions scenarios.

A-6 CLIMATE AND CONTINUAL IMPROVEMENT.

USACE evaluated climate risk in the design process for shore protection at Utqiagvik, Alaska. First, a climate change dataset was developed to establish projected changes in air temperature over time using an ensemble of climate models and scenarios. Using this dataset, thermal analyses were conducted to assess the potential for an eroding permafrost slope to thaw, based on the planned construction and potential changes in future climate. This is an example of the first stage of the MAC process for assessing climate risks. Details of each stage of the MAC process are described below.

A-6.1 First Stage.

The initial stage of the MAC process involves the assessment of climate risks. For engineering foundation design, this includes establishing historical climate conditions and obtaining projections of future climate conditions for climate-related design parameters. Climate risk thresholds may then be established for when key climate parameters may affect the foundation designs. Depending on the projected changes, the uncertainty in these parameters, and the sensitivity of the foundation design, climate risks may be identified and ranked. These risks may depend on a given climate parameter meeting or exceeding a predefined value.

A-6.2 Second Stage.

In the second stage of the MAC process, adaptation options are developed to address the climate risks identified in the first stage. Adaptation pathways provide decision-making support on when to implement the adaptation options. For engineering foundation design, this may include adjusting the initial design to account for projected climate changes or developing provisional measures that can be phased into the project over time as climate risk thresholds are reached.

A-6.3 Third Stage.

The final stage of the MAC process involves monitoring and surveilling designs at climate risk thresholds established in the first stage. Given the level of uncertainty involved in future climate projections, this step acts to confirm the risks identified in the first stage and the adaptation options implemented in the second stage as new information becomes available. This information may include new on-site observations or updated climate projections. If climate risk thresholds are approached or met, the MAC process cycle may be repeated with this new information.

A-7 SLOPE GEOHAZARDS.

When selecting building sites or routes for linear infrastructure, it is important to remember that slopes in permafrost areas migrate downslope over time due to the force of gravity, depending on ground ice content, active layer moisture, and ground ice temperature. The slope movements constitute geohazards that must be considered when planning a project. Table A-1 lists some of the more common slope processes, the relative speed at which they occur, and related engineering issues. Figure A-1 through Figure A-5 show representative examples of some geohazards. Additional illustrations of permafrost features are found in the following:

- *Glossary of Permafrost and Related Ground-Ice Terms*, by Harris et al.
- *Permafrost, A Guide to Frozen Ground in Transition*, by Davis
- *The Periglacial Environment*, by French

- *Geocryology: Characteristics and Use of Frozen Ground and Permafrost Landforms*, by Harris et al

Table A-1 Slope Processes and Related Engineering Concerns

Speed of Process	Process	Description	Engineering Issues
Slow	Solifluction	• Geomorphic features produced by solifluction include uniform sheets of locally derived surficial materials and tongue-shaped lobes.[1] • Can occur on slopes as low as 3°.[2]	• Disturbing solifluction lobes, when or as they are thawed, can cause slides to occur. • Structures located on these lobes can move or be disturbed, including localized impact on piles.
	Creep	• Related primarily to the presence of ice within soil.	• Structures can move or be disturbed.
Intermediate to rapid	Frozen debris lobe	• Described in “Frozen Debris Lobe Morphology and Movement: An Overview of Eight Dynamic Features, Southern Brooks Range, Alaska” by Darrow et al.	• Structures can be displaced or disturbed. • Can result in severe structure damage, entire loss, or need to relocate.
	Thermo-erosion gullying	• See definition in paragraph B-3 • This process is occurring in the upland silts of interior Alaska.	• These features can cause sinkholes and instability, most commonly in horizontal structures.
Rapid	Active-layer detachment	• Common on colluvial slopes in areas of fine-grained, ice-rich deposits, where they occur as shallow slumps. • Occur more frequently during warm summers or following disturbance of the vegetation or ground surface by, for example, tundra or forest fires or engineering activity, when the depth of thaw is greater than normal.[3]	• Structures can move or be disturbed. • Detachment failures that expose massive ice or icy sediments can develop into retrogressive thaw slumps.
	Thaw slumping	• Geomorphic features produced by thaw slumping are retrogressive thaw slumps. These can be large features with an exposed face more than several meters high with a long crest length.	• Structures will likely move or be disturbed. • Can result in severe structure damage and entire loss.

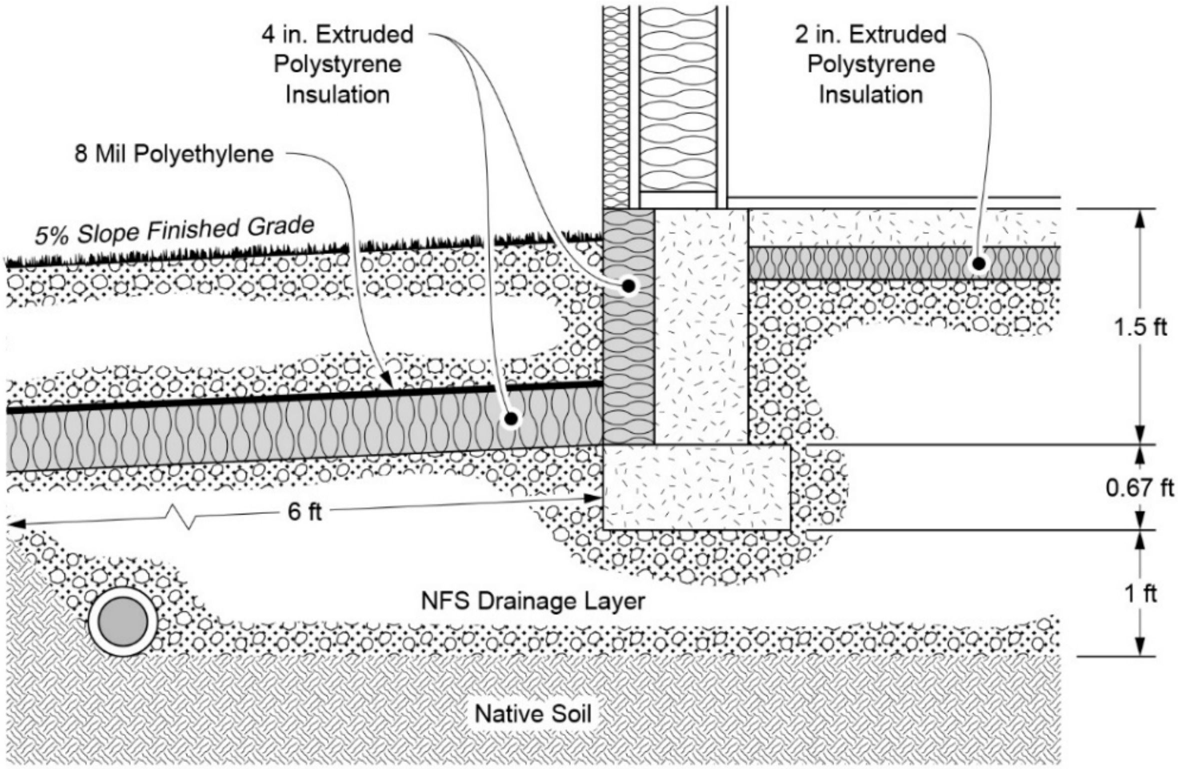
A-8 FROST PROTECTION.

Frost effects on foundations are discussed in paragraphs 7-5 and 7-6. Frost effects include frost jacking due to frost heave in seasonally frozen ground, basal or upward thrust when soil beneath footings freezes and heaves, and lateral thrust on retaining walls due to freezing of the ground. General measures to mitigate frost effects on foundations include isolation of deep foundations within the freezing soil or deeper installation to provide sufficient uplift to resist frost heave forces, flanges to increase uplift resistance, use of NFS material to reduce capillary action and formation of ice within the freezing soil, and drainage to cut off water that may migrate to the freezing front and enhance formation of ice within the freezing soil. *Cold Region Structural Engineering,* by Eranti and Lee, provides further discussion.

Figure A-6 illustrates a frost-protected shallow foundation used in seasonal frost areas to mitigate formation of frost beneath footings though a combination of insulation and heat flow through the building foundation (see paragraph 7-5.3). The effects of floor insulation used to improve energy efficiency must be carefully considered if heat flow is being relied on to prevent frost formation and may require adjustment of design parameters.

Figure A-6 Example of Frost-Protected Shallow Foundation



Source: Reproduced from *Shallow Insulated Foundation at Galena, Alaska: A Case Study,* by Danyluk, Figure 4.

A-9 FOUNDATION OPTIONS.

There are many options and design variations for shallow and deep foundations in Arctic and Subarctic areas, depending on site-specific conditions and facility requirements. Granular pads may be part of a building foundation subsystem or a foundation for horizontal structures. Pads should be constructed from NFS material, and they may incorporate passive or active cooling, insulation, ventilation, or some combination of these thermal techniques to mitigate heat flow from structures, maintain the existing thermal regime, and minimize frost heave potential. Table A-2 presents a partial list of foundation types, but options continue to evolve as new technologies are developed or environmental conditions dictate adaptations.

Table A-2 Partial List of Foundation Types

Shallow Foundation	Deep Foundation	Foundation Subsystem
• Spread footing • Post and pad • Raft foundation • Structural slab • Frost protected	• Slurry piles • Driven piles • Drilled (helical) piles • Adfreeze piles • Passively cooled piles (thermopile or thermosyphon) • End bearing piles • Shear piles • Micropiles • Vibe piles	• Granular pad • Insulated pad • Passively cooled (thermosyphon) pad • Ventilated pad (ducts, air cooled embankment) • Combination of the above

Examples of shallow foundations like those discussed in Chapter 8 are presented in Figure A-7 through Figure A-10 for conditions where permafrost is present. Figure A-8 and Figure A-9 also illustrate how the permafrost level can aggrade into thick foundations when climatic conditions are favorable.

A-10 THERMOSYPHONS.

Thermosyphons like those discussed in paragraphs 8-5.5.4 and 9-3 are widely used to provide passive cooling of foundation systems in permafrost areas. They are used in both single pipe flat loop configurations, as discussed in *Review of Thermosyphon Applications,* by Wagner, and shown conceptually in Figure A-11 and Figure A-12. Vertical thermosyphons can be configured to fit within a pile or be installed adjacent to them, or a pile can be built as a thermosyphon. Hybrid thermosyphons are another configuration that uses a low-energy chiller below the condenser to activate the thermosyphon when the ambient air temperature is above freezing. Figure A-13 and Figure A-14 present representative thermosyphon applications.

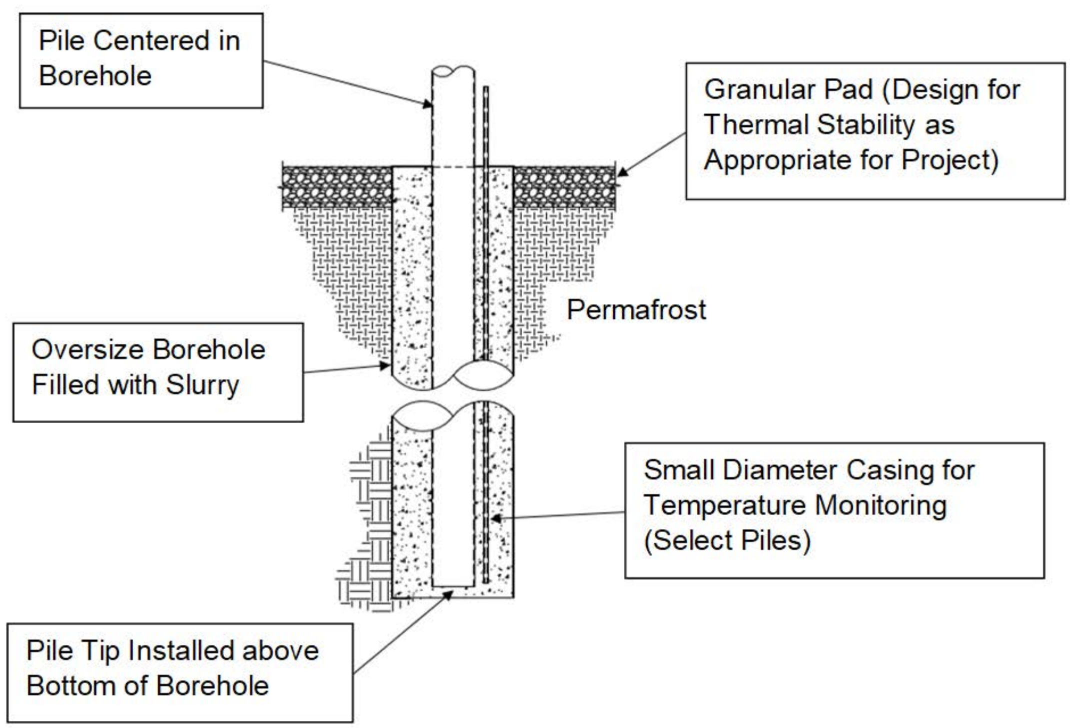
A-11 EXAMPLE PILE INSTALLATIONS.

As described in Chapter 9, piles can be configured in many ways, depending on specific foundation design criteria and structural support requirements. In North America (in 2024), steel piles are the most common type used for industrial applications, but timber piles were historically used extensively and may be encountered in existing facilities. Concrete piles are also used in permafrost areas, but to a lesser extent than steel piles. The designer should be familiar with local practices and the availability of pile materials.

A-11.1 Slurry Piles.

Figure A-15 illustrates a simple slurry pile installed in permafrost. This type of pile is generally supported by adfreeze between the pile and slurry, and the design for long-term compressive loads is typically controlled by the allowable creep rate defined in the foundation design criteria. Conventional adfreeze piles are installed with their tip above the bottom of the borehole as they typically do not include an end-bearing component. Additionally, adfreeze piles are often fixed-length with a prefabricated cap, so suspending them in the hole allows the cap to be precisely set. Many adfreeze piles are also installed open ended; and slurry at the base is preferable to icy cuttings. However, piles can bear on the bottom and be cut off to design elevation depending on details of the connection and other design requirements. For ice-poor conditions, other configurations may be appropriate, as indicated in Chapter 9.

Figure A-15 Example Slurry Pile



A-11.2 Pile Drilling.

Specialized drilling equipment like that shown in Figure A-16 may be required to advance oversize boreholes in permafrost.

Figure A-16 Example Drilling Oversize Borehole (North Slope, Alaska)

Photo courtesy of WSP USA.

A-11.3 Helical Piles.

The capacity and creep resistance of adfreeze piles may be increased by use of shear plates or a helical wrap like those shown in Figure A-17. Figure A-18 shows finished thermo-helix piles supporting a large, elevated structure. The thermo-helix piles are a thermopile with the addition of helical wrap. Helical piles like that shown in Figure A-19 may be an efficient option for some types of structures, especially when clearances are tight. The success of the installation depends on ground conditions and available equipment.

Figure A-17 Example Helical Shear Piles

Photo courtesy of Arctic Foundations.

Note: The coating at the top of the pile is to reduce solar radiation gain and provide corrosion protection in the active layer.

APPENDIX B GLOSSARY

B-1 INTRODUCTION.

The following acronyms and terms are used in this document and are specific to cold regions foundation engineering, design, and construction. UFC 3-130-01 provides a more comprehensive list of acronyms and terms for general cold regions engineering.

B-2 ACRONYMS.

1D	One-dimensional
2D	Two-dimensional
3D	Three-dimensional
AR5	IPCC Fifth Assessment Report
AR6	IPCC Sixth Assessment Report
ASCE	American Society of Civil Engineers
ASTM	American Society for Testing and Materials
BIA	Bilateral Infrastructure Agreements
BNQ	Bureau de Normalisation du Quebec
C	Celsius
DDC	Deep Dynamic Compaction
DoD	Department of Defense
DoR	Designer of Record
EM	Engineering Manual
EPS	Expanded Polystyrene
F	Fahrenheit
FGS	Final Governing Standards
FS	Factor of Safety
ft	Foot
ft^2	Square Foot
ft^3/s	Cubic Foot per Second

GCM	Global Climate Model
HNFA	Host Nation Funded Construction Agreements
IBC	*International Building Code*
in.	Inch
IPCC	Intergovernmental Panel on Climate Change
kg/m^3	Kilogram per Cubic Meter
km	Kilometer
kPa	Kilopascals
kph	Kilometer per Hour
lb/ft^3	Pound per Cubic Foot
m	Meter
m^2	Square Meter
m^3/s	Cubic Meter per Second
MAC	Mining Association of Canada
mi	Mile
mm	Millimeter
MPa	Megapascal
mph	Mile per Hour
NASA	National Aeronautics and Space Administration
NEX-GDDP	Earth Exchange Global Daily Downscaled Projections
NFS	Nonfrost-susceptible
OEBGD	*Overseas Environmental Baseline Guidance Document*
ppt	Part per Thousand
psi	Pound per Square Inch
RCP	Representative Concentration Pathway
SEI	Structural Engineering Institute

SNAP	Scenarios Network for Alaska + Arctic Planning
SOFA	Status of Forces Agreements
SSP	Shared socioeconomic pathway
UFC	Unified Facilities Criteria
USCS	Unified Soil Classification System
XPS	Extruded Polystyrene

B-3 DEFINITION OF TERMS.

Active layer detachment: A slope failure in which the thawed or thawing portion of the active layer detaches from the underlying frozen material.

Adfreeze: The process by which two objects adhere to each other via ice.

Aufeis: The type of ice that forms when water emerges from the ground under freezing conditions and is exposed to extremely cold air.

Basal heave: An upward normal force that acts on base, or bottom face, of shallow foundations or pile caps that bear within the frost depth.

Frozen debris lobe: Elongated, lobate permafrost features that mostly move through shear in zones near their bases.

Granular soil: Gravel, sand, or silt with little or no clay content.

Horizontal structures: Roads, airfields, and similar structures.

Longwave radiation: Electromagnetic thermal radiation emitted by Earth's surface, atmosphere, and clouds.

Multichannel analysis of surface waves: A seismic method that measures the shear-wave velocity distribution, which can be used to determine the depth to bedrock and shear strength or soil stability. This can be used in liquefaction studies, sinkhole mapping, fault mapping, and assessments of earthquake resilience.

Radiative forcing: The change in energy flux in the atmosphere caused by natural or anthropogenic factors of climate change as measured in watts per meter squared (W/m^2).

Sensible energy: The energy that causes a change in temperature of a substance without phase change. This is also the energy felt by humans as heat. It is the amount of energy needed to increase or decrease the temperature of a substance.

Shortwave radiation: Incoming ultraviolet, visible, and a limited portion of infrared energy from the sun.

Surface energy balance: Balance between all surface energy inputs and outputs at the surface over a given interval of time.

Talik: A perennially unfrozen zone below the active layer or within permafrost. Taliks may penetrate the permafrost (a "through talik") or be a zone between the active layer and the top of the permafrost.

Thaw degradation: Change in thermal state from frozen to thawed, usually accompanied by volume change in excess moisture from thawed ice structures.

Thaw points: Pipes that allow steam to be used to enhance thawing of permafrost.

Thaw-stable material: Frozen soil or rock that undergoes minimal volume change or strength loss when it thaws, such as clean granular soil or quarry rock without interstitial ice.

Thaw strain: The amount that frozen ground compresses upon thawing.

Thaw-unstable material: Frozen soil or rock with total ice content greater than its water content under normal consolidation conditions.[1] Also referred to as *thaw-sensitive* or *ice-rich*.[2] Thaw-unstable material will lose significant strength and settle when it thaws. An example of this material is fine-grained soil with a significant volume of interstitial ice. Rock also may be thaw unstable when fractured and containing significant ice within the rock structure.

Thermo-erosion gullying: Thawing permafrost can result in ground-ice erosion and sediment displacement (thermo-erosion), which can lead to permafrost tunneling and development of gully networks. A combination of mechanical erosion and gravitational processes results in soil subsidence and channel inclusions, resulting in a mixing of soil horizons and continued erosion of adjacent soils. Thermo-erosion gullies enlarge both retrogressively upslope and through deepening and widening of the initial incision.

Thermopile: A structural pile built to function as a thermosyphon.

Thermosyphon: A passive refrigeration device charged with a two-phase working fluid, such as carbon dioxide (CO_2) (in liquid and gaseous states), that uses natural convection to passively exchange heat between the ground and environment without a mechanical pump.

Transient layer: An ice-rich zone that acts as a thermal buffer to protect the underlying permafrost due to its relatively higher ice content and the significant heat needed to thaw this layer.

Trumpet curve: The envelope of ground temperature bounding all whiplash curves. The shape and limits of the trumpet curve may shift right or left depending on ground

[1] *Frozen Ground Engineering*, Andersland and Ladanyi.
[2] *Glossary of Permafrost and Related Ground-Ice Terms*, Harris et al.

temperature and with time at a given site in response to changes in ground temperature.

Vertical structures: Buildings, towers, and similar structures.

Whiplash curve: Ground temperature at a given moment; in aggregate, these form the trumpet curve.

FOREWORD

The Unified Facilities Criteria (UFC) system is prescribed by MIL-STD 3007 and provides planning, design, construction, sustainment, restoration, and modernization criteria, and applies to the Military Departments, the Defense Agencies, and the DoD Field Activities in accordance with USD (AT&L) Memorandum dated 29 May 2002. UFC will be used for all DoD projects and work for other customers where appropriate. All construction outside of the United States, its territories, and possessions is also governed by Status of Forces Agreements (SOFA), Host Nation Funded Construction Agreements (HNFA), and in some instances, Bilateral Infrastructure Agreements (BIA). Therefore, the acquisition team must ensure compliance with the most stringent of the UFC, the SOFA, the HNFA, and the BIA, as applicable.

UFC are living documents and will be periodically reviewed, updated, and made available to users as part of the Military Department's responsibility for providing technical criteria for military construction. Headquarters, U.S. Army Corps of Engineers (HQUSACE), Naval Facilities Engineering Systems Command (NAVFAC), and Air Force Civil Engineer Center (AFCEC) are responsible for administration of the UFC system. Technical content of UFC is the responsibility of the cognizant DoD working group. Defense Agencies should contact the respective DoD Working Group for document interpretation and improvements. Recommended changes with supporting rationale may be sent to the respective DoD working group by submitting a Criteria Change Request (CCR) via the Internet site listed below.

UFC are effective upon issuance and are distributed only in electronic media from the following source:

- Whole Building Design Guide website http://www.wbdg.org/dod.

Refer to UFC 1-200-01, *DoD Building Code*, for implementation of new issuances on projects.

TABLE OF CONTENTS

CHAPTER 1 INTRODUCTION

1-1 BACKGROUND.

The field of Arctic and Subarctic engineering, also known as cold regions engineering, covers a wide range of multidisciplinary topics and principles. Unique issues exist in the planning, design, construction, and operation of infrastructure and facilities in Arctic and Subarctic regions. Among them are permafrost, seasonal ground frost heave and thaw settlement, extreme low temperatures, high wind loads, heavy snow loads, and remote construction sites. Additionally, the implications of the rapidly changing climate in Arctic and Subarctic regions exacerbate these unique challenges.

The Unified Facilities Criteria (UFC) Arctic and Subarctic series includes five volumes that summarize relevant information and the most feasible approaches and solutions for planning, design, construction, and maintenance of infrastructure and facilities in the Arctic and Subarctic areas of the globe.

1-2 REISSUES AND CANCELS.

This document supersedes and cancels inactivated UFC 3-130-07, 16 January 2004.

1-3 PURPOSE AND SCOPE.

The Arctic and Subarctic UFC series provides technical guidance and available technical requirements for planning, design, construction, and maintenance of DoD facilities worldwide for all service elements in Arctic and Subarctic environments. These guidance and technical requirements are based on the International Building Code (IBC) and the requirements in UFC 1-200-01. The UFC 3-130 series covers many aspects of Arctic and Subarctic engineering with the specific exception pavements, which is incorporated into the UFC 3-250 and 3-260 series as discussed in UFC 3-130-01, paragraph 1-6.3. In addition to this volume, there are four other series volumes:

- UFC 3-130-01, *Arctic and Subarctic Engineering*. UFC 3-130-01 serves as an introduction to the Arctic and Subarctic UFC series.
- UFC 3-130-02, *Arctic and Subarctic Site Assessment and Selection*. UFC 3-130-02 provides applicability and technical guidance for geotechnical site assessment for the Arctic and Subarctic environment conditions.
- UFC 3-130-03, *Arctic and Subarctic Foundations for Freezing and Thawing Conditions*. UFC 3-130-03 includes horizontal and vertical foundations, considerations affecting foundation design, and construction and monitoring of facilities in the Arctic and Subarctic areas.

- UFC 3-130-05, *Arctic and Subarctic Utilities*. UFC 3-130-05 provides criteria and guidance for the design of utility systems for military facilities in Arctic and Subarctic regions.

This UFC provides criteria and guidance for the planning, design, and construction of DoD-owned facilities in Arctic and Subarctic regions. Only criteria and guidance unique to cold regions (the Arctic and Subarctic) are provided. The Arctic and Subarctic regions present unique challenges in every aspect of facility planning, design, construction, operation, and maintenance. Refer to UFC 3-130-01 for background and general criteria for Arctic and Subarctic engineering. This UFC references the fundamental building design and construction requirements from UFC 1-200-01, and the associated core UFCs and the UFCs referenced therein. It adapts those criteria for Arctic and Subarctic conditions, and transitions activities from completed Installation Master Planning, Area Development Plans, or other planning products described in UFC 2-100-01.

1-4 APPLICABILITY.

This UFC follows the same applicability as UFC 1-200-01, paragraph 1-3, for those geographic locations in Arctic and Subarctic regions worldwide.

1-5 GENERAL BUILDING REQUIREMENTS.

This UFC is an integrated part of the Arctic and Subarctic UFC 3-130 series. Use the other documents of this series in conjunction with this UFC to address construction aspects unique to cold regions. See UFC 3-130-01, Chapter 2 for the definitions of Arctic and Subarctic.

Often, conventional construction practices are acceptable in Arctic and Subarctic regions with appropriate modification to account for extreme cold temperatures, frost heaving soils, and permafrost areas. This UFC modifies and supplements the criteria found in the core UFCs. Utility provider’s or Installation specific requirements must be considered.

1-6 LEVEL OF CONSTRUCTION.

See UFC 1-200-01, paragraph 1-3.2, for the definitions of permanent construction, temporary construction, and facilities in support of military operations.

1-7 CYBERSECURITY.

Facility-related control systems (including systems separate from a utility monitoring and control system) must be planned, designed, acquired, executed, and maintained in accordance with UFC 4-010-06, and as required by individual Service Implementation Policy.

1-8 BEST PRACTICES.

Appendix A contains guidance rather than requirements. It communicates proven facility solutions, systems, and lessons learned, but these are not the only solutions that meet requirements. It identifies additional background information and practices for accomplishing building design and construction. The Designer of Record (DoR) must review and interpret this guidance and apply the information according to the needs of the project. If a Best Practices document guideline differs from a UFC, the UFC requirements take precedence. For Best Practice guidelines not discussed in a UFC, the DoR must submit to the Government Project Manager a list of the guidelines or requirements being used for the project with documentation sufficient for review and approval prior to completing the design.

1-9 GLOSSARY.

Appendix B contains acronyms, abbreviations, and terms specific to this document. UFC 3-130-01 provides additional terms commonly used in cold regions engineering.

1-10 REFERENCES.

Appendix C contains a list of references used in this document. The publication date of the code or standard is not included in this document. Unless otherwise specified, the most recent edition of the referenced publication applies.

This Page Intentionally Left Blank

CHAPTER 2 DESIGN CONSIDERATIONS

2-1 ENVIRONMENTAL FACTORS AND CONSIDERATIONS.

The Arctic and Subarctic environment affects most stages of building design, construction, operation, and maintenance. UFC 3-130-01 and UFC 3-130-02 cover the important environmental considerations for the configuration and orientation of individual structures in Arctic and Subarctic locations. Reference UFC 3-130-03 for criteria and guidance on ground conditions, the presence of permafrost, or seasonally frozen and thawing soils as needed for building design.

[C] 2-1 The interior building environment is usually drastically different from ambient Arctic and Subarctic conditions, placing severe stresses on building components. Rapid deterioration and costly maintenance are inevitable unless these stresses are carefully considered during planning, material selection, and throughout construction. In addition to designing for occupant comfort, building design must account for hazardous conditions, such as poor visibility caused by whiteout conditions, fog, or darkness, coupled with high winds, blowing snow, and low temperatures. It is essential to minimize personnel encounters with the environment.

2-2 ENVIRONMENTAL SEVERITY AND HUMID LOCATIONS.

Comply with UFC 3-101-01 and associated references therein, such as the American Society of Heating, Refrigerating and Air-Conditioning Engineers' (ASHRAE) *Cold-Climate Buildings Design Guide* and ASHRAE *Handbook—Fundamentals*, for appropriate climate design values. See also UFC 3-400-02.

[C] 2-2 Knowledge of individual site conditions is important for developing effective facility designs. The winter months in Arctic and Subarctic locations exhibit the greatest range and severity of conditions on the planet.

This Page Intentionally Left Blank

CHAPTER 3 ARCHITECTURAL

3-1 GENERAL.

Comply with UFC 1-200-01 and UFC 3-101-01 and associated references therein for architectural considerations. See Appendix A for guidance on Architectural Best Practices.

[C] 3-1 Consider issues related to snow and ice early in the design process. Special designs and construction techniques are required for buildings, primarily due to prolonged and extreme low temperatures, snow, wind, seasonally frozen and thawed ground, permafrost ground conditions, and special transportation, equipment, and maintenance requirements. Designers must provide a functional building while considering the factors required to provide an environment that meets the total needs of the occupants, contributes to high morale and productivity, and is energy efficient and sustainable.

3-2 BUILDING ORIENTATION.

Refer to UFC 3-101-01, Appendix A, for general guidance on building orientation.

[C] 3-2 Snow and ice significantly affect the design, operation, and maintenance of buildings and the safety of the building's occupants. Building orientation, building geometry, and climatic conditions are factors in snow shedding (snow sliding) off roofs, snow drifting, and drainage.

3-2.1 Snow Drifting.

Comply with UFC 3-301-01 criteria on snow loads, to address snow drifting potential. See Appendix A for guidance on Best Practices to reduce issues from snow drifting for buildings. Properly seal penetrations through the building envelope.

[C] 3-2.1 Snowdrift accumulations can have severe implications for occupant health and safety, such as when emergency equipment access is blocked or building egress is obstructed in an emergency.

3-2.2 Snow and Ice Creeping, Sliding, and Falling from Roofs.

To prevent falling snow and ice from blocking entrances, locate building access at the gable ends or control with the use of dormers and canopies. Refer to the *Site-Specific Case Studies for Determining Ground Snow Loads in the United States,* by Buska et al., to address this and other related design issues.

Refer to the Cold Regions Research and Engineering Laboratory (CRREL) Sliding Snow Calculator Summary Sheet and Sliding Snow Calculator tool (https://www.erdc.usace.army.mil/Portals/55/docs/CEERD-RV/CEERD-RR-H/BuildingTechnology/Tools/Sliding%20Snow%20Calculator.xls) to estimate the potential zone impacted by snow and ice shedding from roofs.

3-2.3 Local Site Conditions.

Observe site-specific conditions during winter site visits for indicators of potential snow-drifting problems. Aerial photographs also provide valuable information. Consult historical weather records to determine the intensity, direction, variability, and frequency of storms. Refer to Appendix A to estimate snow transport directions and volumes, which are useful for site planning with a snow transport analysis.

> [C] 3-2.3 The primary factors facilitating snow transport and influencing potential drift locations are high winds and dominant wind directions. Snow-drifting conditions are highly variable, even at nearby sites, and are affected by topography, vegetation, surrounding buildings, and so on, even when the locations are not separated by large distances.

3-3 PREFABRICATED STRUCTURES.

Prefabricated systems must be specifically designed for extreme cold climates—most off the shelf prefabricated options currently available may fail in the Arctic and Subarctic. The design factors that govern the selection of primary systems and backup systems are system reliability, ease of access for regular operation or to conduct maintenance, system simplicity, and cost. See Appendix A for further information.

3-4 BUILDING ENVELOPE.

The building's exterior envelope must provide a continuous barrier to air infiltration, a layer of insulation, and a vapor retarder around heated spaces. Maintain the continuous air barrier and air-vapor barrier at penetrations, windows, doors, and around elements of the structural system. Design thermal breaks in locations with little resistance to heat loss, such as between metal framing and the outside air. Comply with UFC 3-101-01, Appendix A, and associated references therein. Refer to ASHRAE *Cold-Climate Buildings Design Guide* for specific building-envelope considerations for Arctic and Subarctic climates.

> [C] 3-4 It is critical to control the transfer of heat and infiltration of air and moisture through the individual components of walls, ceilings, roofs, and floors and to maintain a continuous barrier at their transitions.

3-4.1 Heat.

Reduce heat loss and maximize energy efficiency. Provide insulation with effective R-values in foundations, walls, ceilings, roofs, and elevated floors to meet the minimum requirements of applicable energy codes. Install insulation carefully, completely filling the spaces between wall framings, door frames, and window frames to provide continuous insulation and minimize cold air penetration and infiltration. In exterior walls avoid gaps, uninsulated gaps can create air currents. For above-grade floor systems where the under-building surface is exposed to the ambient air temperature, for example in a building on a pile foundation, insulate floors in a manner that is similar to that used for exterior walls.

[C] 3-4.1 Different insulation R-values are appropriate for different geographic locations, depending on the severity of the thermal conditions, and for above- and below-grade walls.

3-4.1.1 Insulation.

Install insulation in walls, ceilings, roofs, floors, and elevated floors to regulate thermal transfer between interior and exterior surfaces according to the specific requirements of the application. Exterior foundation walls must have properly designed perimeter insulation board extending from the top of the footing to the bottom of the floor slab. Depending on the wall construction, the insulation may be on the exterior or interior face of the wall. Design insulation to meet fire protection requirements, flame spread and smoke development rating requirements, and to comply with UFC 3-600-01.

3-4.1.2 Thermal Bridging.

Design for thermal breaks to avoid problems such as below-freezing temperatures on warmer interior surfaces, at the connections, and at places of contact between the interior and exterior surfaces. On the cold portions of interior sheathing, add thermal breaks to reduce condensation and mold growth.

[C] 3-4.1.2 Thermal bridging is the conduction of heat between two areas of high thermal conductivity where there is little resistance. This phenomenon is observed in construction materials such as metal, masonry, wood, and concrete, which exhibit higher thermal conductivity compared to insulation materials. While wood-frame construction has lower thermal conductivity and fewer issues with frost buildup, it is also subject to issues of thermal bridging, shrinkage and water damage.

3-4.2 Air.

Use a well-sealed and continuous air barrier to control air leakage into and out of the building envelope, including walls and floors. The wall assemblies must be designed to minimize both moisture intrusion and air infiltration. In accordance with ASHRAE guidelines, it is imperative that wall assemblies integrate well-designed vapor and air barriers to regulate the movement of air and moisture. These barriers play a crucial role in preventing exterior air infiltration while facilitating the escape of interior moisture, ensuring an optimal balance in moisture control within building structures. Comply with the air barrier requirements of UFC 3-101-01, and the references therein.

> [C] 3-4.2 Air leakage is a significant issue for buildings located in Arctic and Subarctic regions; however, appropriate mechanical ventilation needs to be addressed during the design process.

3-4.3 Moisture.

Moisture from exterior and interior sources, and vapor ladened indoor air, can become trapped in the insulated cavity between the vapor retarder and the exterior surface material. The building envelope must be designed to limit moisture intrusion into these cavities as much as possible. Take extra precautions when dealing with transitions and penetrations in walls, floors, and ceilings. These areas are critical for minimizing the movement of air and moisture. Provide vapor relief if needed to avoid trapping moisture that can freeze within the building envelope and build up ice, leading to deterioration of the insulation material and rendering it ineffective. Refer to UFC 3-101-01, ASHRAE *Cold-Climate Building Design Guide,* and *Guide for Resilient Thermal Energy Systems Design in Cold and Arctic Climates*, by Zhivov. During winter in the far north, some facilities require humidification due to low air humidity and the low relative humidity associated with heated structures. Humidifying facilities in cold climates is often problematic and requires careful design.

3-4.3.1 Vapor Retarder.

Exterior wall systems require a layer that retards the infiltration of interior moisture into the insulation. A Class I or II vapor retarder (such as 6-milimeter polyethene sheeting) is required by the International Building Code for the Arctic and Subarctic climate zones. Use vapor retarders on or near the warm interior side of the building envelope. Vapor retarders must extend below slabs on grade, and along crawlspace walls and floors. See Appendix A for further information.

3-4.3.2 Ventilation.

Design ventilation to prevent trapping moisture or provide relief to allow moisture to escape. Ventilate the space between the roof insulation and the roof finish to maintain the integrity of the insulation and the roof structure and help prevent ice dams and water leakage. See Appendix A for further information.

3-4.3.3 Condensation.

Controlling condensation in Arctic and Subarctic regions requires a complete and continuous vapor retarder on the warm side of the exterior enclosure of the building; insulation to maintain the interior surfaces and the vapor retarder at a temperature warmer than the dew point; and a vapor-permeable exterior surface of the building enclosure (for a roof, this may require ventilation). Where a facility requires or there is high humidity within a building, such as in medical facilities or water-treatment plants, exercise special care to control air leakage and prevent condensate from forming on or within cold walls, windows, and ceilings. Make provisions to avoid water dripping onto personnel and critical equipment. Allow no condensate to drip on floors, particularly in front of doors that open to the outside.

[C] 3-4.3.3 Satisfactory building-envelope design requires balancing three factors—vapor retarder, insulation, and vapor dissipation.

3-4.4 Daylighting.

Window design must consider the range of available daylight hours throughout the year and its effect on energy use and efficiency. Comply with UFC 3-101-01, paragraph 3-7.1, and include design considerations for snowdrift previously discussed in paragraph 3-2.1. See Appendix A for further information.

3-5 ROOFS.

Comply with UFC 3-110-03 and applicable paragraphs of UFC 3-600-01. Keep roof geometry simple. Complex roof geometries and configurations create problems if they contain valleys, dormers, ice dams, or other features that restrict or block ventilation. Minimize the adverse effects of snow and ice on roofs. Design roof systems to prevent ice damming and excessive snow accumulation. Increase roof pitches, use low friction materials, or site buildings to avoid areas of low wind where blowing snow may accumulate. Roof system designs must be able to withstand ice and snow removal activities. For further guidance, see:

- “Minimizing the Adverse Effects of Snow and Ice on Roofs,” by Buska and Tobiasson;
- “Electric Heating Systems for Combating Icing Problems on Metal Roofs,” by Buska et al.;
- “Guidelines for Ventilating Attics and Cathedral Ceilings to Avoid Icings at their Eaves,” by Tobiasson et al.;
- “Roof Ventilation to Prevent Problematic Icings at Eaves,” by Buska et al.,
- “Standing Seam Metal Roofing Systems in Cold Regions,” by Tobiasson and Buska; and
- “Snow Guards for Metal Roofs,” by Tobiasson et al.

Ventilated roofs need careful design consideration in non-wood framed structures due to thermal bridging, condensation, and other issues noted paragraph 3-4. A ‘hot roof’ system may be used in conjunction with a low sloped roof for non-wood framed structures but must be carefully designed as the roofing materials and insulation need to be compatible. Avoid large roof steps as lower roofs must be designed for snow drift loading and this additional load can be significant with large roofs and high ground snow loads. Pitched roofs require consideration of unbalanced snow loads. Steep roofs with slippery surfaces, such as standing seam metal roofing, pose a sliding snow hazard at entrances and usually require snow guards (also called “snow stops”) or some other mechanism to help restrain sliding snow. Restrained snow adds to roofing down drag forces that must be considered for roofing attachment. Specify pre-engineered metal building (PEMB) roof systems for more collateral loading assuming another roof system will need to be installed over the original roof system in the future. Extreme changes in temperature at Arctic and Subarctic sites result in large roof panel expansions that tend to work open typical PEMB roof panel attachment fastener locations causing roof leaks. This can be mitigated by using an insulated metal panel standing seam roofing system instead of PEMB standard panels. Protect roof stacks and vents from sliding snow on sloped roofs with slippery surfaces.

[C] 3-5 Address roof design and drainage issues early in the design process. Problems are avoided, and more functional designs developed, when snow and ice issues are considered as the building design evolves. Both low-slope and steep-slope roof designs are commonly used in cold regions. Metal, conventional built-up, and protected-membrane roofs perform satisfactorily if properly constructed.

3-5.1 Drainage for Low-Sloped Roofs.

Comply with UFC 3-110-03. Heat trace roof drains to keep drains functional during freezing weather.

[C] 3-5.1 On low-sloped roofs, secondary roof drainage, such as scuppers, that drain to cold eaves can become blocked by ice formation and build-up and create ponding that increases the potential for leaks and possible roof collapse. Problems commonly occur at scuppers placed along a raised edge.

3-5.2 Gutters.

In Arctic and Subarctic regions, where snow slides off slippery roofs, gutters are not recommended. For low roofs featuring asphalt shingles and areas with lower slopes, incorporate gutters to manage moisture and reduce icicle formation. Integrate heating elements, such as heat tape, into the design of the gutter systems and extend along the entire length of the gutter system, including downspouts.

3-6 FENESTRATION DESIGN.

Comply with UFC 3-101-01. Window design must consider features to avoid condensation and frost buildup. Use higher performing windows with insulated frames including thermal breaks and insulated glazing units to prevent condensation and frost build up in the cold temperatures.

3-7 SEALANTS.

Sealant compounds normally used in temperate regions do not perform satisfactorily in cold regions. Select sealant materials that remain flexible and provide permanent cohesion and adhesion in extremely low ambient air temperatures to seal joints of precast concrete panels, metal roofing, around window and door frames, and in similar transitions.

[C] 3-7 The extreme variation between low and high summer and winter temperatures causes common sealant compounds to become brittle and lose their cohesion and adhesion.

3-8 EXTERIOR DOORS.

3-8.1 Exterior Personnel Doors.

Provide vestibules, or arctic entrances, near high-humidity areas in buildings and in buildings located in windy areas. An arctic entrance is a vestibule used in Arctic and Subarctic locations to shut out cold air, high wind, or drifting snow after the exterior door closes and before the inside door is opened. Use exterior doors that open inward to preclude being blocked by drifting snow and possibly damaged by high winds. A door that swings inward permits burrowing out when blocked, although it violates the fire code for certain occupancies and functions. Separately evaluate each inward-swinging-door requirement in terms of risk, alternate exits, and other factors related to occupant safety. See Appendix A for further guidance on arctic entrances.

Because of high winds and extreme cold, doors located on the prevailing windward side of the building require special protection (windscreen or baffle) in addition to arctic entrances. Provide wind screens, baffles, or heavy bumper stops mounted on steel posts to protect the doors and hinges from damage and to prevent injury. Insulate and weather-strip both doors and frames to provide an integral thermal break. Where drifting snow is not a problem, follow standard codes for exit doors. Exclusive use of insulated metal or composite doors and frames is highly recommended. For buildings that support child development or other youth programs, provide a protected warming area for patrons to await transportation.

[C] 3-8.1 Exterior personnel doors are normally free from frost buildup unless there is high humidity within the building. Typical high-humidity areas include laundry, showers, kitchen areas in mess halls, dormitories, and indoor swimming pools. For exterior use, metal and composite doors and frames are sturdier, look better longer, are better insulated, and retain their shape better than wooden doors and frames.

3-8.2 Accessibility.

Cover exterior access ramps for accessibility. Otherwise, designs for accessibility must conform to current criteria. See Appendix A for further information.

3-8.3 Overhead Doors.

On shop and warehouse buildings with large doors, use insulated sectional overhead doors. Separate the outside and inside panels with a thermal break. Provide seals at the head, jambs, the sill, and between sections. Individual sections and the entire door assembly must withstand design wind loads. Doors can operate manually or electrically, depending on their location and function. Do not use metal rollup doors in exterior walls. Do not slope floors to the door because melted snow will freeze at the doorsill and hinder the door operation.

[C] 3-8.3 When using electric operators, an important safety feature to incorporate is an automatic safety edge that stops or reverses the door's downward motion when the bottom edge strikes an object.

3-9 FINISHED FLOOR ELEVATION.

In Arctic and Subarctic areas, establish the minimum floor elevation 6 in. (150 mm) to 12 in. (300 mm) above the exterior finish grade to eliminate the possibility of water backing into the building during thaw periods. In extremely flat terrain and where snow drifting is anticipated, the higher elevation is justified. Provide a stoop at exterior doorways other than emergency exits. Construct the stoop to avoid frost heaving by placing additional non-frost susceptible fill material under stoop and anchoring or doweling the stoop to the main foundation wall. A 6 in. (150 mm) step may be an ABA code violation depending on egress points. Ventilated floors or floors in buildings sited on permafrost are not subject to this requirement.

3-10 EXTERIOR LANDINGS, STAIRS, AND RAILINGS.

For elevated walking surfaces on exterior landings and stairs, use materials with serrated open grating to prevent ice and snow accumulating on horizontal surfaces. Interior or enclosed stairways are preferable. Separately support or hinge exterior stairs and landings from the building or cantilever them from the building to allow for movement from frost heave. If differential heave is anticipated, isolate large landing structures or docks from the main structure. Proper foundation treatment may minimize differential movement between warm and cold structures. Refer to UFC 3-130-03 for foundation design.

3-11 INTERIOR FINISHING.

Ensure there are acceptable tolerances for movement and consider that the structure may not always be warm in the interior and may undergo periods of cold soaking during mothballing or prolonged power or mechanical outages. See Appendix A for further information.

3-12 BUILDING RETROGRADE OR MOTHBALLING.

Mothballing or retrograding Arctic and Subarctic buildings involves using strategic measures to protect structures during extended periods of inactivity, typically due to seasonal shutdowns or temporary closures. Key considerations for effective mothballing include comprehensive winterization efforts, ensuring protection against extreme cold temperatures. This involves conducting insulation checks, sealing gaps, and safeguarding plumbing systems from freezing. Additional measures encompass the implementation of a controlled heating system to maintain an adequate temperature within the building, preventing issues like frozen pipes and ensuring the interior environment remains within acceptable limits. Proper ventilation is essential to prevent moisture buildup, condensation, and mold growth, while sealing openings and entry points helps keep out pests. Managing moisture using absorbent materials or dehumidifiers is crucial, as is safeguarding the electrical system and implementing security measures. The drain traps must also be considered as they may need to be filled with propylene glycol or other fluids.

[C] 3-12 Conducting a thorough inspection of the building envelope, preserving equipment according to manufacturer guidelines, and developing a comprehensive mothballing plan with detailed procedures are integral components of the mothballing action. Establish an emergency response plan, adhering to local regulations, and implementing regular monitoring practices, especially before and after extreme weather conditions. In no case is it recommended to totally remove heat from a previously heated structure. These actions help to preserve the integrity of Arctic and Subarctic buildings during periods of inactivity.

This Page Intentionally Left Blank

CHAPTER 4 STRUCTURAL

4-1 GENERAL.

Structural designs for buildings situated in Arctic and Subarctic regions present unique challenges. Unlike more temperate locations, these areas experience compounded challenges arising from distinctive design loads and extensive seasonal climate variations. Comply with UFC 1-200-01 and UFC 3-301-01 and associated references therein. For structures designated as Risk Category V, comply with UFC 3-301-02 and the references therein.

4-2 DESIGN LOADS.

Refer to UFC 3-301-01, Chapters 2 and 3, and UFC 3-301-02, Chapter 2, for design requirements. There are several sources of design load information available. UFC 3-301-01 describes the Structural Load Data Tool (SLDT), hosted on the Whole Building Design Guide website https://www.wbdg.org/ar/tools/sldrt, that provides structural load information for wind, snow, frost penetration, and seismic data for DoD Installations within the U.S. and its territories. The American Society of Civil Engineers (ASCE) ASCE 7 Hazard Tool (https://asce7hazardtool.online/) provides load information for flood, ice, rain, seismic, snow, tornado, and wind for U.S. locations not included in the SLDT. Alaska-specific snow-load data are available from the Structural Engineers Association of Alaska website https://seaak.net/alaska-snow-loads. Ground snow load case studies may be needed for site-specific locations in the U.S. that are not included in published maps due to extreme local variations in snow loads. Use the methodology in *Site-Specific Case Studies for Determining Ground Snow Loads in the United States,* by Buska et al., and the accompanying spreadsheet-based calculator, Snow Load Case Studies (https://erdc-library.erdc.dren.mil/jspui/handle/11681/37574). At locations where load data is lacking, use the best locally available criteria with the approval of the Authority Having Jurisdiction (AHJ).

4-3 MATERIALS.

Common structural materials, such as concrete, wood, and steel, are successfully used in Arctic and Subarctic areas in conditioned (heated) structures with few problems. Comply with UFC 3-301-01 Best Practices for additional information on using these materials in Arctic and Subarctic areas. In non-conditioned (unheated) structures, thermal expansion/contraction must be considered. Comply with American Concrete Institute (ACI) ACI 318 concrete durability requirements for exposure. When using concrete as a building material, additional construction measures are required when ambient temperatures fall below 40°F (4.4°C) to ensure timely strength development and prevent damage due to freezing at early placement ages. These measures may include enclosing and heating the concrete placement, insulation of formwork, or use of accelerating admixtures, solely or in combination. The ACI 306R *Guide to Cold Weather Concreting* provides recommendations for the use of these measures in varying cold weather conditions. Consider low temperature steels with high-notch toughness where structural steel is exposed in arctic conditions. Design with proper joints to account for thermal expansion/contraction.

4-4 FOUNDATIONS.

Comply with UFC 3-130-03. UFC 3-130-03 provides a complete discussion of foundations for freezing and thawing conditions.

.

CHAPTER 5 MECHANICAL

5-1 GENERAL.

Comply with UFC 1-200-01, UFC 3-401-01, and the government criteria referenced therein. Standardize components whenever possible to reduce the necessary inventory of repair materials. Employ redundant or backup heating options that reduce risk to other systems and personnel.

[C] 5.1 While the design and operation of mechanical systems in Arctic and Subarctic regions share similarities with those in the northern regions of the continental U.S., it is crucial to note that extended periods of exceptionally low temperatures and high wind conditions in the Arctic and Subarctic can lead to failures in systems that typically function effectively in more moderate climates. Therefore, mechanical system design for cold regions must be simple, robust, and utilize Arctic-type technical changes and economic considerations. Operation and maintenance considerations are crucial because isolated Arctic sites may lack expert technical assistance.

5-2 PLUMBING.

5-2.1 General Design Requirements.

Comply with UFC 3-130-05 for cold regions utilities requirements to include various types of piping and utilities connections.

[C] 5-2.1 Designing plumbing systems for Arctic and Subarctic regions requires careful consideration of extreme weather conditions, freezing temperatures, and the unique challenges posed by the environment. Some considerations are, insulation, heating pipes, below frost level installation of utilities, and decoupling frost zone penetrations both thermally and mechanically. Thermal decoupling is achieved using thermal breaks and insulation, while mechanical decoupling involves employing flexible joints, slip connections, isolation pads, and other methods.

5-2.1.1 Energy Efficiency and Water Conservation.

Comply with UFC 1-200-01, UFC 3-420-01, and the criteria referenced therein.

[C] 5-2.1.1 Where adequate water supplies are available and normal sewage systems can be installed interior plumbing facilities vary little from those used in temperate climates. However, water is not always readily available. In areas with permafrost, it is difficult to treat and dispose of sewage.

5-2.1.2 Reliability.

To prevent potential freezing in sewage pipes and systems, collect small waste flows and discharge them in slugs rather than allowing the sewage to trickle by gravity within the lines.

5-2.1.3 Piping Arrangement.

Avoid locating plumbing on the exterior walls. Buildings in permafrost areas that are elevated above ground on a piling system expose the area under the floor to cold arctic air. Protect underfloor piping from freezing. See Appendix A for further guidance.

5-2.1.4 Siting.

Do not divert drainage from roof and floor drains into the sewage treatment systems because this increases the volume of sewage requiring treatment and is frequently a violation of applicable plumbing or public health codes. Dispose of sewage (black water) separately from excess surface moisture (snow, ice, or water) runoff. Dry wells located below the depth of seasonal frost may be used in Subarctic regions that are permafrost free and have free-draining soils. Prevent dry wells or connecting drains from freezing with regular monitoring and maintenance to clean out and inspect for the buildup of silt, leaves, or other debris. Avoid frozen conditions that cause wells to back up water toward the roof and create leaks within the building. Install roof drain lines that discharge through an exterior wall onto a splash block and into a concrete trench covered by a grate to carry water away from the building and minimize ice formation on paved surfaces. In shops, install floor or trench drains to collect and carry away melted snow brought in on vehicles; drains, traps, and piping must be kept clear of blockages created by the considerable amounts of mud, gravel, sticks, and vegetation carried in on vehicles. Provide baskets, strainers, and sand and oil traps to keep drains operational. Frozen oil traps become inoperable. Heating is required to keep these traps operational. Alternately, install traps inside buildings. Make sure drains and piping are located such that there is no impact to the building foundation if a thaw bulb is created.

5-2.2 Supplemental International Plumbing Code (IPC) Technical Criteria.

The IPC lays out the general plumbing code, below are considerations for Arctic and Subarctic regions for specific use cases.

5-2.2.1 Food Waste Disposer.

Garbage disposals are generally not installed in Arctic and Subarctic locations at small, remote Installations where sewage treatment and disposal are particularly difficult. Grease traps become inoperable when water within them freezes. To keep these traps operational, they must be either heated or installed inside the building.

[C] 5-2.2.1 If disposals are installed, consider grease removal. Grease may congeal and clog cold sewer lines and may also create operation and maintenance problems at the sewage treatment facility. Oversized exterior grease traps require frequent cleaning. The normal foodstuffs that are run through a garbage disposal tend to reduce the life of a septic system drain field or leach pit.

5-2.2.2 Water Storage Tanks.

Water storage tanks may need to be heated to avoid freezing. Conduct appropriate thermal analysis to determine if this applies to a specific case.

5-2.2.3 Exterior Faucets or Hose Bibs.

Avoid frozen hose bibs by use of a valve on the supply zone inside the heated space that can be turned off in the winter. In this case drain the hose bib and leave open for the winter. Alternatively, frost-proof faucets or hose bibs can be installed to minimize the risk of freezing. Provide adequate drainage paths from exterior hose bibs so that the building foundation is not impacted by excess water.

[C] 5-2.2.3 Frost-proof faucets are designed to drain water away from the remote valve when turned off, preventing water from standing in the exposed portion of hose bib.

5-3 FACILITY HVAC SYSTEMS.

5-3.1 General.

Comply with UFC 3-401-01 and UFC 3-410-01. Minimize cold floors and downdrafts from windows by using adequate floor insulation and locating heating units below windows.

[C] 5-3.1 A reliable and easy-to-maintain heating system is extremely important for personnel comfort and safety. Remote locations, severe climatic conditions, and short daylight hours tend to confine personnel to the site and are the primary reasons for maintaining a good physical environment. While constant circulating heat systems usually provide more uniform room temperatures, it is important to evaluate available information before selecting a system.

5-3.2 Ventilation.

Comply with UFC 3-410-01. Utilize heat recovery ventilation systems to minimize the impact of ventilation on the heating load of the building. Ventilation systems require designs that temper incoming cold air so as not freeze equipment that can cause failures.

[C] 5-3.2 The fresh air requirements for ventilation are principally the same as those in temperate climates. Avoid issues resulting from inadequate or improper ventilation-system design during the design process.

5-3.2.1 Freezing of Heating Coils in Ventilation Units.

Provide a low limit thermostat control in the air discharge from the coil to stop the fan and close the outside air dampers when air temperatures drop to about 35°F (2°C), such as during a power outage. Refer to UFC 3-410-01 for further freeze protection criteria. Prevent air stratification in the mixing box by bringing warm air in at the bottom and cold air in at the top. Refer to UFC 3-410-01 for further ventilation criteria, and Appendix A of this UFC for Best Practice guidance.

5-3.2.2 Outside Air Openings.

See Chapter 3 of this document, UFC 3-410-01, Appendix B, and the ASHRAE *Cold-Climate Buildings Design Guide*.

[C] 5-3.2.2 High winds, blowing snow, rain, damage from falling ice, and the need for screens cause problems with outside air openings used for air ventilation intake and exhaust.

5-3.2.3 Frosting of Filters in Ventilation Systems.

Because fresh air intakes, including filter banks, are generally under negative pressure, seal openings and penetrations that permit more humid air to enter the intake duct or filter bank. Several methods to correct this issue are possible. One method is to install a preheat coil ahead of the filter to heat the air to 30°F (−1°C), but that coil can plug with dirt, lint, and other material during normal summer operation. To obtain the best results, use heat recovery ventilators or energy recovery ventilators, frost resistant filters, or increase the airflow to minimize icing. Refer to UFC 3-410-01, Appendix B.

[C] 5-3.2.3 Icing and frost closure occur when saturated freezing air, usually below −20°F (−29°C), is brought in through a filter. The same problem can occur when fresh air intakes are too close to the exhaust openings and plumbing vents. . Icing and thawing cause throwaway-type filters to get wet, collapse, and jam the face and bypass dampers within a relatively short duration.

5-3.2.4 Insulation of Ducts and Pipes Handling Cold Air.

Provide insulation for pipes and ducts subjected to cold air and seal at the vapor retarder penetration, as described in Chapter 3.

5-3.3 Humidification.

The need to address and control variations in humidity is discussed in Chapter 3. During winter a building may need humidification to be comfortable for habitation. The system must be balanced between humidification and the need to control condensation in the structure.

5-3.4 Condensation.

Maintain an adequate difference between the dew point and the temperature to avoid condensation. Refer to paragraph 3-4.3 for moisture within the building envelope, and to UFC 3-410-01 for heating and cooling load calculations.

[C] 5-3.4 Condensation can cause interior damage when excessive levels of humidity are maintained within the building. Condensation can freeze on the vapor barrier if it is too cold and over repeated cycles.

5-3.5 Low-Temperature Lubricants.

Fans or other moving equipment mounted on a building's exterior or located within unheated portions of the building must be capable of operating at the lowest recorded ambient temperature. Use special low-temperature lubricants. Require manufacturers to guarantee their equipment under the extreme weather conditions expected at the site.

[C] 5-3.5 Many bearings and races may be coated in materials that have incompatible thermal conductivities and expansions. In a cold and dry condition, they may fail exponentially faster.

5-4 HEATING CONCERNS.

Minimize cold floors and downdrafts from windows by using adequate floor insulation and locating heating units below windows. While constantly circulating heat systems usually provide more uniform room temperatures, it is important to evaluate available information before selecting a system. Further design criteria for various types of heating systems are discussed in detail in paragraphs 5-4.1 through 5-4.8. The advantages or disadvantages of each system when used in the arctic environment are noted. Comply with UFC 3-410-01 and the references therein on the selection and design of appropriate heating systems.

[C] 5-4 A satisfactory, reliable, and easy-to-maintain heating system is extremely important for personnel comfort. Remote locations, severe climatic conditions, and short daylight hours tend to confine personnel to the site and are the primary reasons for maintaining a good physical environment.

5-4.1 Freezing of Water and Steam Systems.

Comply with UFC 3-410-01. Guard against system freezing by protecting heating lines and equipment. Properly protect hot water lines located in exterior walls. Constant circulation delays water freezing in the pipes if a boiler, furnace, or heat exchanger stops working. Where automatic room temperature control is not provided, personnel may open windows to provide necessary control, and lines may freeze when the room is left unattended. For this reason, provide individual room thermostat controls. In garages or hangars, interlock unit heaters installed within 20 ft of doors with those doors so that the fans on the unit heaters shut off when the doors open. When fans are left running, cold outside air is blown over the coil, frequently causing the coil to freeze. Install a temperature alarm system in each remote, unoccupied building to alert maintenance personnel when the building interior temperature approaches freezing.

5-4.2 Shop and Hangar Heating.

Comply with UFC 3-410-01, paragraph 3-6. To address Arctic and Subarctic heating challenges in large buildings, several issues must be considered. These include the frequent opening of large doors, the presence of high ceilings, and the imperative for swift heat recovery. It is essential to appropriately size and select projection-type heaters, ensuring their efficiency in managing the vast spaces. Installing snow melting systems beneath hangar doors and ramps helps mitigate ice and snow accumulation, ensuring the doors remain operational. Additionally, incorporating radiant floor heating alongside the standard heating system enhances overall warmth. To minimize heat loss, focus on reducing air infiltration through strategic measures such as well-designed doors, effective weather stripping, and minimizing the use of operable windows. Factor estimates for infiltration into comprehensive heat loss calculations, emphasizing the need for meticulous data and calculations to optimize heating systems in these expansive structures.

5-4.3 Heating Control.

Generally, provide automatic controls for heating and ventilating systems. Provide manual control systems to preclude complete shutdown if automatic controls fail. Consider night temperature setback wherever practical. Heating coils require adequate controls to protect them against freezing. Keep control systems simple because expert maintenance is often not available.

5-4.4 Cooling Water and Recharge Wells.

Cool the water supply and use recharge wells where outside temperatures are too high to cool electronic equipment during summer months. During winter months, discharging wastewater in recharging wells, rather than on the ground surface, can effectively reduce ice fog and glaciation. Reducing ice fog is especially important near airfields. Well water in Subarctic regions typically does not exceed 39°F (4°C).

5-4.5 Fuel Oil Piping and Storage.

Comply with UFC 3-410-01. Fuel oils used in cold regions must comply with proper grading. When used in areas where low temperatures prevail, consider special heating and insulation of fuel lines. When commercial diesel fuels with a higher pour point are used, heating may be required for the system to function properly. Lines may be increased one pipe size; however, larger-diameter pipes reduce velocity and cause sluggish operation. It is not advisable to bury exterior fuel oil tanks in permafrost areas because the supply and return connections are extremely vulnerable to breakage when settlement occurs. Aboveground tanks, however, are exposed to lower temperatures, and a protective shelter may be required. When installing aboveground tanks that are higher in elevation than the burner unit, install a vacuum relief on the fuel oil supply line. Double-wall construction or containment is required for fuel tanks.

5-4.6 Air Elimination.

Provide systems for positive air removal and for draining the piping and equipment.

[C] 5-4.6 Eliminating air in a hot water heating system can be a problem in every climate. It is more critical in Arctic regions because of the need for continuous operation.

5-4.7 Piping in Hot Water Heating Systems.

Maintain positive flows in piping systems unless using an antifreeze-filled system. Antifreeze systems are preferred; however, they do lower the thermal conductivity of the working fluid. Avoid feeding numerous parallel zones from one circulating pump. If parallel zones must be used, provide accessible balancing control, indicating devices, and a manual bypass to allow operation during maintenance.

[C] 5-4.7 An improperly piped system may perform satisfactorily in a temperate zone, but the same system may cause heating problems when exposed to extreme Arctic conditions. Careful design minimizes these problems. Parallel zones are difficult to balance, and eliminating air from the many circuits is difficult. Flow can easily stop in one zone because of poor air elimination. A freeze-up may result, which, when concealed, is extremely difficult to correct.

5-4.8 Design Considerations for Simple, Effective Mechanical Systems.

Ensure adequate space in the mechanical room and around equipment to facilitate inside maintenance during cold weather. Arrange piping connections and space to permit the removal of coils, tube bundles, and filters. Provide ready access to maintain motors, automatic controls, dampers, traps, and so on. Provide systems subject to interior condensation with drain valves to drain moisture annually. Simple mechanical systems that can be serviced by inexperienced maintenance personnel are required.

[C] 5-4.8. Inaccessibility is one of the most frequent problems encountered by maintenance personnel, especially when repairs must be made immediately to reduce system outages; fast repairs require sufficient maintenance space. Sites may be in remote areas where experienced personnel and ready sources of spare parts are not available. In specifications for heating and plumbing piping, emphasize the need to keep dirt and gravel out of piping during construction. Alert inspectors to assure compliance. After years of operation, military bases in Arctic regions are still plagued with stoppages and restrictions from gravel remaining in glycol-grid snow melting systems. Gravel and other debris have also caused stoppages in steam heating and plumbing systems many years after entering service.

5-5 COMPRESSED AIR SYSTEMS.

Colder outdoor air contains less moisture than warmer inside air. Include removal of the excess water vapor in the design of compressed air systems. Use low temperature exterior air as the air source for large compressors because it requires less water removal from the system. Reference UFC 3-401-01, paragraphs on Compressed Air Systems.

[C] 5-5 This applies to instrument air and compressed air systems in shops and hangars where water vapor, if not removed, can freeze and cause the system to quit functioning. Pneumatic control systems require dry air to function properly.

5-6 REFRIGERATION SYSTEMS FOR COLD STORAGE FACILITIES.

Standard refrigeration design for cold storage or air conditioning can be used effectively and must comply with UFC 3-410-01.

CHAPTER 6 ELECTRICAL

6-1 GENERAL.

Standard electrical system design criteria are suitable for buildings in Arctic and Subarctic regions because buildings are heated. However, some special consideration must be addressed. Comply with UFC 1-200-01, UFC 3-501-01, and the UFCs and government criteria referenced therein.

6-2 GROUNDING.

Comply with UFC 3-501-01; UFC 3-550-01; and UFC 3-130-05, paragraph 11-2. UFC 3-130-05 paragraphs 11-2 and A-11.2 provide additional information and resources on electrical grounding.

> [C] 6-2 It is difficult to obtain an effective electrical ground in Arctic and Subarctic regions because of soil and climatic conditions. Grounding is not difficult during summer months but is a problem during the winter if the ground electrode is completely enclosed in frozen soil and cannot achieve an effective ground. In frozen conditions the grounding method may include multiple grounding rods, grounding mats, or grounding wells.

6-3 EXTERIOR LIGHTING AND CONTROLS.

Comply with UFC 3-501-01 and UFC 3-550-01. Exterior wiring and lighting must be rated to −40°F (−40°C). Ensure NEC compliant circuit wiring and protection are provided for heat trace cables used for heating liquid carrying pipes exposed to cold temperature as indicated in Chapter 5.

> [C] 6-3 It's important to emphasize that considerations regarding the temperature rating of wiring, particularly related to the insulation material, extend beyond just exterior lighting and controls. This applies to exterior wiring, whether for power, communications, signaling, etc., installed in low-temperature environments. The challenge arises during installation or movement of wires in cold conditions. In such instances, certain insulation materials may become brittle, making them susceptible to cracking when force is applied, leading to potential damage. This concern is mitigated when wiring is installed within or above the insulation's temperature rating, and post-installation, the wires remain static within the protective raceway.

6-4 EXTERIOR DISTRIBUTION SYSTEMS.

Comply with UFC 3-501-01 and UFC 3-550-01. Where damage from snowplows is likely, elevate utility pedestals that are near roads, typically about 3 ft (1 m) above grade. Provide exterior vehicle electrical plug-ins for parking areas as required by parking practices.

Seal raceways transiting from outdoors to indoors in accordance with NEC requirement for sealing raceways exposed to different temperatures.

6-4.1 Exterior Enclosures.

Use heated enclosures for outdoor-mounted equipment and devices susceptible to adverse effects from cold temperatures. This includes LCD displays, backup batteries in electronic equipment, and mechanisms vulnerable to seizing due to lubricant hardening or freezing.

Utilize specialized Arctic enclosures for outdoor equipment and devices susceptible to adverse impacts from snow, ice, and sleet. This is particularly relevant for devices like cameras and satellite dish antennas, ensuring their functionality despite challenging weather conditions.

[C] 6-4.1 Additionally, heated enclosures prevent moisture buildup from condensation and address concerns like fogging on lenses, especially in outdoor cameras.

6-5 INTERIOR DISTRIBUTION SYSTEMS.

6-5.1 Service Entrance.

Comply with UFC 3-501-01 and UFC 3-520-01. Install the overhead service entrance on the gable end of the building, as explained in Chapter 3. Within a building, locate service entrance equipment in a readily accessible area to allow for quick power disconnection in case of an emergency. Provide one service disconnect for each facility. Provide climate-control for electrical rooms.

For underground services in cold regions employ liquid-tight flexible metallic conduit for the exterior riser conduit leading into the meter base. This mitigates concerns related to frost heaving, which could potentially elevate rigid metal conduit, risking the displacement of the meter from its mounting.

6-5.2 Generators.

Comply with UFC 3-501-01 and UFC 3-540-01*.* Power interruptions, outages, and reliability must be considered. Generator backup power is needed when extreme winter conditions cause issues with power (a life and safety concern) and increase the danger of building freeze-up if power is disrupted for a significant period. For cases of power fluctuations and interruptions, protect sensitive equipment from potential damage.

Use manufacturer recommended Arctic options for generators such as jacket water heaters (preheats the generator coolant), battery heaters, and fuel heaters (this helps the generator during cold startup). The use of generator space heaters maintains the air around the generator at a suitable temperature to prevent moisture buildup due to condensation.

6-5.3 Corrosion Control.

Comply with UFC 3-570-01. In some Subarctic regions, corrosive conditions caused by wind-driven rain, snow, and salt spray are so severe that vault space must be provided inside buildings for transformers and associated service equipment. See Appendix A for further information.

6-5.4 Lightning Protection and Static Electricity.

Comply with UFC 3-575-01. Lightning protection is needed during the summer months. Provide humidity control and use low-static floor coverings in interior spaces to mitigate static electricity.

[C] 6-5.4 During the winter months, static electricity is a significant problem due to low humidity.

6-5.5 Communications.

Comply with UFC 3-580-01. Terminal blocks are routinely installed on the exterior of residences. These must be protected from moisture intrusion and able to withstand the extreme temperature ranges.

This Page Intentionally Left Blank

CHAPTER 7 FIRE PROTECTION

7-1 GENERAL.

Fire protection is critical in Arctic and Subarctic regions. Evaluate the isolation and climate conditions of each site to determine the extent of required fire protection facilities. Principally at isolated sites, guard against fire hazards because the loss of facilities and materials during extreme low temperatures constitutes a major threat to survival. Evaluate the fire hazard at each site by considering the distance to other facilities and the availability and reliability of alternate forms of shelter and transportation. Evaluate each building in terms of the effects of local winds and temperatures on firefighting capability and on survivors. Strong winds can occur for extended periods of time, causing fires to spread rapidly and be difficult to control. Comply with UFC 1-200-01, UFC 3-600-01, and UFC 3-130-05.

7-2 FIRE PROTECTION ENGINEERING SERVICES.

Consult experienced fire protection engineers at the Installation or Command level with expertise in Arctic and Subarctic conditions to develop comprehensive and effective fire protection strategies that address the specific challenges of these environments.

> [C] 7-2 Fire protection involves a holistic approach that encompasses design, materials, systems, and emergency response planning tailored to the unique conditions of the Arctic and Subarctic.

7-2.1 Water Supplies for Fire Protection.

Comply with UFC 3-230-01 for developing water sources and distribution. Applicable fire protection engineering services must comply with local standards and practices.

7-2.2 Water Storage Tank Vents.

Take preventative measures to avoid ice buildup blocking tank vents on facility water storage tanks. Where heavy ice buildup is expected, such as in coastal locations include special protection for tank vents. Alternately, provide protection by venting tanks into the pump house and omitting an exterior vent. The facility storage tank must either have the capacity to store several months’ supply of domestic water, in addition to reserve water for firefighting, or be dedicated solely for firefighting.

> [C] 7-2.2 Driving winds have blocked 6 in. (152 mm) vents, and the vacuum resulting from water drawdown can cause a tank to collapse.

7-3 FIRE PROTECTION SYSTEMS.

7-3.1.1 All-Weather Ground Access.

In Arctic and Subarctic regions, locate fire room access doors on the gable end of the building to prevent snow and ice buildup.

7-3.1.2 Fire Department Connection.

Locate exterior fire department connections on the gable end of the building to avoid snow and ice buildup. To eliminate freeze potential, install a ball drip assembly on the supply low point (more than one may be required) and route to an interior drain.

7-3.1.3 Exterior Antennas.

To prevent snow and ice buildup, mount antennas on the gable end of the building exterior. For a pitched roof, mount each transmitter antenna on the gable end on the face of the eave closest to the fire department or mass notification central station location. Mount each antenna a minimum of 6 in. (152 mm) above the roofline and secure it, using nuts and bolts, to withstand the wind load. It is unacceptable to secure the mounting bracket into the building exterior with screws. Proper installation and operation of each antenna is required for the correct frequency and transmission. Each antenna cable must have a lightning arrester installed inline in a weather-proof box, and each assembly must be properly grounded per the manufacturer’s specifications. Show antenna locations on each floor.

7-3.1.4 Valves.

In Arctic and Subarctic locations, use street valves and then a primary shut-off valve inside buildings, as permitted by NFPA 24, a National Fire Protection Association regulation. Ensure that recirculation and heating systems are working properly to avoid issues. The use of post-indicating valves is not recommended in Arctic or Subarctic climates because they create a thermal bridging issue.

7-3.1.5 Facility On-Site Water Storage.

Heat and insulate water storage tanks exposed to extremely low temperatures with continuous water circulation. Heating techniques include circulating tank water through a heat exchanger or using a flow-through type electric heater.

> [C] 7-3.1.5 Water storage from surface sources may be inaccessible during the winter months due to ice formation, and underground water sources may be unavailable.

7-3.1.6 Fire Pumps.

The use and maintenance of fire pumps in Arctic and Subarctic regions involve special considerations due to the extreme cold temperatures and challenging environmental conditions. Some key factors to consider for fire pumps in these regions, cold weather start-up, enclosure and insulation, heated enclosures, fuel considerations, battery heating, emergency power sources, snow management, and materials and corrosion resistance.

7-3.1.6.1 Fire Pump Room.

To protect against freezing, do not locate fire pumps, jockey pumps, or sensing lines near an exterior door. Provide an acceptable method to continuously monitor the sensing lines within the fire pump room to maintain a minimum temperature of 68°F (20°C).

7-3.1.6.2 Drainage Piping.

In cold climates, include drainage systems in fire protection rooms. To mitigate the risk of freezing and potential blockages, implement freeze protection measures for drains. This can involve the installation of insulation or heating elements as preventive measures.

7-3.1.6.3 Discharge to Exterior.

Locate main drains and auxiliary drains within 2 ft (0.6 m) of grade and not less than a 10 ft (3 m) distance from both the exterior doors and the fire department connection.

7-3.1.7 Fire Pump Controllers.

To protect against freezing, do not locate fire pump controllers or jockey pump controllers near an exterior door. Within the fire pump room, provide an acceptable method for continuously monitoring the controllers to maintain a minimum temperature of 68°F (20°C).

7-3.1.8 Fire Alarm and Mass Notification System Installation.

In Arctic and Subarctic regions, locate or install lines of communication, fire alarm and mass notification panels, transceivers and releasing panels or annunciators inside the building. Do not locate or install these devices in an artic entryway or vestibule. The interior of the building provides better access to and climate control for these systems.

7-3.1.9 Fire Suppression System Testing.

Water recirculation systems used for freeze protection, and other connected systems, must be tested at the same hydrostatic pressure as required for the sprinkler system. Apply this same hydrostatic pressure when testing other systems connected to the sprinkler system, except the incoming domestic water. Pumps on the recirculation system must also be rated for both the working and static pressure of the sprinkler system. To prevent freezing, the domestic lines and fire-suppression line may be combined.

7-3.1.10 Automatic Sprinkler Systems.

Protect wet pipe systems from freezing by providing heat trace for sprinklers under overhead doors. Supply heat trace and insulation for wet pipe sprinkler lines that must cross a hangar. The heat trace must be Underwriters Laboratory (UL) listed or FM Approved for sprinkler systems. The heat trace may need to be on a dedicated breaker in an emergency panel, though this depends on various factors, including local electrical codes, the specific requirements of the heat trace system, and the overall electrical design of the facility. It is essential to consult with a qualified electrician or an electrical engineer who is familiar with local codes and regulations to determine the specific requirements. Provide sprinklers in maintenance vestibules where air-handling units (AHU) are located. Dry sprinklers are also an option for spaces where freezing may occur. Dry sprinklers can be used with a wet system or as a standalone system.

7-3.1.11 Arctic Vestibules.

Provide dry sprinklers in arctic vestibules.

7-3.1.12 Standpipe Systems.

To mitigate the risk of freezing in multi-story buildings, incorporate a standpipe in a heated location for water lines connected to fire trucks exposed to freezing temperatures. This design approach enhances the resilience of the firefighting system in colder conditions.

7-3.1.13 Fire Alarm Systems.

Freeze-protection monitoring guards against lines freezing. Connect fire protection life safety equipment to the Fire Alarm Reporting System. Include freeze-protection monitoring on the fire alarm reporting system when monitoring the incoming water line. The freeze-protection connection to the fire alarm reporting system monitors the proper operation of the main fire protection water line must include, at a minimum, low-temperature alarms, circulation pumps, and no-flow conditions.

To protect against freezing, the fire alarm system must monitor heat trace breakers for sprinkler systems and hydrant systems. Provide a low-temperature alarm near the sprinkler riser in every high-expansion foam room and in sprinkler riser locations. Upon activation of the low-temperature alarm, a supervisory signal must be sent to the fire department. Low-temperature alarms must also be provided in rooftop AHU enclosures with maintenance vestibules that are provided with sprinkler protection. Low-temperature devices must be mounted within 18 in. (457 mm) of the lowest point in the room and must be coordinated with the District Fire Protection Engineer (FPE) for location. For rooms with pits, coordinate with the District FPE for location.

APPENDIX A BEST PRACTICES

A-1 INTRODUCTION.

The Best Practices Appendix contains guidance and not requirements. Its main purpose is to communicate proven facility solutions, systems, and lessons learned. However, these recommendations are not the only viable solutions.

A-2 CANADIAN EXPERIENCE.

The Canadian Arctic covers over 40% of Canada's land mass. Canada has extensive experience with cold regions engineering and infrastructure. The documents provided by the Government of Canda on the Codes Canada website (https://nrc.canada.ca/en/certifications-evaluations-standards/codes-canada) provide valuable guidance for cold regions engineering and construction on a variety of topics.

A-3 SNOW DRIFTING.

The accumulation of blowing snow causes snow drifts. Snow accumulates on buildings in areas of aerodynamic shade created by roof design. Inadequate separation between structures causes intersecting drifts. A single storm can quickly create large drifts on and around structures and block access to utility systems that are necessary for maintenance or repairs and can quickly bury items, such as construction materials, that are stored outside. Snowdrifts often cover doorways. Drifting snow may enter buildings in a variety of ways. For example, it is difficult to tightly seal doors on a building's upwind face to prevent snow infiltration. Dry, windblown snow can enter small cracks in doorways, windows, or louvers that are intended for ventilation.

A-3.1 Snowdrift Indicators.

High winds, rather than the prevailing wind direction, better indicate the direction of drifting snow and where snow drifts will form. The quantity of snow transported by wind is roughly proportional to the 4th power of wind speed. This causes high winds to disproportionately transport more snow than either moderate or low winds.

Determine the transport direction from the orientation of drifts, onsite visits, or aerial or satellite images taken during the winter. Late-winter observations give the best indication of the average transport direction. To determine the drift location and building orientation, use the windward direction and wind orientation based on dominate wind transport directions rather than the prevailing wind direction alone. Lacking direct observations of drift orientation for a snow transport analysis, use meteorological data to estimate transport directions and volumes for site planning. Refer to "Blowing Snow Transport Analysis for Estimating Drift Orientation and Severity," by Haehnel, and *Design Guidelines for the Control of Blowing and Drifting Snow,* by Tabler, for additional information on snow transport analysis.

A-3.2 Problems Due to Snow Drifting.

The list that follows contains additional guidelines and concerns about snow drifting for building design:

- Poorly oriented generator intakes can be become blocked, and ice can coat, or snow can block, warm exhaust stacks and vent pipes.
- Large snowdrifts can accumulate on low roofs and in other areas of aerodynamic shade.
- In permafrost areas, snow infiltration in ventilated foundations can be a serious problem.
- Material and equipment must not be stored adjacent to or under buildings elevated above permafrost because doing so can cause snow drifts that allow soil warming in winter.

A-3.3 Solutions to Snow Drifting Problems.

While drifting patterns are difficult to predict, following the guidelines listed here minimizes problems:

- Place utility distribution systems within or below elevated walkways to facilitate repairs. Walkways placed on grade tend to aggravate snow drifting problems.
- Use trees, shrubs, snow fences, or other obstructions to precipitate snow before it reaches the site proper. Where storms may come from every direction, provide protection for every quadrant.
- Place major roads parallel to the dominant snow transport direction. This may differ from the prevailing wind direction.
- Do not locate roads directly upwind or downwind of large obstructions. Where possible, maintain 100 ft (30 m) upwind and 200 ft (61 m) downwind clearances.
- Locate parking lots alongside roads to function as buffer zones. Do not place parking lots among buildings. Expect additional snow accumulation around parked vehicles and provide ample room for snow storage away from roads and on the downwind end of the lot. Because curbed islands hinder snow removal operations, they are rarely suitable.
- Place parking aprons alongside, not upwind or downwind of, hangers and garages.
- Orient surface structures with their longest side parallel to the winter snow transport direction. Winter storm winds and snow transport may come from a different direction than prevailing summer or winter winds.

- Locate doors along the sides of the building facing toward the upwind end. Doors on the downwind end of the structure may be rapidly blocked by drifting snow; those on the upwind face are difficult to seal. Though main entrances and exits need to open out, it is advisable to have at least one alternate set of doors that open inward for use if drifting snow blocks the main doors. Establish and maintain clear pathways from the building interior to these alternate exits.
- Orient large garage doors parallel to the dominant snow transport direction, even if this results in a building orientation that is perpendicular to the wind. Adjust this orientation slightly to assure that the doors are not in the lee of the upwind corner of the building.
- Place structures in rows perpendicular to the wind. Allow ample space (such as a minimum of two times the width of the snow removal equipment) between buildings to permit effective snow removal. Place each row of structures downwind from the preceding row, either abutting the windward structure or spaced at least the length of the building in the windward direction from the preceding row.
- Provide snow dumping areas to eliminate large piles or windrows of snow in the camp area. Piles and windrows are obstructions that increase future snow removal requirements.
- Avoid decorative earthen berms around buildings and in parking lots. Berms can cause additional snow accumulation problems and interfere with snow removal operations, disrupt building access for maintenance and fire protection, and create moisture problems at the foundation wall.
- For AT/FP structures they may need to be placed further from buildings and have dedicated paths for snow removal and water drainage.
- For buildings on a permafrost foundation system such as thermopiles, elevate the building adequately to allow free flow of air under the building and avoid snowdrift buildup around condensers.

A-4 SNOW AND ICE CREEPING, SLIDING, AND FALLING FROM ROOFS.

In Arctic and Subarctic climates, anticipate that snow and ice will creep, slide, and fall from roofs; this situation can cause significant property damage and injure, or even kill, pedestrians. This is particularly the case with roofs that drain to cold eaves and for steep roof slopes and slippery surfaces. Snow and ice sliding off pitched metal roofs can damage property and injure people as far as 20 to 30 ft (6 to 9 m) away from two-story facilities. Snow sliding off these roofs can block vehicle access to and from critical facilities.

A-5 LOCAL CONSTRUCTION METHODS, MATERIALS, AND SKILLS.

Generally, in Arctic and Subarctic regions, construction methods, materials, and skills are major factors tied to overall project cost. Maximum factory prefabrication is an economical solution to reduce on-site construction, especially given the short construction season, but the benefits of prefabrication must be weighed against higher handling and shipping costs, the risk of damage and breakage during transport, and the effect of shipping delays. Scheduling work so that construction of the outer building shell is completed during mild weather and interior work is completed during severe weather expedites completion, reduces costs, and eliminates many problems. Many materials used in standard temperate construction are used in Arctic and Subarctic locations; however, their availability and transportability are significant concerns. A shortage of skilled labor can cause higher costs.

A-6 BUILDING ENVELOPE.

A-6.1 Vapor Retarder.

A well-constructed and continuous vapor retarder can significantly control air leakage. During installation, exercise care to ensure that joints, corners, and penetrations of the vapor retarder are completely sealed with properly specified mastic or sealants. Create detailed designs and provide careful supervision during construction to obtain maximum retarder continuity between the walls and roof.

A-6.2 Ventilation.

Moisture can become trapped in the insulated cavity between the vapor retarder and the exterior surface material. Given sufficiently low temperature conditions, this trapped moisture can freeze and, over time and with successive moisture trapping and freezing, create ice within the insulated cavity that melts when temperatures warm, deteriorating the insulation material.

An air gap exterior to the envelope insulation, but behind the exterior finish, helps to keep the insulation dry, and does not reduce the insulation value of the envelope. A small air gap behind the wall finish material (also called a rain screen) can also help dry out the wall in the event of bulk water intrusion and offers some drying if vapor enters the wall cavities.

A-6.3 Daylighting.

The positive effects of introducing daylight into interior spaces to improve productivity and the wellbeing of the occupants is well documented. During the three months in midwinter when the sun is at its lowest angle and shines for only a few hours each day, little natural illumination is available through windows. Conversely, during the summer months, there is continuous daylight. Low sun angles during both the fall and spring seasons increase light entering the building and contribute to increased heat gain and glare.

A-7 ARCTIC ENTRANCES.

Where practical, depress the floor and provide grating and a pan to allow snow and water removal from footwear. Provide mats or carpets at the inside door of the arctic entrance to collect snow and dirt at the entry and prevent slippery floor surfaces. Use a canopy over the entrance to protect personnel from falling icicles and dripping water. Protect exterior walkways from falling ice and snow and from water that may freeze, causing a safety hazard.

A-8 INTERIOR FINISHING.

For structures located in Arctic and Subarctic regions, considerations for thermal expansion and contraction, and structural movement due to asymmetrical high wind and snow loading, are crucial when choosing joining methods for interior finishing work. Structures move to some degree throughout the seasons, and the typical tight tolerances for finish work are not appropriate. This is particularly relevant when large areas of sheet products are installed and finish-joined at the seams, both on walls and ceilings. For gypsum board, cracks will propagate along vertical and horizontal finish seams, and diagonally from door and window openings in walls. This is also very important where different materials meet, or where materials meet orthogonal to each other, such as drywall-to-steel ceiling joints, doorways, penetrating beams, and other interfaces in concrete and various finishes where movement and tight finish tolerance induce finish material cracking, especially originating at corners of openings (window and doors).

A-9 HVAC SYSTEMS.

"Best Practices for HVAC, Plumbing, and Heat Supply in Arctic Climates," by Winfiled et al., discusses common HVAC system approaches used in Arctic climate. This paper describes best practice examples of robust and reliable systems with the emphasis on system redundancy, durability, and functionality

A-10 MECHANICAL SYSTEMS MAINTAINABILITY.

System reliability, ease of access for regular operation or maintenance, system simplicity, and cost are governing factors when selecting primary and backup systems. Carefully select backup and emergency systems to account for an outage to prevent issues with freezing under harsh environmental conditions because this poses a danger to station personnel. To address high maintenance costs, consider whether a high initial cost is outweighed by decreased maintenance costs, resulting in a lower total life cycle cost. Maintenance costs may be high due to high local wages, scarce skilled local labor, the need to provide room and board at remote locations, decreased worker and machine efficiency due to environmental conditions, the length and cost of communications and resupply channels, and the difficulties, costs, and risks in shipping materials and equipment. These issues are critical in the event of an emergency.

A-11 PLUMBING PIPE ARRANGEMENT.

A special enclosed and heated crawl space immediately below the ground floor elevation is an option in Arctic and Subarctic building design. The floor can be constructed with removable insulated panels. Run piping, including hot and cold water, heating lines, and waste piping, in this protected space. Tightly seal the area to avoid air infiltration. The benefits of this approach include ready access for maintenance, easy replacement, and a buffer zone to warm the floor above. Another approach places the utility lines underneath the building within insulated enclosures and protecting pipes with heat to prevent freezing. Heat may be applied by wrapping a heat cable in a spiral pattern around the pipe under the insulation layer; installing an immersion cable within the pipe containing the liquid; installing heat cables in small-diameter conduits attached either directly to, or in close proximity to, the carrier pipe under the insulation layer; or preheating the liquid prior to entering the pipeline.

A-12 FREEZING OF HEATING COILS IN VENTILATION UNITS.

Whenever flow of the heating medium within a coil is modulated and coils are subjected to outside air, they are vulnerable to freezing. Circulating an antifreeze solution can avoid freezing while allowing the system to operate at low temperatures. Recirculating air that reheats return air and mixes it with outside air has been successfully used in Arctic and Subarctic regions. Air stratification can occur when warm return air and cold air are improperly mixed before going through the heating coil. An air-to-air heat recovery coil system is useful in locations such as maintenance shops or fuel storage areas where only outside air and exhaust are used for ventilation and the incoming outside air is preheated prior to entering the fan and heating coil assembly.

A-13 CORROSION CONTROL FOR INTERIOR ELECTRICAL SYSTEMS.

Corrosion slows as temperatures fall below freezing. Consider this fact when installing cathodic protection because anodes installed in frozen earth do not protect a heated structure. For an unheated structure, the required cathodic protection current drops significantly and could result in overprotection if the current is not adjusted. Corrosion from the earth is mild when structures require freeze protection. Wind-blown salts in marine environments are so corrosive that summer months provide enough warmth for substantial corrosion.

B-2 DEFINITION OF TERMS.

UFC 3-130-01, Appendix B, provides a list of general terms for Arctic and Subarctic engineering. This appendix includes terms specific to UFC 3-130-04.

Aerodynamic shade: An area protected from wind and strong air movement. An area of relatively calm conditions conducive to the settling of snow.

Arctic entrance: A type of vestibule. The exterior door of the vestibule is closed to shut out the cold air, high wind, or drifting snow before the inside door is opened to enter the building.

Downwind: In the direction that the wind is blowing.

Ice dam: An ice buildup on building eaves that occurs when snow melted by escaping building heat flows to the eaves and freezes when air temperature drops below 32°F (0°C).

Ice fog: Results when a dew point air temperature below 32°F (0°C) meets an available supply of moisture. Ice fog can seriously impair visibility for extended periods.

R-value: A material's ability to resist heat flow. Otherwise known as *thermal resistance*.

Snow fences: Lath-type fences designed to stop windblown snow and protect a downwind facility from snowdrifts.

Snow transport (Q): The mass of snow transported by the wind over a specified time and width across the wind within the first 16 ft (5 m) above the surface, per meter of width across the wind.

Thermal break: An area of low thermal conductivity between two areas of higher thermal conductivity. The opposite of a thermal bridge.

Thermal bridge: An area of high thermal conductivity between two areas of high thermal conductivity. An example is a through-metal connection in a building envelope component.

Upwind: In the direction from which the wind is blowing.

Whiteout: An optical phenomenon occurring in the Arctic and Subarctic regions in which the snow-covered ground blends with a uniformly white sky, blotting out shadows, clouds, horizon, and so on, and destroying all sense of depth, direction, or distance.

FOREWORD

The Unified Facilities Criteria (UFC) system is prescribed by MIL-STD 3007 and provides planning, design, construction, sustainment, restoration, and modernization criteria, and applies to the Military Departments, the Defense Agencies, and the DoD Field Activities in accordance with USD (AT&L) Memorandum dated 29 May 2002. UFC will be used for all DoD projects and work for other customers where appropriate. All construction outside of the United States, its territories, and possessions is also governed by Status of Forces Agreements (SOFA), Host Nation Funded Construction Agreements (HNFA), and in some instances, Bilateral Infrastructure Agreements (BIA). Therefore, the acquisition team must ensure compliance with the most stringent of the UFC, the SOFA, the HNFA, and the BIA, as applicable.

UFC are living documents and will be periodically reviewed, updated, and made available to users as part of the Military Department's responsibility for providing technical criteria for military construction. Headquarters, U.S. Army Corps of Engineers (HQUSACE), Naval Facilities Engineering Systems Command (NAVFAC), and Air Force Civil Engineer Center (AFCEC) are responsible for administration of the UFC system. Technical content of UFC is the responsibility of the cognizant DoD working group. Defense Agencies should contact the respective DoD Working Group for document interpretation and improvements. Recommended changes with supporting rationale may be sent to the respective DoD working group by submitting a Criteria Change Request (CCR) via the Internet site listed below.

UFC are effective upon issuance and are distributed only in electronic media from the following source:

- Whole Building Design Guide website http://www.wbdg.org/dod.

Refer to UFC 1-200-01, *DoD Building Code*, for implementation of new issuances on projects.

CHAPTER 1 INTRODUCTION

1-1 BACKGROUND.

The field of Arctic and Subarctic engineering, also known as cold regions engineering, covers a wide range of multidisciplinary topics and principles. Unique issues exist in the planning, design, construction, and operation of infrastructure and facilities in Arctic and Subarctic regions. Among them are permafrost, seasonal ground frost heave and thaw settlement, extreme low temperatures, high wind loads, heavy snow loads, and remote construction sites. Additionally, the implications of the rapidly changing climate in Arctic and Subarctic regions exacerbate these unique challenges.

The Unified Facilities Criteria (UFC) Arctic and Subarctic series includes five volumes that summarize relevant information and the most feasible approaches and solutions for planning, design, construction, and maintenance of infrastructure and facilities in the Arctic and Subarctic areas of the globe.

1-2 NEED FOR SPECIAL APPROACHES.

Unique problems exist in the planning, design, construction, and operation of water, wastewater, and energy utility systems in Arctic and Subarctic regions. Among them are permafrost, seasonal ground freezing and thawing with its associated frost heave and thaw settlement, extreme low temperatures, and often, remoteness of the construction site. The degree of influence of these factors varies significantly over these regions as they include vast geographical territory. Many components of conventional or temperate climate utilities can be used in cold regions. However, no conventional component should be used without careful analysis of the effects of cold stress on their operation and durability. Analysis should assume that the system will freeze. As a result, all systems should incorporate a plan for the recovery of a frozen component or system.

"Environmental Engineering Failures in Alaska," by Schubert et al., provides case histories of utility failures in Alaska that illustrate the potentially catastrophic nature of utilities systems designed and operated without consideration of the extreme conditions in which they were installed. In some cases, failure resulted in abandonment of the structure or system; in other cases, repair or change in operation was able to correct the design shortcomings. In all cases, the cost of these failures was significant in social (interruption of service), environmental, and monetary terms.

1-3 REISSUES AND CANCELS.

This document supersedes and cancels inactivated UFC 3-130-05, dated 16 January 2004.

1-4 PURPOSE AND SCOPE.

The Arctic and Subarctic UFC series provides technical guidance and available technical requirements for planning, design, construction, and maintenance of DoD facilities worldwide for all Service elements in Arctic and Subarctic environments. These guidance and technical requirements are based on the International Building Code (IBC) and the requirements in UFC 1-200-01. The UFC 3-130 series covers many aspects of Arctic and Subarctic engineering with the specific exception of pavements, which is incorporated into the UFC 3-250 and 3-260 series as discussed in UFC 3-130-01, paragraph 1-6.3. In addition to this volume, there are four other series volumes:

- UFC 3-130-01, *Arctic and Subarctic Engineering*. UFC 3-130-01 serves as an introduction to the Arctic and Subarctic UFC series.
- UFC 3-130-02, *Arctic and Subarctic Site Assessment and Selection*. UFC 3-130-02 provides applicability and technical guidance for geotechnical site assessment for the Arctic and Subarctic environment conditions.
- UFC 3-130-03, *Arctic and Subarctic Foundations for Freezing and Thawing Conditions*. UFC 3-130-03 includes horizontal and vertical foundations, considerations affecting foundation design, and construction and monitoring of facilities in the Arctic and Subarctic areas.
- UFC 3-130-04, *Arctic and Subarctic Buildings*. UFC 3-130-04 includes building design in the Arctic and Subarctic areas.

This UFC provides criteria and guidance for the planning, design, and construction of utility systems for DoD facilities in Arctic and Subarctic regions. Only criteria and guidance unique to cold regions (the Arctic and Subarctic) are provided. Topics covered include water supply; wastewater collection, treatment, and disposal; fire protection; utility distribution systems; and the thermal calculation techniques needed for their cold regions design. These minimum technical requirements are determined by UFC 1-200-01. Where other statutory or regulatory requirements are referenced, the more stringent requirement must be met.

Specific discussion of centralized heating plants and their distribution systems, either steam or hot water, are beyond the scope of this UFC. The American Society of Heating, Refrigeration and Air-Conditioning Engineers (ASHRAE) *District Heating Guide* and *Guide for Resilient Thermal Energy Systems Design in Cold and Arctic Climates* provide excellent references for this topic. Topics such as equipment redundancy and fault detection found in the *Resilient Thermal Energy Systems Design in Cold and Arctic Climates* are applicable to noncentralized systems also. Requirements for distribution pipelines carrying natural gas, manufactured gas, or Liquefied Petroleum Gas (LPG) in its vapor phase, that are installed on DoD owned property, from the point of delivery by the gas supplier to the points of connection to the buildings' fuel gas piping, are provided in UFC 3-430-05. As with water and wastewater piping, the thermal considerations for these pipelines are critical in cold regions. Chilled or warmed pipelines may affect frost heave and thaw settlement in such a way as to be catastrophic to the structural integrity of these systems. Further discussion can be found in resources listed in Appendix B.

1-5 APPLICABILITY.

This UFC follows the same applicability as UFC 1-200-01, paragraph 1-3, for those geographic locations in Arctic and Subarctic regions worldwide.

1-6 GENERAL BUILDING REQUIREMENTS.

This UFC is an integrated part of the Arctic and Subarctic UFC 3-130 series. Use the other documents of this series in conjunction with this UFC to address construction aspects unique to cold regions. See UFC 3-130-01, Chapter 2 for the definitions of Arctic and Subarctic.

Often, conventional construction practices are acceptable in Arctic and Subarctic regions with appropriate modification to account for extreme cold temperatures, frost heaving soils, and permafrost areas. This UFC modifies and supplements the criteria found in the core UFCs. Utility provider’s or Installation specific requirements must be considered.

1-7 CYBERSECURITY.

All facility-related control systems (including systems separate from a utility monitoring and control system) must be planned, designed, acquired, executed, and maintained in accordance with UFC 4-010-06, and as required by individual Service Implementation Policy.

1-8 COMMENTARY.

Because of the unique aspects of cold regions engineering, commentary has been added to the chapters. This commentary speaks to elements that are unique to cold regions applications. Section designations for such commentary are preceded by a “[C]” and the commentary narrative is highlighted with light gray.

1-9 BEST PRACTICES.

In cold regions engineering planning, design, and construction, much of the state of the practice is not codified. Lessons learned and the experiences of the Installation engineering staff are invaluable and may help avoid potentially costly and catastrophic infrastructure failures. Appendix A, Best Practices, provides guidance for accomplishing certain utilities design and engineering services in extreme Arctic and Subarctic environments. The Designer of Record (DoR) must review and interpret this guidance as it conforms to criteria and contract requirements and apply the information according to the needs of the project. If a Best Practices document guideline differs from any UFC, the UFC takes precedence. For Best Practices guidelines not discussed in a UFC, the DoR must submit a list of the guidelines or requirements being used for the project to the Government Project Manager with documentation sufficient for review and approval prior to completing the design.

1-10 GLOSSARY.

Appendix D contains acronyms and abbreviations. See UFC 3-130-01 for definitions of general cold regions engineering terms.

1-11 SUPPLEMENTAL RESOURCES.

Appendix B provides a list of reliable sources for information on subjects related to cold regions engineering, design, and construction. These resources are valuable tools to the civil engineer for additional information on topics pertinent to and affiliated with construction of utility systems in Arctic and Subarctic regions.

1-12 REFERENCES.

Appendix E contains a list of references used in this document. The publication date of the code or standard is not included in this document. Unless otherwise specified, the most recent edition of the referenced publication applies.

CHAPTER 2 PLANNING AND DESIGN

2-1 GENERAL.

Engineering decisions for the planning, design, construction, and maintenance of infrastructure in Arctic and Subarctic regions are based not only on applicable federal, state, and local codes, but also the expertise of engineers or practitioners with experience in dealing with the unique conditions provided by the extreme environment these regions experience. It is the intent of this UFC, and the Arctic and Subarctic UFC series, is to provide requirements and guidance to prevent significant missteps in the planning, design, and construction of cold regions infrastructure. Consultation with experienced engineers at the Command, District, and Installation level is required to ensure technologies and practices that are unsuitable for this environment, or a specific location, are not proposed. This UFC provides indicators of potential problem areas that may require unique engineering solutions outside the realm of those seen in temperate region or standard construction practices.

2-2 ENVIRONMENTAL CONDITIONS IN THE ARCTIC AND SUBARCTIC.

The planning, design, construction, and maintenance of utility systems are all affected by the special environmental conditions found in the Arctic and Subarctic. These conditions include adverse temperatures, extreme temperature variations, wind, humidity, and snow; high costs; remoteness of locations; limited availability of construction materials and labor; need for fuel additives, synthetic lubricants, oils, and greases for construction equipment; thermal stresses; and seasonal ground freezing, frost heaving, and permafrost.

2-2.1 Temperature.

[C] 2-2.1 The low temperatures prevailing in the cold regions are the most critical environmental factor. The intensity of the cold is important, but equally critical is the duration of the cold period. Mean annual air temperatures in the Northern Hemisphere are presented in UFC 3-130-01. Air temperatures in Arctic locations vary from highs of 80°F (27°C) in summer to lows of −75°F (−59°C) in winter. Interior locations away from the tempering effects of oceans or large water bodies tend to have the greatest extremes. Sub-zero temperatures can persist for months, and it is not uncommon for air temperatures to remain below −30°F (−34°C) for a week or more at many locations in Alaska.

2-2.2 Wind and Related Factors.

The combination of wind and low temperatures results in very large heat losses from exposed facilities and presents hazards for personnel. Blowing and drifting snow can create major construction and operational problems even when the total precipitation is low. The location and layout of utility systems and access points for operation and maintenance must be given careful consideration during planning and design to avoid problems with drifting snow.

[C] 2-2.2 Mean annual wind speeds for most Arctic and Subarctic locations are usually about 5 to 10 miles per hour (mph) (8 to 16 kilometers per hour [kph]) in the interior and 10 to 20 mph (16 to 32 kph) at coastal locations. During a 1972 extreme storm event, Thule, Greenland reported wind speeds in excess of 200 mph (322 kph).

2-2.3 Humidity.

Humidity is a critical factor in enclosed spaces, and both high and low extremes may be experienced in arctic situations. Since natural humidity is extremely low due to the low winter temperatures, humidifiers may be desirable in personnel spaces in order to maintain humidity at about 30 percent. Very high humidity is experienced in pump stations and enclosed treatment works, and thus, condensation may occur on cold surfaces causing damage and inconvenience. Corrosion under insulation is one example of the resulting damage, as are the potential negative effects of high humidity on wood (Type V) construction.

2-2.4 Permafrost.

The presence of frozen soil critically impacts the structural considerations for cold regions design and construction, potentially affecting the ability of the ground to support infrastructure loads. Therefore, the presence of permafrost, or perennially frozen ground, is typically a major design consideration. Figure 2-1 in UFC 3-130-01 illustrates the approximate distribution of permafrost in the Northern Hemisphere. In the zone of continuous permafrost, frozen ground is absent only at a few widely scattered locations such as at the bottoms of lakes and rivers. In the discontinuous zone, permafrost is found intermittently. Permafrost and seasonal frost are discussed in more detail in UFC 3-130-01.

2-3 PLANNING CONSIDERATIONS.

In the Arctic and Subarctic, utility systems are usually the costliest component in construction of military Installations. The layout of an Installation is often controlled by the type of distribution and collection systems selected for the utilities network. As a result, planning for a new Installation or the addition of new facilities on an existing Installation in the Arctic and Subarctic must include consideration of utilities at a very early stage to ensure overall cost effectiveness. Use UFC 3-201-01 for preliminary site analysis and evaluation of existing conditions such as geotechnical site investigation, environmental considerations, surveying, and topographic surveying. Use UFC 3-130-02 for site analysis topics specific to cold regions. Review the existing utility maps and Installation planning documents with Installation personnel to develop population estimates and plans for new service areas. Address Installation specific design preferences and standards with responsible engineering and operations personnel as part of the system design analysis.

DoD Installations in Arctic and Subarctic regions vary significantly by size, mission, and remoteness. Engineering design decisions for Installations manned by unaccompanied military, civilian, and contractor personnel may differ from those made for Installations where the tour of duty is accompanied, and family housing is provided on the Installation. In Figure 2-1 high voltage, insulated electrical lines on pipeline sleepers are placed directly on the ground at Thule Air Base, Greenland. Thule Air Base assignments are unaccompanied, limiting Installation access to DoD service members, civilians, and contractors. These ground surface electrical lines would likely be unacceptable for both safety and aesthetic reasons on less remote Installations where family members are present. The Installation, District, or Command engineering personnel must be involved in project planning and throughout the design process to ensure appropriate facilities to meet the locality mission are constructed.

Figure 2-1 Unprotected Insulated Power Lines at Thule Air Base, Greenland

2-3.2 Useful Life.

The harsh operating conditions for utility systems and equipment in cold regions reduces their useful life. Table 2-1 presents typical useful lives for some utilities components in the Arctic and Subarctic.

[C] 2-3.2 Equipment that must operate throughout the winter are particularly critical. Pumps and their controls, required to maintain pipe flow, are examples of critical equipment.

Table 2-1 Approximate Useful Life of Utility System Components in Cold Regions

Component	Useful Life (years)
Wells	30
Pumps and controls	5
Storage tanks	40
Water distribution lines	40
Meters	10
Valves	10
Sewage collection lines	30
Lift stations (not pumps)	30
Buildings	30
Paint (exterior)	10
Service connections	10–15
Trucks	4
Tracked vehicles	2–3
Backhoe (occasional use)	6–10
Compressors	5

2-3.3 Construction Methods.

The three basic construction techniques used are modular, stick built or in-place construction, and prefabricated. The method selected depends on site conditions and transportation facilities available. The normal construction season varies from two to three months along Alaska's Arctic coast to six to eight months in southern areas of Alaska.

2-3.4 Installation Layout.

Consult UFC 2-100-01 for guidelines to Installation planning and infrastructure layout and UFC 3-130-04 for issues specific to cold regions. For existing Installations, consult the Installation Development Plan (IDP), or other Installation planning documents.

2-3.4.1 Utility Networks.

The critical planning decisions for utility networks are (1) whether the pipes should be above or below ground, and (2) whether the pipes should be installed as individual units or combined with other utility services in a utilidor. Heat loss is directly proportional to the difference between the inside and outside temperatures. An aboveground utilidor or pipeline is directly exposed to extreme weather conditions and therefore has a much higher maximum rate of heat loss (and therefore shorter time to freeze) compared to a similar pipeline buried just below the ground surface. In general, adopt belowground installation wherever possible. Pipes buried in permafrost or in the seasonal frost zone must not only be protected from freezing but must also resist the structural effects of heaving in the seasonal frost zone and potential thawing of the permafrost. Additionally, thermal considerations must be concerned with not only protecting the pipe from freezing, but also protecting the permafrost from thawing. The terrain is relatively flat in much of the Arctic, and maintenance of the necessary grades for gravity sewers in either the aboveground or buried mode is difficult. Use pump stations, or pressure or vacuum sewer systems, to overcome these constraints. The decision to combine multiple utility services in a utilidor is determined by a variety of factors. Benefits may be derived both during construction and maintenance, and the combined systems may be easier to protect from freezing. However, utilidors are generally larger structures and more expensive to build. The thermal contribution of multiple pipes in a single space, and their possible interaction, must be considered. Thermal considerations for above and belowground utility installation are covered in detail in Chapter 12 and utilidors are discussed further in Chapter 9.

[C] 2-3.4.1 Aboveground utility systems offer easier access for maintenance and repair and are cheaper to build where site conditions are poor. However, there are disadvantages. They are susceptible to vandalism and traffic damage, disrupt pedestrian and vehicle traffic patterns, and create snow removal problems. Belowground systems allow for more normal Installation layout, however pipe breaks and leaks in belowground pipes are harder to detect and locate, particularly in frozen ground.

2-3.4.2 Network Layout.

Utility network layout is dependent on the source and termination of each component of the system. Utilities may be provided from off Installation by local utility companies. Other Installations have centralized heating or power plants; water source, treatment, and storage facilities; and wastewater treatment facilities all on-site. Service lines from utility mains to individual buildings are the main source of freezing problems. Site buildings as close to the mains as possible with service lines 60 ft (18.3 m) or less in length. Do not design Installation layouts with dead-end streets unless a pipe connection can be made to an adjacent street for the circulating water system. Locate the largest consumers of water at the extremities of the distribution system if possible.

[C] 2-3.4.2 It is typical practice in temperate climates to bury most utility lines in the streets. However, there are thermal disadvantages to this practice in cold regions since clearing the roads of snow will allow greater frost penetration. Burying water and sewer mains in the front or back yards of dwellings, and in open areas where snow will not be removed, maintains warmer ground and pipe temperatures.

2-4 DESIGN.

Use UFC 3-201-01 for topics such as site development, grading, and storm drainage systems. Use UFC 1-200-02 for energy and sustainability.

2-4.1 Design Criteria.

Design utility systems to meet all applicable regulations and requirements of federal, state, and local governments, or overseas equivalent.

2-4.2 Approvals and Permits.

See UFC 3-130-01, paragraph 1-13, for the general approval and permit processes for Arctic and Subarctic construction. For new potable water supply systems, extensions to new areas, rehabilitation, or replacement of existing potable water supply systems, coordinate with the Safe Drinking Water Act primacy agency, as applicable, to determine primacy agency requirements. For new or rehabilitated sanitary sewer systems or facilities such as service extensions, domestic wastewater treatment, or industrial wastewater treatment, coordinate with the applicable primacy agency to determine permitting requirements.

2-5 EQUIPMENT.

For remote Arctic Installations, the initial cost of most utility equipment is not as important as its reliability. Redundant or split systems allow extended operation with a single unit failure for equipment such as boilers. Standby units for critical equipment are essential and are particularly important for emergency power and for heating systems. A large inventory of critical spare parts is recommended and standardization of equipment to reduce the parts inventory will prove economical.

2-6 ALARM SYSTEMS.

Provide alarms and safeguards, such as low water temperature alarms, low flow alarms, and low or high voltage alarms to warn operators of any pending problems. Incorporate instrumentation and monitoring into utility systems and facilities to allow for safe and efficient operation. All critical utility facilities must have instrumentation, monitoring, alarm, and notification systems to indicate critical conditions that would result in:

- cessation of essential service (for example, monitor flow, temperature, and pressure); or
- damage to facilities (for example, monitor for fire and low temperature).

Further discussion is given in paragraphs 3-6.4, 5-2.6, and 7-4.4. Paragraph 10-5 discusses integration of utility alarm instrumentation with the Installation central alarm system.

2-7 REVEGETATION.

Revegetate areas excavated and backfilled for utility systems to prevent erosion. Request planting criteria from the Installation, District, or Command environmental staff.

[C] 2-7 Locations may have significantly different grass, tree, and shrub species lists. The preferred or acceptable planting season may also vary by location.

This Page Intentionally Left Blank

CHAPTER 3 WATER SOURCE DEVELOPMENT

3-1 GENERAL.

The water requirements and design capacity factors for domestic, fire, and other functional uses are specified in UFC 3-230 series. Per UFC 3-230-01, unless otherwise directed by the Government Project Manager, use nearby public potable water systems. However, if that is not practical, sources must be developed on the Installation. Both ground and surface waters are available in the Arctic and Subarctic, but the environmental conditions require special approaches for their development. In addition, ice and snow are sometimes used for water supply augmentation or as emergency or standby sources.

3-2 ENVIRONMENTAL CONSTRAINTS.

In most of the Arctic and Subarctic, precipitation is light, terrain is relatively flat, and runoff is concentrated in the short period during ice breakup. There are many small, shallow lakes, ponds, and numerous rivers and streams. Ice cover varies according to local conditions but generally lasts from 6 to 10 months and approaches 6 ft (1.8 m) in depth in small quiescent water bodies (see Appendix C, Example 1 for procedures to estimate thickness of ice formation). Hydrologic data for these regions are scarce, so it is difficult to predict reliable yields. Because permafrost is essentially impermeable, there is little direct recharge of most aquifers. Any penetration of the permafrost for exploration or for well development requires special engineering consideration and is costly.

3-3 SURFACE WATERS.

Many shallow lakes and small streams freeze completely in the winter, eliminating them temporarily as a water source. Some Installations pump water from such sources in the summer months to store for a winter supply. Larger streams and deep lakes can have liquid remaining beneath the ice, but the volume available is limited since there is no contribution from precipitation in the winter. The large quantity of ice and snow results in major annual flows occurring during the spring breakup. Hydrographs for Arctic rivers in the U.S. are available from the United States Geological Service (USGS) website https://waterdata.usgs.gov/nwis.

3-3.1 Rivers.

The volume of flow is low in the winter for Arctic and Subarctic rivers, but water quality is excellent since sediment transport from glacial sources is minimal and surface runoff recharges do not occur. Winter water temperatures are very low (33°F [0.6°C]), which creates difficulties for treatment, and intakes can clog due to formation of frazil ice. Floating ice during freeze-up and breakup periods can damage or destroy intake structures. Some facilities remove intake structures and rely on water from temporary storage locations during these periods. Development of intake galleries or wells in the stream bottom mitigates ice problems, but it is difficult to locate the permanent channel in alluvial and braided streams. The summer flows are higher in volume than winter flows, but they are poorer in quality, containing sediments which may be difficult to remove. These sediments are primarily glacial silts and are almost colloidal in size.

3-3.2 Lakes.

Deep lakes are a reliable, continuous source of water. The quality of any liquid beneath the ice in a shallow lake or pond is typically poor. Impurities, such as most salts, are rejected from the freezing water, making the ice relatively pure but concentrating the impurities in the remaining liquid. A survey is required to identify lakes and ponds that may freeze deeply enough to create this condition. Chapter 12 discusses the thermal aspects of such an analysis.

3-3.3 Saline Waters.

Distillation or reverse osmosis is used to treat saline or brackish waters; these procedures are costly and energy intensive. Avoid such sources except as the last resort.

3-3.4 Augmentation.

In the Arctic, most of the annual precipitation is in the form of snow. Although total precipitation is low, advantage can be taken of windy conditions to induce snow drifting at selected locations. Collection of the melting snow augments the summer water supply. ASCE *Cold Regions Utilities Monograph,* Section 5.2.1, provides more information.

[C] 3-3.4 Snow fences were used to induce drifting in the watershed of the Utqiagvik, Alaska water reservoir. It was shown that at least 800 gallons (3000 liters) of water were collected for every linear foot of 5-ft-high (1.5-m) snow fence that was installed, with the fences about 250 ft (76 m) apart.

3-4 GROUNDWATER.

Groundwater can be a more reliable water source than surface supplies. It is usually available on a year-round basis and is more consistent in its temperature and mineral quality than surface sources. Very shallow groundwaters are unsuited for potable water supplies without extensive treatment and the yield is limited. Subpermafrost groundwater or permafrost zones thawed by large rivers and lakes are the most reliable sources. Subpermafrost wells are technically feasible when the permafrost extends to a depth of a few hundred feet or less, and they have been successfully used in central Alaska. Costs for drilling and maintenance of such wells are high. The water must be protected from freezing, and the permafrost must be maintained in a frozen condition. This requires special well casings or grouting methods and unique operational methods. Subpermafrost water is generally deficient in dissolved oxygen and can also contain high concentrations of dissolved iron and manganese salts. Hardness is also common. Dissolved organics can create serious treatment problems because of interactions with the dissolved iron and the color imparted to the water. The most reliable and economical groundwater sources in the Arctic and Subarctic are in the thawed zones adjacent to large rivers and lakes. Most of the rivers are braided streams and have shifted their channels many times. The former stream channels may still be underlain by thawed material and represent a potential water source depending on the type of soils involved.

3-5 OTHER WATER SOURCES.

Consider snow, ice, and direct catchment of rainfall as potential water sources for augmentation or emergency supplies and for small facilities, temporary facilities, or facilities in support of military operations with a design life of five years or less. The natural quality of these sources is good, but a stockpile of snow or ice can be easily contaminated. Large volumes of snow are required to produce even small quantities of water and the costs for harvesting and melting are high. It is estimated that 4 to 5 ft^3 (0.11 to 0.14 m^3) of snow is required for every 5 gallons (19 liters) of water produced, and to melt this volume of snow would require about a pint of diesel fuel for the snow melting equipment. Brackish and saline ponds have been improved in quality by pumping out the concentrated brines that remain under the ice near the end of the winter and allowing fresh spring runoff to recharge the pond. If repeated several times the procedure allows the use of an initially unacceptable water source.

3-6 STRUCTURES.

Structures range from wells and their appurtenances, to simple temporary intakes placed on the river ice, to complex dam structures located on permafrost. The complete structural design of any of these is beyond the scope of this UFC (UFC 3-130-03 discusses embankment construction on permafrost). It is the intent of this section to point out those features that may require special attention in the cold regions. ASCE *Cold Regions Utilities Monograph,* Section 5.4, provides additional considerations in design of these structures.

3-6.1 River Intakes.

A permanent intake structure is usually employed for large-scale permanent military facilities in the Arctic. Structural damage from moving ice in the spring and in the fall is the major concern.

3-6.1.1 Temporary Intakes.

Temporary intakes are less expensive and are removed from the river during spring ice breakup; and storage is relied on as the water supply. This approach is suitable for small populations. A temporary intake consists of a pump and simple shelter.

3-6.1.2 Permanent Intakes.

Numerous arrangements and configurations for permanent intake structures have been designed. Special features of these designs include insulation, heat tracing in the wet well and in the intake line, and a recirculating line from the facilities served. Dual intakes are recommended to ensure reliability. Continuous water circulation is then used to prevent freezing. Frazil ice can be a serious problem for intakes during the freeze-up period. Frazil ice occurs as small crystals in flowing water slightly below 32°F (0°C) in temperature. It will adhere to and accumulate on any submerged object it contacts. Water intakes, trash racks and similar structures can become completely choked by frazil ice in a few hours. It can be avoided by locating the intake in a long, calm reach of the river where surface ice will occur before the water becomes supercooled. The surface ice cover then prevents rapid heat loss and precludes frazil ice formation. Heating the intake and bar screens to about 33°F (0.6°C) prevents formation of frazil ice. This can be done electrically or by back pumping hot water or steam.

3-6.2 Infiltration Galleries.

Infiltration galleries remove the structure from risk of ice damage and thereby offer advantages over direct intakes. The gallery is placed in thawed material in the stream bed or adjacent to it. The yield will depend on the type of soil present. Importation of coarse-textured material is necessary for gallery construction in fine-textured silty and clayey soils. Both electrical and steam lines have been used in galleries to prevent freezing. Steam lines are usually placed on the upper surface of the intake laterals and on a second level about 1.5 ft (0.5 m) above that. The heating elements or steam lines are not normally operated continuously but are used only in emergencies to restore a frozen or partially frozen system.

3-6.3 Wells.

See UFC 3-230-02, for basic procedures for water well design. The special concern for subpermafrost wells is not to allow thawing of the permafrost during drilling or operation of the well. The former may require either compressed air or nontoxic drilling muds or fluids with rotary drilling procedures. Avoidance of permafrost thawing during well operation may require multiple casings so that cold air can circulate in the annular spaces. Concurrent with protection of the permafrost is the necessity of maintaining the water in an unfrozen state, which requires heat addition for an intermittently used system. Artesian flow, from subpermafrost aquifers, may also cause issues for wells, especially on valley floors and at the bottom of hill slopes. In *Geologic Hazards of the Fairbanks Area: Alaska Division of Geological & Geophysical Surveys Special Report 15,* Péwé discusses this phenomenon and several cases of uncontrolled flow through and around the well casings in the Fairbanks area.

In nonpermafrost conditions, design wells for frost heave protection in the surface soils. Casings must be designed to prevent the bonding between the frozen soil and the pipe and thereby eliminate heave damage.

3-6.4 Pumping Stations.

Pumphouses provide shelter for pumping equipment controls, boilers, treatment equipment, and maintenance personnel who must operate and service the facility. The structural design depends on the requirements of each location and must be considered individually. The type of equipment housed within the shelter also depends on the individual system and may vary from a simple pump to a complex system with HVAC, standby power, and alarm systems to alert operators of malfunction. Any system must provide the degree of redundancy and other safeguards required by the nature of the operation and location. ASCE *Cold Regions Utilities Monograph,* Section 5.4.4, provides more information.

Alarms should include, but are not limited to, the following:

- no return flow
- low/no return pressure
- low/critical low return temperature
- high supply/fire flow
- high supply temperature
- pump trouble
- heating system or HVAC trouble
- Fire Flow Trouble

Consult Installation, District, or Command engineering and operations staff for specific requirements.

This Page Intentionally Left Blank

CHAPTER 4 WATER TREATMENT

4-1 GENERAL.

See UFC 3-230-01, for the basic requirements, criteria, and procedures for water treatment systems for military facilities. This chapter discuss only those aspects unique to the Arctic and Subarctic. There are three major process concerns: the low temperature of the raw water, removal of glacial silt from surface sources and removal of dissolved minerals, and organics from surface or groundwater sources.

4-2 TEMPERATURE EFFECTS.

The temperature of surface water sources during winter will be at or very near 32°F (0°C), while groundwater sources in permafrost regions may be a few degrees warmer and maintain that level year-round. The water must be preheated to at least 40 to 50°F (4 to 10°C), or the unit processes must be designed for low temperature operation. The effect of low temperatures on equipment operations must also be evaluated during facility design. ASCE *Cold Regions Utilities Monograph,* Section 6, provides further guidance.

4-3 LOW TEMPERATURE TREATMENT.

Almost all physical, chemical, and biological processes used in water treatment are sensitive to temperature either through viscosity effects or as an influence on reaction rates. This must be considered for mixing, sedimentation, filtration, and disinfection. See the ASCE *Cold Regions Utilities Monograph,* Section 6.3, for further details.

As of 2015, there is no longer separate guidance for fluoridation in cold climates. See the UFC 3-230 series for specific requirements for military Installations.

4-4 REMOVAL OF MINERALS AND ORGANICS.

[C] 4-4 Ion exchange water softening is commonly used at smaller Installations with hard water. Lime-soda softening is frequently used when the water is both turbid and has a high hardness. Dissolved iron is common in cold regions groundwater. Aeration or chemical oxidation with chlorine have been successful for precipitation of elemental iron. Iron can foul zeolite and greensand ion exchange resin systems unless they are appropriately designed. If the groundwater has excessively high iron, precipitation is likely a better way to remove the iron, and then use greensand as a polishing measure for any remaining iron. However, iron/organic complexes are present in many cold regions groundwaters. Ozone has been shown to be effective in treating such water. Ozone and carbon adsorption are very effective for color and organics removal.

4-5 TREATMENT OF BRACKISH AND SALINE WATERS.

Distillation, reverse osmosis and freezing have all been used in cold regions to reduce saline concentrations to potable levels. See the ASCE *Cold Regions Utilities Monograph,* Section 6.3.11, for further details.

CHAPTER 5 WATER STORAGE

5-1 GENERAL.

Basic criteria for determination of capacity requirements, design, and construction of water storage facilities can be found in UFC 3-230-01. This chapter discusses only those aspects unique to the Arctic and Subarctic. Water is provided for domestic, industrial, and fire protection services. A design study to determine specific water needs must be undertaken for each new facility so that cost-effective designs for water supply, water storage, and wastewater systems can be ensured.

[C] 5-1 The requirements for water will typically be lower at remote facilities in the Arctic and Subarctic than at similar operations in the temperate zone due to conservation and lower external water needs. The water needs will vary with the type of facility, so general criteria are not possible.

5-2 WATER TANKS.

Structural design of water storage tanks generally follows temperate regions practice. Considerations specific to Arctic and Subarctic construction include insulation, thermal conditions, foundation design (see UFC 3-130-03), and the need to prevent ice damage. Ice buildup, either inside or on the exterior of the tank, due to leakage, may pose serious structural and safety risks. ASCE *Cold Regions Utilities Monograph,* Section 7.5, provides additional details on water tank design.

5-2.1 Tank Materials.

Construction materials for water tanks in cold regions include wood, steel, and concrete. In Alaska, welded steel tanks are the most commonly used. Tank insulation materials include polystyrene or polyurethane boards, or sprayed-on polyurethane. Concrete tanks have been used where aggregate is available and the foundation conditions permit slab construction. Insulate concrete tanks, or cover with earth, to reduce heat losses. Evaluate seismic conditions prior to selection of a rigid concrete tank. Welded steel tanks are more cost effective for high-risk seismic areas.

[C] 5-2.1 Wood stave tanks are constructed with prefabricated pieces that can be shipped relatively easily to any remote site. Leakage is a problem with intermittent or fill-and-draw operations since the joints can open slightly if the wood is allowed to dry.

5-2.2 Corrosion Protection.

Paint steel water tanks in accordance with applicable standards provided in UFC 3-230-01. When selecting paints, the in-service temperature range must include normal and possible extremes. Strictly follow manufacturers' recommendations regarding acceptable temperature limits for the application of these paints to avoid premature failure. Cathodic protection is also required.

[C] 5-2.2 The cost of sandblasting and liner replacement is very high in remote locations so the type of coating initially selected must be of high quality and properly applied.

5-2.3 Insulation.

Common tank insulation materials are earth cover (soil), polyurethane or polystyrene board, or sprayed on polyurethane materials. Selection is affected by factors including moisture exposure, attachment options, and cost, among other considerations. Moisture-resistant layers of insulation materials must be installed in contact with the tank at inaccessible locations since moisture from leaks, condensation, rain, or groundwater can drastically reduce the insulating effect. Insulation applied aboveground requires protection against accidental mechanical damage, vandalism, birds and animals, and weather. Aluminum or steel cladding provides a good barrier against weather and mechanical damage. Insulation materials are further discussed in paragraph 12-7.

[C] 5-2.3 Tanks may also be enclosed with a protective shell. Such an exterior shell is either constructed against the tank or a walkway provided between the tank and the exterior wall. The air gap and the wind protection will reduce heat losses, and this heat loss can be further reduced by installing insulation. Near-hydrophobic plastic foam insulations are readily available and commonly used. Polyurethane can be obtained as either prefabricated boards or foamed in place by spraying directly onto the tank. The latter has been the more common approach in Alaska.

5-2.4 Tank Design.

Design water storage tanks to prevent the formation of ice in the tank under all foreseeable circumstances, and tanks must be completely drainable. Surface icing can be avoided by maintaining the water temperature above 39°F (4°C) and ensuring continuous circulation. Double-wall, testable heat exchangers are recommended for sanitary purposes.

[C] 5-2.4 Floating ice in the tank can destroy interior appurtenances, and ice formed on the walls can collapse and cause structural failure or punctures in the tank bottom. In some cases, the return line of a circulating water distribution system is discharged to the storage tank to promote circulation and maintain temperatures. In other cases, a small amount of water is withdrawn, heated with a boiler or heat exchanger, and pumped back into the tank.

5-2.5 Appurtenances.

Locate breather vents on the inside of the tank and vent into an attached pump house or building rather than directly to the outside. Install overflow piping inside the tank or protect it with insulation and heat tracing if placed on the exterior.

[C] 5-2.5 Locating vents as discussed prevents ice from forming in an exposed vent due to condensation, which would cause a vacuum to form in the tank as water is withdrawn and, possibly, the tank to collapse.

5-2.6 Instrumentation.

Instrumentation includes water level indicators, with high- and low-level alarms, and thermal probes at various levels for control and alarm. Air temperature above the water surface is likely to be of interest. Since ice can damage float type water level indicators, a pressure type transducer is recommended. External lighting may improve security and an internal light may assist inspection. Thermal monitoring of permafrost foundation soils may be part of the overall project.

5-2.7 Thermal Considerations.

Whenever practical, tanks must be buried or covered with soil to reduce the effect of low air temperature. Avoid elevated tanks unless they are absolutely necessary for the water distribution system since they expose the greatest surface area to the worst climatic conditions. Insulate all exposed tank surfaces and pipe risers for elevated tanks. Thermal calculations are necessary to size heating systems when they are used to replace heat losses or to heat the water for distribution. The unit capacity of a heat exchanger or boiler must be equal to the maximum rate of heat loss. Water circulation within the tank or boiler heating are common for tanks with intermittent flow and refill.

5-2.8 Tank Foundations.

Foundation considerations for tanks are like those for other Arctic and Subarctic structures and are covered in UFC 3-130-03.

[C] 5-2.8 Foundation design for tanks is complicated by the very high loads imposed by the stored water and the need to keep the water in the unfrozen state. The unfrozen water is a heat source that can have an adverse effect on the underlying permafrost and must be considered during design for a tank on grade.

5-3 EARTH RESERVIORS.

Construct earth embankments for water reservoirs in accordance with UFC 3-130-03. A liner is necessary within the embankment, or to seal the entire reservoir, when permeable soils are present or used for construction. Ice formation, and its effect on the function of the reservoir, must be considered. ASCE *Cold Regions Utilities Monograph,* Section 7.3, provides more detail.

[C] 5-3 Water impoundments for domestic and industrial water supply and for hydropower have been successfully constructed in the Arctic and Subarctic. The most likely configuration for military facilities is an earthen embankment to either increase the storage capacity of an existing lake or stream or to impound water in a natural drainage swale.

CHAPTER 6 WATER DISTRIBUTION

6-1 GENERAL.

See UFC 3-230-01 for the basic criteria for design and construction of water distribution systems. This chapter presents information that is unique to the Arctic or Subarctic. Pressurized pipe distribution systems are used for exterior utilities and interior plumbing in most military facilities in the cold regions. An exception might be small, remote facilities separated from the main distribution network. If individual wells are not feasible, then vehicle delivery of water would be necessary. Truck delivery systems are common at remote civilian communities in Alaska, Canada, and Greenland. The location of pipe distribution systems and whether they should be buried, aboveground, or in a utilidor are discussed in Chapters 2, 8, and 9.

6-2 RECIRCULATION SYSTEMS.

6-2.1 Single Loop.

6-2.1.1 General.

Single pipe recirculation, or loop, systems are recommended for Arctic conditions. As shown in Figure 6-1, a single loop system consists of one uninterrupted loop originating at a recirculation facility and returning to that point without any branch loops. This layout eliminates dead-ends and related freezing problems and requires the minimum amount of piping as compared to other circulation methods. A simple, positive control of distribution is possible with flow and temperature indicators on the return lines at the recirculation facility. Typically, water pressure is regulated at the water recirculation facility. Manual and automatic control valves are frequently used, along with variable speed pumps to maintain pressure. Pipe network design uses the same procedures used for standard water systems. The return line does not have to be of the same size as the delivery pipe because of withdrawals in the network. If possible, locate mains at the rear of buildings or in areas not cleared of snow, rather than in the streets.

6-2.1.2 Water Temperatures.

Normally, water is pumped out at 39 to 45°F (4 to 7°C) and returns at 33 to 39°F (0.5 to 4°C). Where the mainline provides fire protection, NFPA 24 Chapter 7-5.2.2 requires water to be maintained above 40º F (4.4°C) for freeze protection, when exposed to freezing conditions. Otherwise, two scenarios exist:

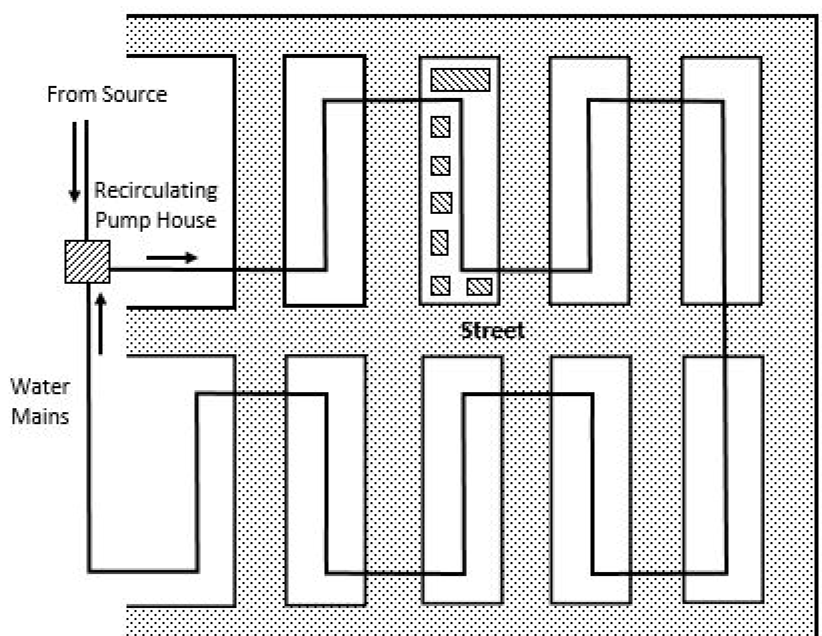
- Seasonally frozen ground with insulation/insulated pipe or pipes buried outside of the active layer—a minimum return temperature of 35°F (2°C) is suggested. Supply temperatures may vary by system parameters, but 5 to 10°F (9 to 18°C) above the minimum return temperate is common.
- Permafrost and above grade—suggest keeping the minimum return temperature at 40°F (4.5°C) if it is a circulating system. Return water may pick up heat on the way back to the recirculation building and can mask

lower temperatures realized in the field. Supply water temperature may be 5 to 15°F (9 to 29°C) above this setting to keep the return temperatures above the minimum.

Supply water temperature may be controlled by the source water (such as a tank or reservoir), which could cause higher temperatures than the recommended limits for part of the year. Water temperatures may need to be kept low to prevent thawing of permafrost soils in order to maintain stable foundation conditions. Return flow, temperature, and pressure monitoring are as essential as monitoring supply and heat addition.

[C] 6-2.1 Single loop mains also prevent water quality impairment because of low disinfectant residual and formation of disinfection byproducts which may occur in dead-ends. The use of circulating mains also allows for compliance sampling to occur at the point of return, generally in the water recirculation facilities, effectively centralizing operations, and daily compliance sampling. Fire water flow can be supplied through both the supply and return lines if required to meet hydrant or sprinkler flow requirements. In many cases, using both the supply and returns for fire flows can reduce the water main size as compared to using only the supply main.

Figure 6-1 Layout and Location of Mains for Single Pipe Recirculation



6-2.2 Branch Loops.

Branch loops use small bore piping take-offs with circulation pumps pumping around a full-bore check valve. This allows for flow monitoring and alarming but adds complexity and requires operational balancing. There are some requirements worth noting since the use of check valves affects fire flow. For example, circulated hangar loops should be pushed, not pulled. Branch loops also require more decentralized monitoring by operators. In Alaska, more complex distributions systems require more operator training/higher certifications to operate (State of Alaska 18 AAC 74.120).

6-3 ALTERNATIVE SYSTEMS.

Several types of alternate systems have been used historically. Three are discussed briefly here. ASCE *Cold Regions Utilities Monograph*, Section 8.6.3, provides more detail on these systems.

6-3.1 Conventional—No Recirculation Systems

For conventional water pipe mains with no recirculation high-volume consumers are placed at the ends of the main lines to ensure continuous flow. Return loops are therefore unnecessary. Sizing of the pipe network and other design details follow conventional practice. In Alaska, more complex distributions systems require more operator training/higher certifications to operate (State of Alaska 18 AAC 74.120).

> [C] 6-3.1 Single pipe no recirculation systems, such as branch systems, are possible but require careful planning in the initial site layout for military Installations.

6-3.2 Dual-pipe Pressure Differential Systems

Dual-pipe systems are complex, and the control mechanisms tend to be elaborate as varying consumption in different locations can result in stationary water in certain areas at certain times. For these reasons, they are no longer commonly installed.

> [C] 6-3.2 Dual-pipe pressure differential systems rely on a large diameter supply line and a small diameter return line with a pressure differential between them. The return line is sized to maintain the desired flow in the system. For typical service connections from a dual system, the service lines tap from the main and return to the smaller diameter return line. The pressure differential between the delivery and the return line must be sufficient to induce circulation in the service loop.

6-3.3 Summer Line Systems

[C] 6-3.3 Some facilities have utilized seasonal transmission mains to convey the water from a summer source to storage tanks. Drain or blow out these lines each fall to reduce potential for freeze damage and properly disinfect them at the beginning of each use season.

6-4 SERVICE LINES.

The design of service lines must prevent freezing of the contained water but must also consider the effects of permafrost thawing, frost heaving and differential settlements between the pipes and the building. The minimum depth of burial, to be below the frost depth, varies depending on the specific location and its temperature conditions. Circulation in these service connections is the recommended method to prevent freezing. Insulation with heat tape is also commonly installed as a backup. The two most common methods for circulation are either a small pump inside the building or the use of pitorifices. Backup freeze protection is usually provided by a thermostatically controlled electrical heat tracer. If copper pipe is used for the service lines, an electrical connection between the two service pipes at the main allows electrical resistance thawing from within the building as a second backup system. See Appendix A, paragraph A-7.1, for references that provide example schematics of service lines and minimum depth of burial for various locations.

6-5 MATERIALS.

Select pipe materials in conformance with UFC 3-230-01; the UFGS, such as UFGS 33 11 00; and the standards listed therein. Standards listed in the UFC and UFGS may provide specific cold weather requirements (for example, ASTM F2620).

Materials must be selected to meet specific site conditions and soil characteristics. Consider freeze tolerance and thermal expansion of pipe material according to pipe location and flow temperatures. The discussion that follows is intended to give some indication of the performance of these materials in the Arctic and Subarctic. Note that though no longer approved for installation, asbestos cement pipes may be encountered in existing systems. ASCE *Cold Regions Utilities Monograph*, Appendix A, provides more information and discussion on piping material options.

6-5.1 Copper.

Copper pipe selected must be rated for utility service, typically Type K. Copper should have only conditional use, consult Installation, District or Command engineering and operations staff. Install copper pipe in continuous runs where joints are minimized or eliminated, unless installed in a controlled space such as utilidor box with access points at each joint or in seasonally frozen ground. Isolation for corrosion potential may be required. Copper may be coated to meet this need.

[C] 6-5.1 Copper pipe is commonly used for service lines because it can be thawed by using electrical resistance, while plastic pipes cannot be thawed in this manner.

6-5.2 Ductile Iron.

Ductile iron pipe can take some shock loadings and is slightly flexible. It is a heavy, durable pipe often used in rocky areas or where adequate pipe bedding materials are not available. Ductile iron pipe is generally available in 18–20 ft (5.5–6.1 m) lengths, which may offer easier shipping and construction logistics than longer steel pipe. It can be thawed with electrical resistance.

Ductile iron has poor corrosion resistance, and lining is necessary. Corrosion protection is required in corrosive soils such as magnesium anodes and pipe bonds. Consider isolation if used above grade. Some ductile iron pipe installations may warrant specialty coatings for corrosion protection.

6-5.3 Steel Pipe.

Steel pipe is less commonly used in Alaska. Expansion and contraction, including necessary thrust anchors, as well as the differential expansion and contraction between a steel pipe and rigid heat tracing components or insulation attached to the pipe, must be considered. Corrosion protection is required in corrosive soils such as magnesium anodes and pipe bonds. Consider isolation if used above grade. Some steel pipe installations may warrant specialty coatings for corrosion protection.

[C] 6-5.3 Steel pipe is lighter, more flexible, and more corrosion resistant than ductile iron. Continuously welded steel pipe has been used to obtain maximum span between piles. It can also be thawed using electrical resistance.

6-5.4 High Density Polyethylene (HDPE).

High Density Polyethylene (HDPE) is recommended for Arctic Installations. Typically, HDPE water pipe is pre-insulated and then covered with a polyethylene, aluminum or steel jacket as discussed in paragraph 6-5.7. Joints must be leak-free and have the same or higher strength than the pipe, and either butt-fusion or electrofusion joints should be considered. Insulate field joints and cover with heat shrink couplings. Consider thermal expansion and contraction when using HDPE pipe owing to its high coefficient of expansion. Heat trace systems are recommended when freeze protection is warranted, see paragraph 6-7.1.

[C] 6-5.4 HDPE pipe is very flexible and impact resistant, with a high coefficient of expansion and contraction, high corrosion resistance, and a smooth interior, but it cannot be threaded. Butt-fused polyethylene pipe has been used extensively in Canada for water and sewer mains. The most common use has been in buried systems, and experience has shown that the pipe and contained water can freeze solid without breaking the line.

6-5.5 Polyvinyl Chloride (PVC).

PVC is not recommended for use where there is a chance of the pipe being exposed to freezing conditions. Heat trace systems are recommended when freeze protection is warranted, see paragraph 6-7.1. Conditional use of PVC pipe for certain applications may be considered such as:

- Burial—seasonal frozen soils only, and pipe must be located below maximum season frost in snow cleared soil plus factor of safety or protected by designed insulation (insulation canopy or factory installed pre-insulated and jacketed pipe).
- Above grade—insulated and heat traced locations only.

Joint types should be solvent weld or bell and spigot. PVC pipe is at higher risk for shipment damage or loss.

[C] 6-5.5 PVC can be threaded, is corrosion resistant and has a smooth interior but is not as flexible as polyethylene. It may become brittle and rupture if pipe and contents freeze.

6-5.6 Concrete.

Concrete pipes may be considered. Reinforced concrete is usually used for large transmission lines. Concrete pipe is at higher risk for shipment damage or loss.

6-5.7 Pre-Insulated Pipe.

Pre-insulated pipe units are composed of an inner-core pipe, insulation, and outer jacket, heat tracing may be provided for freeze protection. The pipe materials described above, with the exception of concrete, are typically insulated with high density urethane foam at the factory and covered with either a steel, HDPE, or aluminum jacket, depending on the final conditions of exposure in the field. The jacketing protects the insulation from moisture and mechanical damage. Prefabricated pipe units are shipped to the job site with preformed half shells of urethane insulation for the joints. Heat shrink sleeves or special tape is used to complete the field joint when HDPE is used as the outer jacket. Pipe insulation, such as spray foam, maybe done on-site, but cost and quality control must be considered. Factory prefabrication usually ensures better quality insulation. Exceptions are appurtenances, such as hydrants, where foamed-in-place urethanes are commonly employed. Design calculations to determine insulation thickness and insulation materials are described in Chapter 12. ASCE *Cold Regions Utilities Monograph*, Section A.6, provides more information and an expanded discussion on pre-insulated pipes.

6-6 APPURTENANCES.

On a typical water distribution system, these include hydrants and valves. ASCE *Cold Regions Utilities Monograph,* Section 8.8, provides additional considerations for design of these structures.

6-6.1 Hydrants.

Hydrants must be dry-barrel type conforming to AWWA C502. Hydrants installed on an aboveground water main must have an insulated hydrant box specially designed and fabricated to fit the equipment to be used at the specific location. Insulate the hydrant barrel and wrap the hydrants in polyethylene sheeting prior to backfill to prevent frost heave damage; hydrants that are insulated and jacketed with a polyurea coating do not need polyethylene sheeting wrap for frost jacking. After use, during the winter months or when ambient air temperatures at the hydrant location drop below freezing at any point during the day, the hydrant must be pumped out since frozen ground conditions may prevent self-draining. Alternate freeze protections such as secondary heat tracing or food grade propylene glycol protection are options if hydrants cannot be reliably drained or pumped out. In-ground or buried hydrants on airfields require special consideration to prevent freezing and maintain service. Consult Installation, District or Command engineering and operations staff. See Appendix A, paragraph A-7.4, for references that provide example schematics of hydrants.

For a buried water main, install hydrants directly on the main to minimize the possibility of freezing, with a frost-isolating gasket between the hydrant barrel and the tee into the main. Isolating valves are typically put in the main or both sides of the tee to allow for hydrant repair or replacement. The vertical riser from the main to the hydrant base should be as short as possible, limited to the tee's branch length plus the height of a flange connected to it, and freeze protected so that heat conducted from the water flowing in the main can keep the hydrant from freezing. If laterals are used, their length must be minimized. Dead-end segments at hydrants run the risk of water quality issues without regular operator flushing programs. Typically, the maximum dead-end leg length is 10 ft (3 m) to prevent freezing for systems that rely on depth of bury rather than a recirculation system. Consider installing heat trace if secondary freeze protection is required. ASCE *Cold Regions Utilities Monograph,* Section 8.8.1, provides additional considerations for design of these structures.

[C] 6-6.1 Water main alignment can be selected to minimize or eliminate dead-end legs to hydrants, by placing the hydrant tee in the flow path of the main, with the hydrant directly above the tee. This will eliminate any horizontal piping but may require additional mainline fittings to accomplish.

6-6.2 Valves.

The riser stem for buried valves is insulated in a manner similar to that described above for hydrants. Nonrising stem-gate valves are most practical for buried or completely insulated locations.

6-7 BACKUP FREEZE PROTECTION AND THAWING.

Backup freeze protection is provided by reserve systems to either prevent freezing if circulation stops in the lines or to thaw the system if freezing occurs. The procedures apply to both main lines and service piping, and wastewater systems. They include heat tracing to prevent freezing, and various methods to thaw systems. ASCE *Cold Regions Utilities Monograph,* Section 8.9 and Appendix D, provide additional information for heat tracing and thawing of frozen systems.

6-7.1 Heat Trace Systems.

A heat trace system is the standard backup used in most piped water distribution systems. Constant monitoring is required on such electrical systems if they are to perform as intended. Easy replacement of heat trace lines should be a standard feature of any system. For under insulation heat trace systems self-regulating heat trace designs are the preferred solution. With these systems, end of line illuminated terminations provides easy verification that the system is functioning and are preferred where a simple monitoring method is required. Some heat trace can generate higher temperatures than HDPE and PVC can withstand; however, pre-insulated HDPE piping is available with the appropriate heat trace pre-installed in channels under the insulation.

> [C] 6-7.1 If the controlling thermostats are not working properly or the sensors are in the wrong location, either too much electric energy will be expended at great cost, or the heat trace will fail to do its job when required. If the heat trace is in a channel or tube, it is typically easy to replace by exposing both ends. When it is placed under the insulation and applied directly to the pipe, replacement is very difficult.

6-7.2 Steam or Hot Water Thawing.

Steam or hot water thawing systems can be used with most types of pipe materials but are not recommended for plastic pipes which could melt or be damaged.

> [C] 6-7.2 These systems use a source of steam or hot water introduced under pressure into the frozen pipe via a suitable hose or tube to thaw out the pipe. Units specifically designed for this purpose are available commercially.

6-7.3 Service Line Thawing.

[C] 6-7.3 Small-diameter service lines of any material may be thawed by pushing a flexible 0.5 inch (1.27 cm) or smaller plastic tube into the frozen pipe while pumping warm water into the tube. Water pressure can be obtained from a nearby building, either directly or by connecting to the building plumbing. A conventional hand pump filled with warm water can also be used. Commercial units produce a pulsating stream of water to pump warm water through a tube attached to the frozen pipe by a special fitting to ease installation and reduce spillage.

6-7.4 Electrical Resistance Thawing.

ASCE *Cold Regions Utilities Monograph,* Section D.3 provides additional discussion.

[C] 6-7.4 Historically, the thawing of metal pipes using electricity was fairly common, and equipment specifically designed for this purpose is available commercially. This method is still in use in some rural areas, but not typically on larger military Installations. Caution must be exercised to prevent electrical or fire mishaps.

CHAPTER 7 WASTEWATER COLLECTION

7-1 GENERAL.

See UFC 3-240-01 for the basic criteria for design of wastewater collection or sanitary sewer systems for military facilities. The unique aspects of design and construction of these systems in cold regions are discussed in this section. In addition, some further detail is included on the use of pressure and vacuum sewers since the flat terrain and permafrost may make it difficult to design a conventional gravity sewer system in the Arctic. Combined utility systems, or utilidors, are covered in Chapter 8. Table 7-1 compares the characteristics of gravity, vacuum, and pressure systems for use in cold regions. Vehicle hauling of water and wastewater is still used at some remote sites, but generally, military facilities are serviced by piped collection systems. Normally, a conventional gravity sewer system has the lowest life cycle cost and should be used whenever practicable. Gravity systems have an additional advantage over pressure systems in that they seldom flow full. As a result, gravity pipes are less likely to break if freezing occurs.

Table 7-1 Characteristics of Wastewater Collection Systems

Type	Soil Conditions	Desirable Topography	Economics	Other
Gravity	Nonfrost-susceptible or slightly frost-susceptible with gravel backfill	Gently sloping to prevent deep cuts or lift stations	Initial construction costs high, but operational costs low unless aboveground or lift stations used	Low maintenance; must have adequate grade; larger diameter pipes required; flushing of low-use lines may be required
Vacuum	Most useful for poor soils or bedrock conditions; can be used with any soil type	Level or gently sloping	Initial construction costs moderately high; operational costs moderately high	Low water use requirement; traps every 300 ft; must have central holding tank for each 30 to 50 services with additional pumps to pump waste to treatment facilities; can separate gray and black water; uses small pipes; no exfiltration
Pressure	Most useful for frost susceptible or bedrock soils; can be used with any soil type	Level to hilly topography	Initial construction costs moderate; operational costs moderately high	Low water use, if low water use fixtures are installed; number of services not limited; no infiltration; uses small pipes

7-2 DESIGN CONSIDERATIONS.

As described in Chapter 2, the location of the pipe, above or below ground, is critical to satisfactory performance. An aboveground location with the piping installed on piles may be necessary because of soil conditions. However, the grades necessary for gravity flow are difficult to maintain with aboveground sewers. Aboveground sewers also hinder transportation, block surface drainage and snow removal, have high heat losses, and are more susceptible to vandalism.

[C] 7-2 The operation and maintenance costs for aboveground systems are about three times higher than those for similar systems buried underground. Aboveground construction costs for a single pipe depend on the foundations required. If the pipe can be laid directly on the surface, construction costs may be 20 to 40 percent of that required for the same pipe installed on piling.

7-2.1 Sewage Temperatures.

Domestic wastewater from dormitories, dining halls, and family housing on military installations in the cold regions will range from 50 to 60°F (10 to 16°C) at the source. Wastewater from facilities not having hot water heaters can be as low as 35°F (2°C). The temperature of wastewater in utilidors (Chapter 8) can be increased if steam or hot water lines are also included in the utility package. However, if temperatures are too high, hydrogen sulfide may form, requiring hydrogen peroxide injection. The thermal design of the sewer piping (Chapter 12) must include these wastewater temperatures for cost-effectiveness. Do not admit storm water to sewers in cold regions.

[C] 7-2.1 Storm water lowers the temperature of the wastewater and increases the cost of pumping, treatment, and disposal.

7-2.2 Pipe Materials.

Select materials sewer systems in accordance with the criteria given in UFC 3-240-01 and UFGS 33 30 00. Chapter 6, paragraph 6-5 discusses the cold climate aspects of these materials.

7-3 APPURTENANCES.

Appurtenances include manholes, cleanouts, building or service connections, and flushing siphons.

7-3.1 Manholes.

Manholes or access holes require protection from frost heaving because of uplift forces on the sides or under the structures. Polyethylene sheeting around the outside of the manhole can prevent bonding of the soil to the structure and thereby reduce damage from frost heaving. Insulate manholes around the outside, and appropriately treat the insulation to prevent moisture damage. Provide an insulated cover over the wastewater chamber to further reduce heat loss. A firm foundation is essential to prevent settlement and may require either installation of pilings under the manhole or over excavation and backfill with nonfrost susceptible soil (sand and gravel). If a poured-in-place concrete invert is used in the manhole and permafrost is at a relatively shallow depth, place the concrete on insulation board to reduce the downward heat losses. Space of manholes in accordance with UFC 3-240-01. Solid manhole covers are required to prevent entry of surface water. Any electrical device in a manhole must be electrically rated as well as be sealed should a manhole be flooded—this may include thermostatic controls or heat tracing.

[C] 7-3.1 Manholes provide multidirectional access for sewer maintenance, but confined space is required for access. Manhole flow channels may either be traditional open channels or closed piped through the manhole.

7-3.2 Cleanouts.

Cleanouts are typically used in building connections and, in some cases, are installed in place of manholes as described in UFC 3-240-01. Like manholes, they require protection from frost heave uplift forces. Wrapping polyethylene sheeting around the outside of the cleanout riser and the use of non-frost susceptible backfill soils can prevent bonding of the soil to the riser and thereby reduce damage from frost heaving.

[C] 7-3.2 Cleanouts provide above grade access to sewer mains for inspection and obstruction clearing without the need for confined space access and significantly less capital cost to install. Cleanouts are directional for access, one direction, unless a bidirectional cleanout is installed. They are typically provided at large changes in sewer direction and at intervals along a main or service. The same thermal design considerations are needed to prevent transmitting cold into the sewer main, but supplemental heating may not be needed for all installations.

7-3.3 Siphons.

Avoid sewers subject to low flows and velocities, if possible, in the system design since a trickle flow may result in gradual freezing and ice build-up in the pipe. If such sewers are necessary, then a pump station or a flushing siphon must be included. These must be designed to discharge a slug of relatively warm water into the system. If there is insufficient wastewater available to operate the siphon frequently enough to avoid freezing, it may be necessary to add water, with proper precautions taken to prohibit cross connections.

7-3.4 Building Connections.

Building connections for gravity sewer systems in cold regions may be through either the wall or floor of the building. Special attention to prevent freezing of water and wastewater connections and separation or damage because of differential settlement is required, especially for buildings with ventilated spaces beneath the structure. For floor penetrations, avoid bringing the riser up into the building less than 5 ft (1.5 m) from any exterior wall to prevent freezing.

[C] 7-3.4 Wall penetrations are more flexible than the floor penetrations and will permit more differential settlement without damage to the sewer line.

7-4 PUMP STATIONS.

The basic hydraulic design of pumping stations must be in accordance with UFC 3-240-01. Special requirements and concerns for use in cold regions are discussed below. See ASCE *Cold Regions Utilities Monograph,* Section 9.7, for further discussion.

7-4.1 Insulation.

Insulate the outside of the station structure with at least 3 inches (7.6 cm) of urethane or polystyrene, with an outer covering to protect the insulation from moisture. Place insulation beneath the station when permafrost is present at a shallow depth to prevent settling because of ground thaw. Polyethylene sheeting or other bond breakers are required to reduce frost jacking in the active layer. If thawing and settling under the station are anticipated, pile foundations extending well into permafrost may be required. All stations must be attached to concrete base slabs to provide sufficient weight to overcome the buoyancy of the station. Pressure couplings or flexible connections are required for the inlet and outlet pipes to prevent station differential movement from breaking the lines.

7-4.2 Condensation.

A prefabricated, below-grade pumping station must not be installed without immediately placing the heater and dehumidifier into operation. Condensation caused by the surrounding cold earth could corrode the controls and electrical equipment before the system is put into service.

7-4.3 Multiple Units.

Duplicate all critical components, such as pumps and compressors, in pump stations serving base infrastructure where service disruption is unacceptable. Stations must have at least two pumps for redundancy with each pump capable of providing at least 2/3 of required capacity of the pump, lift station, or systems it serves. A single pump may be used for a wastewater pumping station serving extremely low flows, such as a remote gate house, when justification is provided to and approved by the Installation engineering staff.

Where possible, maintain replacement equipment on the shelf for backup. If not possible, service kits need to be stored on-site to repair equipment. Electrical components such as motor starters are often overlooked and should be included in backups.

7-4.4 Alarms.

Provide alarms in accordance with the requirements of UFC 3-240-01. In addition, set alarms to warn of freezing temperatures in the station and to warn of sump pump malfunctions. Alarms must be annunciated as required in UFC 3-240-01. Consult Installation, District or Command engineering and operations staff for specific requirements.

Alarms should include, but are not limited to, the following:

- high or critical high level
- low or critical low level
- low wastewater temperature
- pump trouble
- water in motor (if pump is equipped with sensor)
- heating system or HVAC trouble
- atmosphere detection or gas detector alarm

7-4.5 Standby Power.

Because of the dangers of freezing associated with extremely low temperatures, provide standby power facilities for each major pump station. Where multiple pump installations are required, as discussed in paragraph 7-4.3, it is implicit that the site is more critical in nature and requires backup power or contingency for portable backup power connection. Otherwise, consult the Installation engineering staff to evaluate the need for standby power for smaller pump stations depending on the nature of the collection area.

7-4.6 Maintenance.

Extend all entrance manholes sufficiently above the ground surface to be above any flooding or snow drifts. Supply all pump stations with devices for measuring flow rates. Corrosion protection must be provided in accordance with UFC 3-240-01. Sacrificial anode type systems do not work well when the ground surrounding the anode or pump station is frozen.

7-4.7 Force Mains.

Force mains are pressure lines into which the sewage pumps discharge. They must comply with all temperate region standards required in UFC 3-240-01. Design force mains to have scour velocities during pumping (2.5 to 3.5 ft per second [0.76 to 1.1 m per second]) and to drain between pumping cycles. This can be accomplished by an electrically operated ball valve in the line to allow drainage back into the wet well between pump cycles. If this is not possible, the line must be placed in a heated utilidor, or heat traced. Another option would be to time the pumping cycle so that wastes stay in the line for a calculated period, and to size the wet well at the pump station to hold at least the volume of the force main.

[C] 7-4.7 Consideration may be given to increasing the flowrate or reducing pipe size. Doubling velocity through the pipe approximates the same flowrate through the pipe with a single pipe diameter reduction. This would not change the heat flux to the pipe appreciably, but it halves the contact time a slug of wastewater is in contact with the pipeline for the perceived purpose of freeze protection. The designer needs to determine which is more important: transferring heat to the force main pipe system to maintain a thawed condition or minimizing the resident time of wastewater in the main.

7-5 PRESSURE SEWERS.

The hydraulic design of pressure sewer systems is not unique to the cold regions, use criteria found in UFC 3-240-01. Design the pressure piping to drain by gravity to a low point or sump in case the system must be shut down in the winter. The grinder pump units, holding tanks, and septic tanks must have a firm foundation and must be protected from frost heaving as discussed previously for manholes (paragraph 7-3.1). Water conservation measures in each of the buildings served are required to reduce the costs of equipment and energy for pumping.

[C] 7-5 The main advantage of pressure sewers is that specific grades need not be maintained throughout the system. Typically, grinder pump units are used so that smaller diameter pipes can be installed without the risk of clogging. Grinder pumps may be installed in each building or in a holding tank serving several buildings. An alternative to grinder pumps is to install a two-compartment septic tank with a conventional submersible pump in the second compartment.

7-6 VACUUM SEWERS.

Vacuum sewers do not depend on a specific grade for successful operation. They operate at a vacuum of 8–10 psi (55–69 kPa), and so are limited to an elevation difference of 15 to 20 ft (4.6 to 6.1 m) within the system. The hydraulic design is not unique to the cold regions. The concept depends on providing traps in the system to maintain a vacuum. Since these traps are full of water for extended periods, they must be insulated, heated, or both, for extreme low temperature conditions. The traps should also be drainable under emergency situations.

CHAPTER 8 WASTEWATER TREATMENT

8-1 GENERAL.

See UFC 3-240-01 for basic design criteria for domestic wastewater treatment systems. UFC 3-240-01, paragraph A-6.6, also includes special considerations for cold and Arctic locations outside the U.S. This chapter provides additional information and requirements on those aspects unique to cold regions and presents general design criteria for treatment systems most commonly used in the Arctic and Subarctic. More detailed information is provided by ASCE *Cold Regions Utilities Monograph*, Section 10. *Prevention of Freezing and Other Cold Weather Problems at Wastewater Treatment Faculties* provides design information and case studies on the prevention of freezing and other issues for cold regions wastewater treatment facilities.

8-2 WASTEWATER CHARACTERISTICS.

Wastewater characteristics in the cold regions are generally different from those in temperate regions with respect to quantity, quality, and temperature. The total quantity of wastewater discharged at military Installations in cold regions tends to be very close to the quantity supplied for potable water use since there is little external or industrial use, storm water is usually excluded, and groundwater infiltration is not a factor in the newer insulated and tightly sealed pipe systems. As a result, wastewater in the Arctic and Subarctic tends to be more domestic in nature and higher in strength than at comparable facilities elsewhere.

8-2.1 Quantity.

Determine design flows by a specific analysis of the Installation. The population equivalents and capacity factors presented in UFC 3-240-01 tend to overestimate the volume of flow to be expected at remote Installations in the Arctic and Subarctic with small populations. This may result in operational problems with some biological treatment units. Selection of less sensitive processes or use of two smaller units in parallel avoids the problem if the design cannot be determined by actual flows.

8-2.2 Quality.

The mass of pollutants in cold region wastewaters is comparable to that in other locations, but the concentration will generally be higher because of lower water usage rates.

8-2.3 Temperature.

The wastewater temperature at many cold region facilities tends to be at least 50°F (10°C) owing to transmission in insulated and sometimes heated lines. Consider the heat available in this incoming wastewater during process design.

8-2.4 Flow Variations.

The diurnal flow pattern at military Installations tends to be the same regardless of climate.

8-3 UNIT OPERATIONS.

Practically all the basic unit operations used in wastewater treatment are affected by temperature through liquid viscosity changes or changes in chemical reaction rates. An analysis during the early stages of design is required to predict the thermal status of major components in the treatment system. If wastewater temperatures above 50°F (10°C) are expected and the entire system is to be housed in a heated building, then conventional practice as defined in the UFC 3-240-1 must be used. If temperatures below 50°F (10°C) are expected or significant temperature changes are allowed to occur within the system, then adjustments are necessary for the design of the unit operations. ASCE *Cold Regions Utilities Monograph,* Section 10.4.2, provides additional information on design adjustments required for mixing, sedimentation, filtration, gas transfer, and adsorption and chemical reaction operations for wastewater treatment facilities in the Arctic and Subarctic.

8-4 UNIT PROCESSES.

Unit processes include preliminary treatment, primary treatment, and a variety of biological or chemical processes for secondary treatment. All are subject to temperature influences on their performance. ASCE *Cold Regions Utilities Monograph,* Section 10.4.3, provides additional information.

8-4.1 Preliminary Treatment.

Preliminary treatment commonly includes screening, grit and scum removal and grinding, or comminution. Conventional equipment can be used, and basic design criteria must be in accordance with UFC 3-240-1 with appropriate adjustments in grit chamber detention time for the projected operating temperatures. Construct protective, insulated shelters over trash racks, bar screens, and grit chambers to avoid icing problems in the winter. Where structures are unheated, condensation and icing may occur on the inner surfaces of exterior walls. In these instances, select materials and coatings accordingly, and locate controls on dry interior walls or in another remote location.

8-4.2 Primary Treatment.

Adjust the design detention time of primary clarifiers for the projected operating temperatures. In general, design tanks in the conventional manner as buried or partially buried structures. However, the presence of shallow permafrost, particularly ice-rich, fine textured soils, requires aboveground tanks or special foundations (see UFC 3-130-03). Temporary covers for heat retention purposes are recommended for winter operation of buried or exposed tanks in the Arctic and Subarctic. Tanks above grade also require sidewall insulation or enclosure in a protective structure.

Mechanical measures for primary treatment are also commercially available, such as microscreens and rotating belt filters. These technologies have been used in indoor wastewater treatment applications for years and can achieve primary treatment in about 1/10th the footprint of a conventional gravity settling basin. These systems require a heated, insulated building.

8-4.3 Secondary Treatment

In cold regions where mechanical treatment is used, the biological treatment systems deployed are often similar to warm weather processes, with additional insulation or housed entirely inside of a heated building. Packaged treatment systems are commercially available and must be housed in appropriately insulated and climate-controlled buildings. Certification may be required for the operators of these systems.

Biological systems for secondary treatment that have been successfully used in cold climates include lagoons or ponds, both facultative and aerated, several activated sludge variations and attached growth systems. Each has special requirements for successful cold regions performance.

[C] 8-4.3 In general, biological alternatives using outdoor lagoons require a large footprint, but will have minimal operations and maintenance needs and offer moderately good effluent quality. Biological treatment using indoor systems require a much smaller footprint; will have higher operations, maintenance, and electrical power needs, with the associated costs; and provide superior effluent quality.

8-4.3.1 Lagoons.

8-4.3.1.1 Facultative.

The treatment performance of facultative lagoons during winter is greatly reduced by low temperatures and by ice and snow cover, with removal rates roughly comparable to those of primary treatment alone. Total retention of wastewater during winter months may be required with controlled discharge commencing in late spring and in early fall. Standard construction techniques can be used except where permafrost is present. Fine textured, ice-rich permafrost must be avoided if possible since thawing can result in failure or at least require frequent repair of dikes and berms. Lagoons may be installed in permafrost that is physically stable after thawing. Additional design and construction information is provided in ASCE *Cold Regions Utilities Monograph*, Section 10.4.3.

[C] 8-4.3.1.1 Where sufficient land area and suitable soil conditions exist, facultative lagoons are the most economical alternative in the cold regions because of their low construction cost and simplicity of operation.

8-4.3.1.2 Aerated.

Partially mixed aerated lagoons, also called facultative-aerated ponds, have been used successfully in cold regions. Basic process design criteria are similar to those of temperate regions. Additional design and construction information is provided in ASCE *Cold Regions Utilities Monograph*, Section 10.4.3.

[C] 8-4.3.1.2 Aerated lagoons require less land area but more energy and more operational attention than facultative lagoons.

8-4.3.2 Treatment Plants.

8-4.3.2.1 Activated Sludge Systems.

Activated sludge systems that have been successfully used in cold regions include conventional and pure-oxygen activated sludge, contact stabilization, and extended aeration concepts in both package plants and oxidation ditches. Basic design criteria for these processes must be in accordance with UFC 3-240-1. When the system is enclosed and incoming wastewater temperatures exceed 50°F (10°C), basic design criteria apply. Special measures are necessary only when incoming wastewaters are below 50°F (10°C) or if a significant temperature drop is expected within the system. All the biological reaction rates involved are temperature sensitive and must be adjusted using Equation 8-1.

Equation 8-1. Biological Reaction Rate Coefficient

$$k_T = k_{20}\theta^{(T-20)}$$

Where:
k_T = reaction rate coefficient at the temperature T
k_{20} = reaction rate at 20°C (68°F)
θ = temperature coefficient
T = temperature in °C

Use the θ values given in Table 8-1 in Equation 8-1 to adjust the reaction rate for the design wastewater temperature. Additional design and construction information is provided in ASCE *Cold Regions Utilities Monograph,* Section 10.4.3.

8-4.3.2.2 Attached Growth Systems.

These include trickling filters, rotating biological discs, and other devices with plastic, rock, or wooden media. Effective treatment depends on maintaining a thin film of liquid over the media. These units are susceptible to freezing and must therefore be enclosed in a protective structure. Use criteria from UFC 3-240-01 for design, along with the temperature coefficients given in Table 8-1. The need for additional heat in the protective structure depends on the temperature of incoming wastewater and on the degree of treatment required. Additional design and construction information is provided in ASCE *Cold Regions Utilities Monograph,* Section 10.4.3.

Table 8-1 Temperature Coefficients for Biological Treatment

Process	θ	**Temperature Range (°F)**
Oxidation pond	1.072–1.085	37–95
Facultative lagoon	1.06–1.18	39–86
Anaerobic lagoon	1.08–1.10	41–86
Aerated lagoon	1.026–1.058	36–86
Activated sludge	1.00–1.041	39–113
Extended aeration	1.037	50–86
Trickling filter (conventional)	1.035	50–95
Biofilter (plastic media)	1.018	–
Rotating disc		
Direct filter recirculation	1.009	50–86
Final effluent recirculation	1.009	55+
Final effluent recirculation	1.032	40–55

8-5 SLUDGE MANAGEMENT.

Large-scale, conventional treatment facilities and those operating in a heated environment can be expected to produce sludge at rates similar to those of conventional temperate zone practice. Thickening, digestion, and dewatering of sludge all follow temperate zone practice in accordance with UFC 3-240-01.

8-5.1 Freeze-thaw Dewatering.

Sludge from water or wastewater treatment operations can be flooded onto conventional open sand drying beds in layers and allowed to freeze. It is important to avoid rewetting the sludge once it has been freeze-thawed by providing a roof overhead or physically moving the solids around after they have been frozen.

8-5.1.1 Depth of Sludge.

Calculate the depth of sludge that can be frozen (or thawed) with Equation 8-2.

Equation 8-2. Application Depth of Frozen Sludge

$$X = m_s(I_A)^{1/2}$$

Where:
X = depth of sludge that can be frozen (inches)
m_s = proportionality coefficient for sludge, use 0.6 for sludge concentrations in range of 0–7% solids (higher concentrations are difficult to spread on bed) (°F-days)$^{-1/2}$
I_A = Air freezing (or thawing) index (°F-days)—use warmest winter of record for freezing calculations

Sludge with an undrainable jelly-like consistency will dewater immediately upon thawing and then have a granular consistency. Solids concentrations of 20–25 percent immediately after thawing are typical and after a few more weeks of drying will approach 50 percent.

8-5.1.2 Repeated Applications.

The total depth of sludge that can be frozen is also related to the depth of frost penetration that will occur in a particular location. Repeated applications in thin layers are recommended to ensure that each layer freezes completely. Use Equation 8-3 to estimate the potential total depth of sludge that could be frozen (applied in 3-inch [7.6-cm] layers) if the maximum depth of frost penetration for a site is known.

Equation 8-3. Potential Total Depth of Frozen Sludge

$$\Sigma X = 1.76(f_p) - 40$$

Where:
ΣX = total depth of sludge that could be frozen in 3-inch (7.6-cm) layers (inches)
f_P = maximum depth of frost penetration for area (inches)

[C] 8-5.1 At most facilities it is not be cost effective to depend entirely on freezing since this would require sludge storage during the warmer months. The optimum design to avoid storage determines the amount of material that can be frozen and then thawed by early summer so that the beds can be used in the conventional drying mode for the balance of the warm season.

8-5.2 Sludge Disposal.

Landfills or land application of sludge are the most appropriate techniques for disposal in cold regions. Temporary sludge storage will be necessary where winter conditions or frozen ground prevents surface application or landfill operations. Disposal must be in accordance with local environmental regulations.

8-6 OUTFALLS.

Outfall structures require special consideration to prevent freezing of the effluent and to prevent structural damage from ice in the receiving waters. In some cases, these problems can be avoided by designing for seasonal discharge. However, an unused outfall is still exposed to damage by ice in the winter and during spring thaw. Insulate and heat-trace exposed outfall piping. The thermal design must be in accordance with Chapter 12. A submerged outfall is recommended wherever possible. However, in shallow streams the pipe must be protected from ice scour that can occur during spring break-up. If possible, install the pipe underground with the outlet completely submerged in water and below the maximum penetration depth of winter ice. If these conditions cannot be satisfied an elevated outfall is required. Design the support piling in accordance with UFC 3-130-03 to resist the uplift forces generated by a floating ice sheet. This is particularly critical at coastal locations with significant tidal action. It is usually not practical to design simple pile supports to resist the lateral forces from ice movements during spring break up. Use break-away couplings to prevent complete destruction of the outfall structure. Design elevated outfalls, in general, to discharge on top of the ice since an open water surface cannot always be maintained. Most of the effluent will then freeze and form a large mound of ice as the winter progresses.

8-7 ALTERNATIVES TO TREATMENT AND DISPOSAL.

At many remote Installations that have small populations or with intermittent usage, it may not be cost effective or technically feasible to construct one of the treatment or disposal options discussed above. Consider small-scale on-site systems that may be feasible for these situations. Conventional septic tanks and soil absorption systems have been used throughout Alaska with mixed results. Sludge accumulates at high rates in septic tanks in low temperature soils. Annual sludge removal is required to avoid clogging problems in the adsorption field. Design procedures are similar to conventional practice for these systems. Insulation of the septic tank is desirable and recommended for intermittently operated systems. Where feasible, deep seepage pits are preferred over conventional absorption fields because of their greater thermal efficiency. In locations where in-ground disposal is not practical or feasible, vault storage and truck haul may be required.

CHAPTER 9 UTILIDORS

9-1 GENERAL

A utilidor is a structure that contains multiple utility systems such as water, sanitary sewer, fuel oil, gas, electrical power, communications, and central heating in various combinations or, in some cases, all together. The term is often applied to aboveground insulated water and wastewater piping as well. They are commonly used at military Installations and civilian communities in the North American Arctic. Utilidors may be constructed above- or belowground, or at ground level, and range in size from a simple insulated conduit to a walk-through passageway. Their size and shape are determined by considering the number and sizes of the pipes they will contain, their location relative to the ground surface, and the ease of access desired for maintenance or repairs. A 1981 survey of Fort Wainwright, Alaska reported approximately 200 configurations of utilidors with sizes ranging from 1 ft by 1 ft to 7 ft by 9 ft (30 cm by 30 cm to 2 m by 3 m), and pipe sizes varying from 1 inch to 24 inch (2.54 cm to 61 cm) in diameter.[1] The ASCE *Cold Regions Utilities Monograph,* Section 11, provides additional discussion of utilidors and their design considerations.

9-2 DESIGN CONSIDERATIONS.

Use Chapter 12 procedures for the thermal design of utilidors. Design foundations in accordance with UFC 3-130-3. Both designs should consider the types of utilities to be included. The inclusion of power, telephone, and gas lines, along with water and sewer pipes in a utilidor is common, but the overall utilidor design must account for the interactions between these components. Locate the heat sources for freeze protection near the bottom of large utilidors, if possible, to ensure distribution of heat.

The installation of pipe identification markers or stenciling is recommended within manholes. Flanged elbows or pipes must be large enough to insert cleaning or thawing equipment. Standard fittings or smaller pipes do not provide adequate access in both directions. Figure 9-1 illustrates cross sections of two typical utilidors. Utilidors may be prefabricated. When transport methods permit, prefabrication of the major utilidor components is recommended to reduce construction costs in the field.

[C] 9.2 The inclusion of central heating lines in utilidors is often beneficial. Their heat losses are usually great enough to protect the water and sewage pipes from freezing, but the utilidor is most often larger to provide continuous easy access to steam and condensate lines, and therefore, construction costs will increase. Problems also occur because this heat source operates all or most of the year. In the summer, undesirably high domestic water supply temperatures may result because of exposure to the excess heat (>80°F [>27°C]). Thermal stratification can cause freezing of the lower pipes in large utilidors even when the average air temperature is above freezing.

[1] *Losses from the Fort Wainwright Heat Distribution System*, Phetteplace et al.

9-2.1 Materials.

It is critically important to calculate thermal expansion and contraction of the various types of piping material within the utilidor. Unlike buried pipes, pipes located in a utilidor can experience a large temperature range throughout the year, especially if steam or condensate piping are not operational year-round. Expansion joints or flexible couplings may be required to prevent a rupture, major leak, or pipe anchor failure.

9-2.2 Insulation.

Separate insulation of domestic water lines is recommended to maintain acceptable cold-water temperatures for domestic use, and to prevent condensation and pipe corrosion. Do not install insulation on the hydrant lateral piping between the water main connection and the riser penetration through the utilidor roof.

9-2.3 Water and Sewer Line Proximity.

For Installations in the state of Alaska, placement of water and sewer lines (including sump drain lines) within a single utilidor requires a waiver from the State of Alaska, Department of Environmental Conservation (ADEC) under *Standard 18 AAC 80, Drinking Water.* This is a part of the standard permitting process in the state of Alaska (Section 2-3.2). When both water and sewage lines are exposed in the same utilidor, the sewer access cleanouts must be sealed to prevent cross contamination.

9-3 MOLD.

Utilidors are kept warm for water and sewer utility piping. They are normally dry unless a leak or infiltration has occurred. Consider low point drains or positive ventilation in walk-through passages. For box or pipe utilidors use closed cell insulation with a moisture barrier to keep moisture out of the foam. Polyureas or plastic resist mold formation if they are clean and free of dirt or other materials.

[C] 9.3 Mold growth is inhibited by keeping utilidors clean and disinfected.

9-4 MAINTENANCE CONSIDERATIONS.

Maintenance and inspection should be determined by construction materials and the following:

- Above grade or at grade—If operators perform daily service rounds, the system should be observed during those activities. General conditions should be inspected and documented monthly. Program maintenance based on surface finish conditions and corrosion observations. Base mechanical equipment maintenance on manufacturer’s recommendations.
- Buried—If the utilidor is a walk-through passage, operators should review conditions during daily rounds and perform monthly inspections. Pipe or

box systems are difficult to access. Buried utilities should be inspected and cleaned during any maintenance activity.

This Page Intentionally Left Blank

CHAPTER 10 FIRE PROTECTION

10-1 GENERAL.

Use UFC 3-600-01 for fire protection requirements. The ASCE *Cold Regions Utilities Monograph*, Section 15, provides additional information.

10-2 HYDRANTS.

Cold regions hydrant features were discussed in paragraph 6-6.1. Hydrants must be accessible and operable at all times regardless of frost depth, snow cover, and temperature.

10-3 TRUCK SYSTEMS.

Where winter operation in the Arctic requires tank trucks on standby, provide heated garages and a freeze-protected water point with a pumping capability of at least 350 to 500 gallons per minute (1,325 to 1,900 liters per minute) for refilling the tank trucks if hydrants are not available.

[C] 10-3 Historically, motorized fire pumping apparatus with booster tanks and hoses provided protection for remote buildings not serviced by the water distribution system or sprinklers within the facility.

10-4 FIRE PROTECTION SYSTEMS.

Fire protection systems are covered in Chapter 9 of UFC 3-600-01. The use of post-indicating valves on the main lines coming into buildings is not recommended as they act as a thermal bridge to the water lines. Street valves are permitted. Locate the primary shutoff valve inside the building in a room accessible from the exterior per National Fire Protection Association (NFPA) 24. A minimum 1-hour fire rating is required unless otherwise approved by the Installation, District or Command engineering and operations staff.

[C] 10-4 If recirculation and heating systems are used, this may not be an issue.

Foaming equipment will not function at optimum levels in air temperatures below –15°F (–26°C) since aspiration of the foam is not complete. Standard carbon dioxide fire extinguishers will also not function properly at below-freezing temperatures. Dry chemical extinguishers have been used successfully and range in size from hand-held units to large dolly-mounted units containing about 350 pounds (160 kilograms) of chemical. Per paragraph 9-16 of UFC 3-600-01, installation of a new Halon 1301 systems is prohibited except by special approval of Service Signature Authority.

10-5 ALARM SYSTEMS.

Design central alarm systems in accordance with UFC 3-600-01. For Installations with direct digital control (DDC), see UFC 3-410-02. Monitoring and alarm systems must be compatible with the Installation reporting system. Transmit all signals to the fire department and other central alarm centers where appropriate action can be initiated.

[C] 10-5 In many cases, it is advantageous to integrate the systems with other utility system sensors for protection of the water distribution network and sewage transmission lines (see Chapter 6 and Chapter 7).

CHAPTER 11 POWER DISTRIBUTION AND COMMUNICATION SYSTEMS

11-1 GENERAL CONSIDERATIONS.

With a few exceptions, the basic design requirements for wire and cable networks for power transmission and communication systems are not unique to the cold regions. Use UFC 3-501-01, UFC 3-550-01, and the regulatory and industry standards adopted therein, for design of these systems. Power distribution and communication systems must also comply with any specific requirements of the Installation or, for privatized systems, the utility contractor. Special attention is needed to ensure proper grounding in permafrost areas, to maintain stability of towers, poles, guy wires and anchors, and for direct burial of cables.

11-2 GROUNDING.

Soils in both seasonal frost and permafrost areas may not provide acceptable grounding conditions owing to the high electrical resistivity of frozen ground—up to several orders of magnitude higher than that of unfrozen soil. This may require finding areas where soils are less likely to freeze or where the seasonal frost zone or permafrost layer is thinnest and installing ground rods or piles in the warmer soils. *Electrical Grounding in Cold Regions*, by Henry, discusses this further. In some permafrost locations all the facilities are tied together, including electrical wiring; petroleum, oil, and lubricant (POL) piping metal building; POL storage tanks; water and sewer lines; and so on, to form one large grid network. This network is then connected to a water well casing that penetrates the permafrost layer and results in an acceptable ground. If no well casing exists, the grid system is connected to a ground rod that does not penetrate the permafrost. This provides a common floating ground with everything at the same electrical potential. This is an acceptable approach as long as everything is bonded to that common ground. Another possibility is to place a grounding cable grid into a nearby lake or other body of water that does not freeze. The ASCE *Cold Regions Utilities Monograph*, Section 17.5.3, provides additional information on the grounding. All grounding measures must comply with UFC 3-550-01.

11-3 UNDERGROUND SYSTEMS.

Power and communication networks have been successfully installed in the utilidor systems described in Chapter 8. However, some Installations do not install electrical distribution systems within utilidors. Directly burying cables in frost-susceptible soils within the active layer must be carefully considered. Place buried conduits or ducts in nonfrost susceptible backfill materials. Otherwise, place a gravel or other nonfrost-susceptible material pad on the existing ground surface and bury the cables in this new pad if a buried system is required. The gravel pad may also serve as a road or walkway.

Buried cables, or conduit, connected to a wall mounted cabinet may rip the cabinet off the wall because of conduit jacking. Similarly, direct buried cables terminating in a post mounted termination cabinet can be pulled out of their terminations as a result of the post and cabinet being subjected to long term jacking. If jacking conditions are present, provide sufficient cable or flexible conduit slack to permit cable movement and prevent cabinet damage.

[C] 11-3 The freezing and expansion of soils in the active layer may result in structural failure of cables or severe mechanical damage. Oil industry facilities near the Arctic Ocean use direct burial single phase armored cables instead of conductors in conduit for below grade construction.

11-4 AERIAL SYSTEMS.

Ice buildup is a problem for aerial cables, particularly in coastal locations. Preventative measures have included the use of a steel conductor to increase tensile strength and to allow resistance thawing. The major engineering problem with aerial systems in the cold regions is the stability of the supporting towers or poles. The practical effect of frost heave on towers and poles is an upward force to the unit that may result in overstress and mechanical failure or in differential vertical movement between components. It is necessary to design towers and poles to resist these upward forces, or to allow the units to float up and down with the expansion and contraction caused by heaving of the active layer, or to replace the frost-susceptible soils with clean gravel. In many cases, the utility pole will move up due to the heaving forces but cannot return to its original position because of the flow of soil into the void. The net effect is an annual increment of upward movement that will eventually jack the pole out of the ground.

[C] 11-4 The upper soil layer, known as the active zone, goes through a freezing and thawing cycle on an annual basis. In the spring, this zone may go through several freezing cycles because of warm days and cold nights. This freezing causes significant soil expansion, or frost heave, depending on the soil type and moisture content. The expansion is very significant with fine-textured silty soils when a source of unfrozen water is available. Further details on frost heave can be found in UFC 3-130-3.

11-4.1 Poles.

As mentioned in paragraph 11-4, a very strong bond can develop between the frozen soil and the surface of an imbedded power pole. This bond, if developed in the active layer with frost-susceptible soils, will lift the pole out of the ground. This phenomenon is called frost jacking. Wooden poles are commonly used for both power and communications systems. Two measures are commonly taken for permanent construction where permafrost is relatively close (3–5 ft [0.9–1.5 m]) to the surface;

- The pole is sufficiently embedded in permafrost so that the bond developed in that zone can resist the uplift forces due to heaving in the active layer.

- The active zone portion of the hole is backfilled with nonfrost-susceptible materials, or this portion of the pole is wrapped with a 10-mil polyethylene sleeve to prevent development of a bond.

Set poles to a minimum depth of 10 percent of the aboveground height plus another 4 ft (1.2 m) into the permafrost (ASCE *Cold Regions Utilities Monograph,* Section 17.5.3). For example, a 50 ft (15 m) aboveground height would require 9 ft (2.7 m) of embedment. However, this depth may need to be increased to fully prevent frost jacking. Holes for these poles or support piles are made with a drill or soil auger and are made slightly larger (3–4 inch [8–10 cm]) than the diameter of the pole. A slurry of native soil or sand with water is then placed around the pole to the top of the permafrost. This construction is often done in the winter when the active layer is also frozen to allow easier access with minimal environmental disturbance. Rock-filled cribs are used where permafrost is very deep, the rock is very shallow, or for temporary facilities or facilities in support of military operations with a design life of five years or less.

11-4.2 Towers.

Typical designs for tower foundations are gravel pads with footings constructed on frost-susceptible soils or gravel backfill with footings in frost-susceptible soil. Foundations are discussed in UFC 3-130-3.

[C] 11-4.2 Above-surface gravel pads provide some surcharge for resistance to heaving forces, but some vertical movement is likely. At the end of the thaw period, the pad will settle to its original position. The anchors for guyed towers provide the major resistance to uplift and provide lateral stability. If the footings for towers are placed in the frost-susceptible material, they will be moved upward during the heaving phase, but as described in paragraph 11-4.1, the footing will not then settle back to its original position when seasonal thawing is complete. A progressive failure will result because the footing will be moved upward another increment each year until the resistance to overturning is insufficient.

11-4.3 Anchors.

Design anchors for tower guy wires in accordance with UFC 3-130-3. Both grouted and ungrouted anchor types used in temperate climates may also work in areas of seasonal frost or permafrost. However, the embedment depth must be such that the anchor can withstand frost jacking forces within the active layer as well as the design guy line loading. Manufacturers' ratings for design capacities of commercially available earth anchors may be reduced by 75% if placed in thawed soil above the permafrost layer.[1] Install anchors into the permafrost when it exists and is shallow. The active layer

[1] *Design and Construction of Foundations in Areas of Deep Seasonal Frost and Permafrost*, Linell and Lobacz.

dynamics will cause loose guy lines unless anchors are firmly installed into the permafrost and below long-term warming thaw depth.

An additional major concern is progressive movement, or creep, of anchors embedded in ice-rich permafrost with temperatures just below the freezing point. Make provisions for adjusting the tension of guy lines in both summer and winter, since the pole, tower, or structure being guyed and anchored may experience heave or settlement quite different from that of the anchors.[2]

11-5 SPECIAL CONSIDERATIONS.

The following other special considerations relate to construction of electrical distribution systems in the cold regions because of responses to low temperatures or other environmental factors:

- Nylon-jacketed conductors (type THWN), when used at low ambient temperatures, tend to experience separation of the insulation from the jacket.
- Molded case circuit breakers and stored potential switches are not always dependable at extremely low temperatures. Consider the alternative use of fuses, if approved by Installation engineering personnel, or supplemental heat provided to raise the ambient temperature of the equipment enclosure.
- Low temperature, special alloy steel is frequently used for transformers, circuit breakers and other exterior electrical distribution apparatus.
- At some Installations, such as Thule Air Force Base (AFB), electric and communication conductors are installed on the ground surface supported by sleepers, as shown in Figure 2-1. Timber sleepers are typically 4 inch by 4 inch by 24 inch (10 cm by 10 cm by 61 cm), and generally spaced 10 to 15 ft (3 to 4.6 m) apart. Conductors are clamped to the sleepers. All the conductors are insulated and armored to protect personnel. This method avoids issues with icing and wind damage and keeps costs low. This type of installation is not recommended on facilities with accompanied personnel, because of potential hazard to children.

[2] Ibid.

CHAPTER 12 THERMAL CONSIDERATIONS

12-1 GENERAL CONSIDERATIONS.

The thermal aspects of utility system designs are among the most critical elements for cold regions systems. The potential problems are failure of pipes due to freezing of water, thaw settlement or heaving of foundation soils, thermal strains and the associated stresses, the cost-effective selection of materials and insulation thicknesses, and economical operation of the system. This chapter presents criteria for the most critical thermal calculations that might be required for design of pipes, utility structures, and appurtenances. Example problems of the use of the thermal consideration equations are given in Appendix C.

EPA-600/8-79-027, Section 15.10; ASCE *Cold Regions Utilities Monograph*, Section 4.7; and Chapter 6, “Heat Transfer Calculations for Piping Systems,” of the ASHRAE *District Heating Guide* provide additional discussion and example problems.

12-2 FREEZING OF PIPES AND TANKS.

Damage or failure occurs due to the expansion of water changing to ice. The hydrostatic pressure on the still-unfrozen liquid can reach several hundred atmospheres, and it is this pressure, not the contact of the ice, which typically causes pipe failure. Prevention of freezing is accomplished via the most cost-effective combination of insulation, heat trace, circulation, and other measures. Insulation alone does not necessarily prevent freezing; it reduces the rate of heat loss and extends the freeze-up time. Small diameter service connections may have a freeze-up time measured in minutes or a few hours. These are the most vulnerable portions of the system and will usually freeze first. Thawing capability is mandatory for these small diameter pipes.

[C] 12-2 There are some methods of insulating (such as foam board) that allow capture of ground heat, such as those employed at Joint Base Elmendorf-Richardson. These systems are sufficient on their own to prevent freezing. References listed in paragraph A-8 discuss these methods.

12-3 THAWING OF FROZEN PIPES.

Remote electrical thawing methods that can be incorporated in the original design include skin effect, impedance, and various resistance wire and commercial heating cable systems. Frozen wells have been thawed by applying a low voltage from a transformer to a copper wire located inside the riser. Once a small annulus is melted, the flow can be restarted, and it will thaw the remaining ice. Chapter 6 discusses thawing of frozen pipes.

12-4 HEAT LOSS FROM PIPES.

The total heat loss and the freeze-up time are dependent on the ambient and internal temperatures in the pipe system. Aboveground piping systems must be designed for the lowest expected air temperatures, which range from –40 to –75°F (–40 to –59°C). These extreme surface temperatures are attenuated by burial, depending on the thermal properties of the soil. Frost penetration is greatest in rock or bare, dry soils. A snow cover typically reduces the depth of frost penetration by an amount equal to the snow depth. Locating utility lines away from snowplowed surfaces takes advantage of this potential.

[C] 12-4 For example, the air temperature at the surface might have an annual variation of 150°F (66°C). At a depth of 6 ft (2 m), the temperature may vary slightly with the season, and at 30 ft (9 m), seasonal temperature fluctuations are negligible. There is also a time lag involved with frost penetration so that maximum depth of frost penetration will occur long after the extreme winter temperatures. At a depth of 6 ft (2 m) the lag time may be one to five months after the onset of freezing conditions at the surface. The specific time depends on soil properties and moisture conditions.

12-4.1 Direct Burial.

Water and sewer mains are typically buried below the maximum depth of seasonal frost. In cold regions, the frost penetration is often greater than the common pipe burial depths of 6 to 10 ft (1.8 to 3 m) and may be 20 ft (6 m) or more in exposed dry soil or rock. Deep frost penetration, high groundwater, hilly terrain, rock, or other factors make it more practical and economical to install all or portions of the utility system within the frost zone. In these cases, the degree of freeze protection necessary depends on the ground temperatures at the pipe depth. Where pipes are only intermittently or periodically within frost, such as during a particularly cold winter or at a more temperate location, conventional bare pipes may be adequate, provided a minimum flow can be maintained by circulation, bleeding, or consumption. Frost-proof appurtenances, appropriate monitoring and alarms, stable backfill, and some heating may also be necessary. Provide continuous monitoring of any system buried above the seasonal frost depth to alert for malfunction. Heat loss and freeze danger are significantly reduced by insulating the pipes. Insulated pipes may be installed in shallower trenches or within berms at ground surface. In these cases, the minimum depth of cover would be 1.5 to 3 ft (0.5 to 1 m) for exposed ground surfaces. Greater depths are necessary if heavy surface traffic is expected. For long pipelines which are trenched, installed in frozen soils, and which rely on the soil bond to overcome expansion forces, initial warm up of the pipes after construction may result in upheaval buckling of pipeline if backfill material is not allowed sufficient time to consolidate and secure the pipe in the trench.

12-4.2 Insulation Barrier for Buried Pipes.

Buried pipes within seasonal frost can also be protected by placing a layer of insulation board, usually polystyrene, above the pipe. This method, using bare pipes and fittings and board insulation, is often less expensive (for materials) than use of prefabricated insulated pipe; however, the construction cost will be higher, and the effectiveness of the insulation is lower than direct insulation on the pipes. The board method has been used where the soils underlying the pipe are frost-susceptible, since frost penetration beneath the pipes can be prevented by the insulation board. The necessary thickness and width of the board increases for shallower pipes and deeper frost penetration. The relative economics, compared to that for insulated pipes, is improved when pipes are placed in a common trench under insulation board and when warm sewer or central heating lines are included. Generally, the insulation should be a minimum of 4 ft (1.2 m) wide for a single pipe, and the thickness is determined by the proposed depth of burial and the expected or calculated frost penetration. The heat loss and trench width may be reduced by placing the insulation in an inverted U on both the top and sides of the pipe. Example 3 in Appendix C illustrates frost penetration calculations beneath an insulation board.

[C] 12-4.2 In terms of reducing frost penetration, 2 inches (5 cm) of polystyrene foam insulation (k = 0.02 Btu/hr·ft·°F [0.035 W/m °C]) is roughly equivalent to 4 ft (1.2 m) of sand or silt or 3 ft (0.9 m) of clay cover over the pipe.

12-4.3 Deep Burial.

Deeper pipes will experience less extreme ambient temperatures, lower maximum rates of heat loss, and a longer safety factor time against freezing. However, pipes installed in permafrost require freeze-protection all year.

12-5 PHYSICAL METHODS FOR REDUCING HEAT LOSS.

The primary physical method of reducing heat loss is insulation. It is impractical to prevent ground moisture, humidity, or water from pipe failures from reaching the insulation, and since moisture content is a key factor in determining the thermal performance of insulations, use only near-hydrophobic insulations. Even these insulations usually require some physical and moisture protection. Consideration corrosion resistant external coatings of pipe segments or factory applied insulation which is bonded to the pipe surface and forms a water impervious barrier. Assure pipes are protected from moisture entry at joints, connections, and other features where moisture may come in contact with pipe materials.

12-5.1 Amount of Insulation.

Perform an economic analysis to balance heating and insulation costs to determine the minimum amount of insulation that is required. Include factors such as the freeze-up time, the maximum rate of heat loss, and practical dimensional considerations. Heat loss estimates for pipe systems must consider exposed sections of pipes, joints and appurtenances, and thermal breaks such as at pipe anchors. To ensure safe design, the thermal resistance around appurtenances must be 1.5 times that required around adjacent pipe sections. Where insulation is applied to relatively complex equipment features that require frequent maintenance or access, a removable insulated blanket may prove cost effective.

[C] 12-5.1 For example, a 5-inch (13-cm) gate valve has a surface area equivalent to 3 ft (1 m) of bare pipe. If this valve were left exposed, it would lose as much heat as about 200 ft (61 m) of 5-inch (13-cm) pipe insulated with 2 inches (5 cm) of polyurethane insulation, and freezing would occur at the valve first.

12-5.2 Location of Insulation.

The amount of heat loss from a single pipe or multiple pipe system is reduced by minimizing exposed surface area. Minimizing the surface area also requires less insulation. This is especially important for aboveground pipes, facilities, and appurtenances where insulation is most effective when it is placed directly around the source of heat. For a single pipe, insulation is best applied in an annulus directly around the pipe. Where there is an air space, for example between an insulated pipe and a jacket or casing, the thermal resistance of the air space may be quite significant and must be considered. For the same total volume of insulation, it is more effective to group several pipes in a single insulated conduit or small utilidor than to separately insulate each pipe. The ASCE *Cold Regions Utilities Monograph*, Section 4.5, and Chapter 6, “Heat Transfer Calculations for Piping Systems,” of the ASHRAE *District Heating Guide* provide additional discussion and example problems.

12-6 HEAT LOSS REPLACEMENT.

If ambient temperatures are below 32°F (0°C), freezing will eventually occur in the pipe unless the cold fluid is replaced by warmer fluid, or heat is added to the fluid. Heat can be added either at point sources, such as pump stations, or continuously along the length of the pipe with heat tracing. Friction generated by the fluid moving through the pipe may also generate heat, but it is negligible at typical flow velocities.

12-6.1 Fluid Replacement.

Freezing will not occur if the liquid residence time in the pipeline is less than the time necessary for it to cool to the freezing point. The quantity and temperature of the replacement water must be sufficient, and the flow must be reliable. Operation without additional heating is restricted to situations where relatively warm water supplies, such as groundwater, are used or where the flow rate is reliable and high, such as in some water supply pipelines or mains. Recirculation will maintain a flow and a uniform temperature within the system and prevent premature freezing at locations with lower-than-average ambient temperatures or at poorly insulated sections. However, the water temperature will still decline unless warmer water is added, or the recirculating water is heated.

[C] 12-6.1 Bleeding of water has been used historically to maintain or enhance the flow in service lines, dead-ends, and intermittent flowing pipelines, but the wasting of large quantities of water is inefficient, costly, and results in water supply and wastewater treatment problems.

12-6.2 Point Sources of Heat.

Water may be heated at the source, treatment plant, pumping stations, along the pipeline, or within distribution systems as required. There must also be sufficient flow within the piping system to distribute the heat. If the normal water demand is too low or is intermittent, then bleeding or recirculation is necessary. Maintain a minimum water temperature within the piping system by increasing either the flow rate or the input water temperature while keeping the other parameters constant or by adjusting them simultaneously. Higher velocities must be balanced with the electrical energy requirements for pumping and are not usually practical for large diameter mains. The ASCE *Cold Regions Utilities Monograph*, Section 4.4.2, provides additional information.

12-6.3 Heat Tracing.

Replacement of heat losses and maintenance of minimum temperature can also be accomplished with pipe heat tracing systems. Circulation of warm air has been used in large, open utilidors, but the most common heat tracing systems use either separate fluid or electrical lines as the heat source.

12-6.3.1 Fluid Heat Tracing.

For pipe heat tracing, fluids generally between 175°F and 200°F (79°C and 93°C) are much simpler to use than either steam or higher temperature water. The ASCE *Cold Regions Utilities Monograph*, Section 4.4.3, provides additional information.

12-6.3.2 Electric Heat Tracing.

Electric heat tracing systems are relatively easily installed and controlled. They can be installed continuously on water and sewer pipelines or only at freeze-susceptible locations, such as road crossings, service connections, or at appurtenances such as fire hydrants. A variety of electric heat tracing systems and products are available from a number of manufacturers. Exterior heat tracing on pre-insulated pipe is commonly installed within a raceway channel or conduit attached to the pipe surface, which facilitates fabrication, installation, removal, and replacement. Plastic pipes, insulation, and the electric heat tracing system itself must be protected from overheating unless the self-limiting heating cable is used. To provide freeze protection, automatic control systems must activate the electric heat tracing system at a set point above 32°F (0°C) to provide some lead time and allow for variances in the temperature detection sensitivity of the thermostat and sensor. To provide economical operation, the controls also cut off the power supply when heating is not required. The sensors must be located with care to provide proper control, freeze-protection, and prevent the waste of energy. They should be located where the lowest pipe temperatures within the section being controlled are expected, such as at exposed windswept areas or shallow buried sections. The ASCE *Cold Regions Utilities Monograph*, Section 4.4.4, provides additional information.

12-6.4 Pipe Friction.

Friction heating is negligible for smooth pipes with fluid velocities less than 6 ft per second (1.8 m per second), which is about the desirable upper limit for flow in pipes. At high velocities, frictional heat is significant, but deliberately increasing velocity for this purpose is an inefficient method of heating since the energy is supplied by pumping. The equations for frictional heat input are presented in Figure 12-1.

12-7 INSULATION MATERIALS.

Insulation materials include, but are not limited to, polyurethane foam, extruded polystyrene board, fiberglass, molded calcium silicate, and molded polyisocyanurate. Insulation can be installed in the form of boards or may be factory applied on the pipe with appropriate jacketing. Factory insulated pipe may also include heat tracing or channels for heat tracing installation. The insulation materials selected must be in accordance with the criteria given in applicable UFGS, such as UFGS 23 07 00. The ASHRAE *District Heating Guide* provides additional information on insulation types and thermal properties, including obsolete insulation materials that may be found on renovation projects.

For design purposes, the structural and thermal properties for the worst conditions must be used. These conditions occur after aging, compaction, saturation, and freeze-thaw cycles. Other selection considerations are ease of installation, vapor transmission, burning characteristics, and susceptibility to damage by vandals, animals, chemicals, and the environment. The insulating value of a material depends more or less directly on the volume of entrapped gas in the material. If the material becomes wet and the voids filled with water, the insulating properties are lost since the thermal resistance of air is about 25 times that of water and 100 times that of ice. In the past, the lack of a near-hydrophobic insulation made the design of piping in moist environments very difficult and is a major reason for the development of aboveground utilidors.

12-8 THERMAL CALCULATIONS.

The analytical thermal equations presented in this section use a number of simplifying approximations. The user must determine their applicability to specific problems and consider the various models and a range of values for physical and temperature conditions. This chapter’s equations include time-independent steady-state heat flow procedures as well as calculations to determine ground temperature and the depth of freezing and thawing. The symbols used for this chapter’s figures are defined in Table 12-1. The thermal conductivity values of common materials are given in Table 12-2. Solutions to utility system example problems are given in Appendix C to illustrate the methods involved.

12-8.1 Steady-State Pipeline Heat Loss.

Steady-state calculations include typical cases for bare and insulated pipes, and single and multiple pipes in above- and belowground configurations. These methods are presented in Figure 12-1, 12-2, 12-3 and 12-4.

- Figure 12-1 presents equations for estimating the temperature drop (or gain) along a pipeline system. In addition, simple procedures to determine freeze-up times under no-flow conditions are included.
- Figure 12-2 presents equations for estimating heat flow from above-surface pipes. The pipe configurations include bare pipe, an insulated pipe, a single pipe in an insulated box, and a utilidor carrying multiple pipes. In each case, some of the major approximations, in addition to the implied time-independent steady-state assumptions, are indicated. Some comments intended to facilitate application of equations are also included. Where applicable, procedures are given for relevant thermal resistance, rates of heat flow and insulation thicknesses.
- Figure 12-3 presents equations for estimating heat flow from buried pipes. The pipe configurations include a bare pipe with no thaw, a bare pipe with a thaw zone, an insulated pipe with no thaw, and an insulated pipe with a thaw zone. In addition, equations are included to estimate the dimension of the thaw zone.
- Figure 12-4 presents equations for estimating the thermal resistance of typical applications of pipe insulation and utilidor insulation.
- Steady-state thermal influences in isotropic, homogenous soils can be summed, and geometric modifications and approximations can be made to the basic steady-state equations. For example, a layered soil can be represented by an effective soil thickness with the same total thermal resistance as the layered soil.
- When pipes are buried below the area influenced by short-term air temperature fluctuations, the ground temperatures around the pipeline resemble a slowly changing series of steady-state conditions.[1] The heat loss from deeply buried pipes can be calculated from steady-state equations for a cylinder of material around a pipe if the fluid temperature and the soil temperature at a known distance from the pipe are measured, and the soil and insulation thermal conductivities are known. Heat loss from deep pipes can also be estimated by replacing the ground surface temperature in the steady-state equations with the undisturbed ground temperature at the pipe depth.[2] Calculate heat loss from a buried pipe over a time period from the heating index during that period. ASCE *Cold Regions Utilities Monograph*, Section 4.6, provides additional discussion.

Table 12-1 List of Symbols used in Thermal Calculations shown in Figures 12-1 through 12-4

Variable		Subscript	
A	thaw factor [Figure 12-3]	A	air [Figures 12-1 and 12-2]
a	height of insulation (ft) [Figure 12-4]	C	conduit [Figure 12-2]
b	width of insulation (ft) [Figure 12-4]	D	design [Figure 12-1]
c	equation variable (ft) [Figure 12-3]	E	exterior casing (of utilidor) [Figure 12-2]
C	volumetric heat capacity (Btu/ft3 °F) [Figure 12-1]	f	friction [Figure 12-1]
d	insulation thickness (ft) [Figures 12-2 and 12-4]	f	freezing or frozen [Figure 12-3]
δ	effective thickness of fictitious soil layer (ft) [Figure 12-4]	F	freeze [Figure 12-1]
D	scaling parameter (ft) [Figure 12-1]	G	ground (surface) [Figure 12-3]
f	friction head loss (ft/ft) [Figure 12-1]	I	Insulation [Figures 12-2–12-4]
F	friction heat constant, 0.2515 Btu/ft4 [Figure 12-1]	j	denotes pipe number [Figure 12-2]
h	thermal film or convective heat coefficient [Figures 12-2 and 12-4]	L	refers to thermal lining (of utilidor) [Figure 12-2]
k	thermal conductivity (Btu/h ft °F) [Figures 12-1–12-4]	P	pipe [Figures 12-2–12-4]
l	length (ft) [Figure 12-1]	S	soil [Figures 12-3 and 12-4]
L	volumetric latent heat (Btu/ft3) [Figure 12-1]	SF	safety factor [Figure 12-1]
N	equation variable [Figure 12-2]	t	thawed, thawing [Figure 12-3]
p	separation between pipes (ft) [Figure 12-4]	U	utilidor [Figure 12-2]
P	perimeter (mean) (ft) [Figure 12-2]	W	water (fluid) within a pipe [Figures 12-1 and 12-2]
q	fluid flow rate (ft3/s) [Figure 12-1]	Z	refers to zone of thaw [Figure 12-3]
Q	rate of heat loss per unit longitudinal length (Btu/ft h) [Figures 12-1 and 12-2]	0	(zero) refers to freezing point of water [Figures 12-1–12-4]
r	radius (ft) [Figures 12-1–12-4]	1, 2	input fluid, output fluid [Figure 12-1]; layers [Figure 12-4]; Pipes [Figure 12-4]
R	thermal resistance of unit longitudinal length (h ft °F/Btu) [Figures 12-1–12-4]		
s	offset of cylindrical insulation (ft) [Figure 12-4]		
S	equation variable [Figure 12-4]		
t	time (unit varies) [Figure 12-1]		
T	temperature (°F) [Figures 12-1–12-3]		
W	wind function [Figure 12-2]		
v	fluid mean velocity (ft/h) [Figure 12-1]		
V	wind velocity (mph) [Figure 12-2]		
x	depth [Figure 12-3]		

Table 12-2 Thermal Conductivities of Common Materials[1]

Material	Unit Weight (dry) lb/ft^3	Specific Heat Capacity Btu/lb-°F	Thermal Conductivity Btu/ft·h·°F
Air, no convection (32°F)		0.24	0.014
Air film, outside, 15 mph wind (per air film)			0.50
Air film, outside (per air film)			0.14
Polyurethane foam	2	0.4	0.014
Polystyrene foam	0.19	0.3	0.020
Rock wool, glass wool	3.4	0.2	0.023
Snow, new, loose	5.3	0.5	0.05
Snow, on ground	19	0.5	0.13
Snow, drifted and compacted	31	0.5	0.4
Ice at –40°F	56	0.5	1.54
Ice at 32°F	56	0.5	1.28
Water at 32°F	62.4	1.0	0.34
Peat, dry	16	0.5	0.04
Peat, thawed, 80% moisture	16	0.32	0.08
Peat, frozen, 80% ice	16	0.22	1.0
Peat, pressed, moist	71	0.4	0.40
Clay, dry	106	0.22	0.5
Clay, thawed, saturated (20%)	106	0.42	1.0
Clay, frozen, saturated (20%)	106	0.32	1.2
Sand, dry	125	0.19	0.06
Sand, thawed, saturated (10%)	125	0.29	1.9
Sand, frozen, saturated (10%)	125	0.24	2.4
Rock, typical	156	0.20	1.3
Wood, plywood, dry	37	0.65	0.10
Wood, fir, or pine, dry	31	0.6	0.07
Wood, maple, or oak, dry	44	0.5	0.10
Insulating concrete (varies)	12 to 94		0.04 to 0.35
Concrete	156	0.16	1.0
Asphalt	156		0.42
Polyethylene, high density	59	0.54	0.21
PVC	87	0.25	0.11
Wood stave (varies)	–		0.15

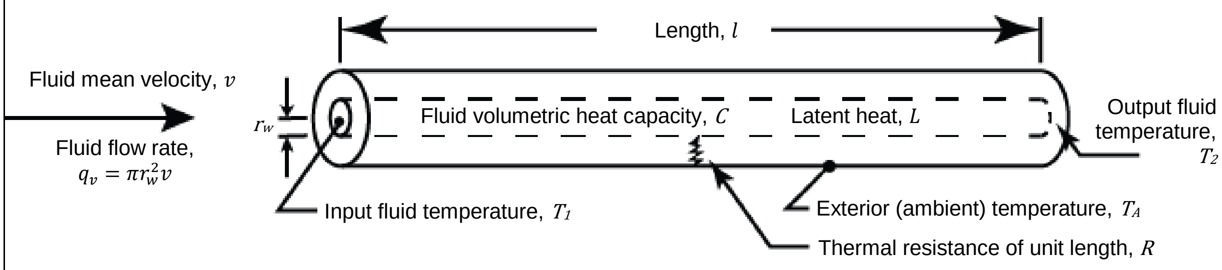
Ductile iron	468		30
Aluminum	169	0.21	115
Copper	550	0.1	220

[1] Values are representative of materials, but most materials have variable properties.

Figure 12-1 Temperature Drop and Freeze-Up Time in Pipes (After "Calculation of Heat Loss in Pipes," by Thornton)

Heat Loss and Temperature Drop in a Fluid Flowing through a Pipe	**Freeze-Up Time for a Full Pipe Under No-Flow Conditions (v = 0)**



Comments: The above is a schematic. R and T_A appearing in these equations can be replaced by the thermal resistance and corresponding exterior temperature for any shape or configuration.

D = scaling parameter $= \pi r_w^2 vCR$

Calculate T_1 or T_2, given R, T_1 or T_2, T_A

$$T_1 = T_A + (T_2 - T_A)/\exp(-l/D)$$

$$\cong T_A + (T_2 - T_A)/(1 + l/D), \text{ if } \frac{l}{D} \leq 0.1$$

$$T_2 = T_A + (T_1 - T_A)\exp(-l/D)$$

Calculate R, given T_1, T_2, T_A

$$R = l/\pi r_W^2 vC \ln[T_2 - T_A/T_1 - T_A]$$

Calculate v, given T_1, T_2, T_A, R

$$v = l/\pi r_W^2 RC \ln[T_2 - T_1/T_1 - T_A]$$

Calculate heat loss (Q), given T_1 or T_2, T_A, v, R

$$Q = D/R\,(T_1 - T_A)[1 - \exp(-l/D)]$$

$$\cong (\tfrac{l}{R})(T_1 - T_A) \text{ for } l/D \leq 0.1$$

$$= D/R(T_2 - T_A)[\exp(l/D) - 1]$$

Calculate Friction Heating (Q_f), given v, f

$$Q_f = F r_W^2 v f$$

Freeze-up Times, given R, T_1, T_A

Assume that thermal resistance of the ice, as it forms, and the heat capacity of the pipe and insulation are negligible.

Design Time (Recommended)

t_D= Time for the fluid temperature to drop to the freezing point.

$$t_D = \pi r_W^2 RC \ln\left[\frac{T_1 - T_A}{T_O - T_A}\right]$$

Safety Factor Time

t_{SF}= Time for the fluid to drop to the nucleation temperature. Same as t_D but with T_0 replaced by 27°F

Complete Freezing Time

t_F= Time for the fluid at freezing point, 32°F, to completely freeze solid.

$$t_F = \pi r_W^2 RL/(T_O - T_A)$$

Figure 12-2 Steady-State Thermal Equations for Above-Surface Pipes (After "Calculation of Heat Loss in Pipes")

	(a) Bare Pipe	(b) Insulated Pipe	(c) Single Pipe in Utilidor	(d) Multiple Pipes in Utilidor
Sketch				Assumptions	Thin-walled pipe ($r_p \leq 2r_W$). R_W is negligible, $R_P \leq R_A$.	All thermal resistances but that of the insulation are neglected.	Convection ensures the temperature inside the utilidor, T_U is uniform. Utilidor air spaces are neglected.	Same as (c).
Thermal Resistance	$R_P = \frac{\ln(r_P/r_W)}{2\pi k_P}$ $R_A = 1/2\pi r_P h_A$ $h_A = N\left(\frac{T_W - T_A}{r_P}\right)^{0.25} W(V)$ $N = 0.23\ Btu/h\,ft\,°F$ $W(V) = \sqrt{12.5V + 1}$ for V in mph $R_C = R_P + R_A$	$R_C = R_I = \frac{\ln(r_I/r_P)}{2\pi k_I}$	Calculate R_C the thermal resistance of the interior conduit by using (b) if insulated or using (a) if bare and replacing T_A in the formula for h_A by an estimate for $T_U (\leq T_W)$. $R_L = d_L/P_L k_L$ $R_E = d_E/P_E k_E$ $R_U = R_L + R_E$ $R = R_C + R_U$ $T_U = \frac{(T_W/R_C) + (T_A/R_U)}{(1/R_C) + (1/R_U)}$ If bare pipe, solution is found by iteration of T_U.	Calculate R for each pipe as in (c) to get R_J Where: $J = 1, 2, 3 \ldots$ Calculate R_U as in (c). $T_U = \frac{\sum_J (T_J/R_J) + (T_A/R_U)}{\sum_J (1/R_J) + (1/R_U)}$ If bare pipes, solution is found by iteration of T_U.
Rate of Heat Loss	$Q = (T_W - T_A)/R_C$	$Q = (T_W - T_A)/R_I$	$Q = (T_W - T_A)/R$	$Q_J = (T_J - T_U)/R_J$ (per pipe) $Q = \sum_J Q_J = (T_U - T_A)/R_U$
Insulation Thickness (given Q)	N/A	$r_I - r_P$ $= r_P\left\{exp\left[\frac{2\pi k_1 (T_W - T_A)}{Q}\right] - 1\right\}$ $= \pi k_I (T_W - T_A) Q$ if $r_I \leq 2r_p$	Obtain R_E and R_C as above $d_L = R_L k_L [\frac{(T_W - T_A)}{Q} - R_E - R_C]$ If bare interior pipe, iterate T_U, R_C and hence d_L.	Given acceptable Q_J, calculate R_J as above and evaluate $T_U = T_J - R_J Q_J$ for each pipe for which Q_J is known. Using the maximum T_U found, calculate new Q_J as above. Using these Q_J and the same T_U, evaluate $d_L = P_L k_L [\frac{T_U - T_A}{\sum Q_J} - R_E]$ If bare pipes, iterate T_U, R_J and hence d_L.
Comments	Often, for metal pipes, R_P may be neglected. If R_P is significant, the expression above h_A will generate an overestimate of Q. If $T_A > T_W$ switch T_A and T_W in the expression for h_A.	The neglected thermal resistances given in (a) may be included if desired. Estimate a value for the insulation surface temperature and calculate h_A and R_A, iterate.	The value of h_A, and hence R_A, is insensitive to the choice of T_U, and so one iteration of T_U is usually sufficient. Often R_E may be neglected. A similar calculation may be performed for pipes and utilidors of different cross section.	Same as (c). If one pipe dominates the heat loss process, (c) may be used to estimate T_U. It is wise to consider the heat loss from the various pipes if certain other pipes cease to function.

Figure 12-3 Steady-State Thermal Equations for Below-Surface Pipes (After “Calculation of Heat Loss in Pipes”)

	(a) Bare, No Thaw	(b) Bare, with Thaw Zone	(c) Insulated, No Thaw	(d) Insulated, with Thaw Zone
Sketch				Assumptions	Neglect all thermal resistances except that of the soil.	Same as (a), but accounting for the different conductivities of thawed and frozen soil.	Neglecting all thermal resistances except those of the soil and insulation. Outer surface of insulation assumed to be isothermal. $r_I - r_P \ll H_P$.	Same as (c) but accounting for the different thermal conductivities of thawed and frozen soil.
Thermal Resistance and Thaw Zone Parameters	$R_S = \frac{\text{arccosh}(\frac{H_P}{r_P})}{2\pi k_S}$ $= \frac{ln\left\{\left(\frac{H_P}{r_P}\right) + \left[\left(\frac{H_P}{r_P}\right)^2 - 1\right]^{1/2}\right\}}{2\pi k_S}$ $\cong \frac{\ln(2H_P/r_P)}{2\pi k_S}$ if $H_P \geq 2r_P$	$T'_W = \frac{k_t}{k_f}(T_W - T_O) + T_0$ $T' = \frac{(T_O - T_G)}{(T'_W - T_G)}$ $c = \sqrt{H_P^2 - r_P^2}$ $A = T'\,\text{arccosh}(\frac{H_P}{r_P})$ $H_Z = c\coth A \quad r_Z = c\,\text{csch}\,A$ R_t, R_f, and R_S (= $R_t + R_f$) as given in (d), but with r_t replaced by r_P	R_1 as given in Figure 12-2 (b), R_S as given in (a), but with r_P replaced by r_I. $T_I = T_W - \frac{R_I(T_W - T_G)}{R_S + R_I}$ For known T_W, T_G, and R_S, the minimum thermal resistance to prevent thaw, R'_1, (such as $T_I = T_O$) is given by: $R'_1 = \frac{T_W - T_O}{T_O - T_G} R_S$	R_I as given in Figure 12-2 (b) T'_W, T', c, H_Z, r_Z and R'_S as in (b) but with r_P replaced by r_I and using: $A = T'[\text{arccosh}(H_P/r_P) + 2\pi k_t R_I]$ $T_I = T_W - \frac{R_I(T'_W - T_G)}{R'_S + (k_t/k_f)R_I}$ Also, $R_t = \frac{[\text{arccosh}(H_P/r_I) - \text{arccosh}(H_Z/r_Z)]}{2\pi k_t}$ $R_f = \text{arccosh}(H_Z/r_Z)/2\pi k_t$ $R_S = R_f + R_t$
Rate of Heat Loss	$Q = \frac{T_W - T_G}{R_S}$	$Q = \frac{T'_W - T_G}{R'_S}$ Where: $R'_S = \frac{\text{arcosh}(H_P/r_P)}{2\pi k_f}$	$Q = \frac{T_W - T_G}{R_I + R_S}$	$Q = \frac{T'_W - T_G}{R'_S + (k_t/k_f)R_I}$
Insulation Thickness	N/A	N/A	For no thawing outside the insulation the minimum insulation thickness is given by: $r_I - r_P = r_P[\exp(2\pi k_I R'_I) - 1]$	$R_I = [(A/T') + \text{arccosh}(H_P/r_I)]/2\pi k_t$ $r_I - r_P$ as in (c) but with R'_I replaced by R_I from above.
Comments	For calculations of heat loss when there is a temperature gradient in the soil and $H_P > 2r_P$, T_G may be replaced by T_{H_P}, the undisturbed ground temperature at the pipe axis depth. For an upper limit on heat loss, use $k_S = k_f$, otherwise use $k_S = (k_f + k_t)/2$.	The thawed zone is a circle in cross section.	May be used to approximate (d) if $k_t \cong k_f$ and/or $r_Z \cong r_I$, and thaw zone parameters are not required. Use $k_S = k_f$ or $k_S = (k_f + k_t)/2$ as in (a).	Often the above expressions for R_t, R_f and R_S are not required.

$$\delta = \frac{k_S}{h_G}$$
For further soil thermal resistance calculations this thickness is simply added to the actual burial depth of the pipe.</td></tr>
<tr><td>Composite wall</td><td></td><td>$$R = \frac{1}{h_I}+\frac{1}{h_O}+\frac{d_1}{k_1}+\frac{d_2}{k_2}$$</td></tr>
</table>

12-8.2 Depth of Freezing and Thawing

Obtain the depth of freezing or thawing of soil, and the ice thickness on water bodies, by field measurements when possible. If required, they can be estimated using one of the many analytical solutions available. Because of the assumptions necessary in these analytical solutions, such as assuming a step change in surface temperature or neglecting the soil temperature changes, they generally overestimate the maximum freezing isotherm depths for the given conditions and are, therefore, conservative for engineering applications.

12-8.2.1 Basic Analytical Solution Form.

Analytical solutions are generally Neumann- or Stefan-based equations which have the basic form:

Equation 12-1. Depth of Freezing or Thawing (Stefan Solution, Empirical Coefficients)

$$X = m\left(I_g\right)^{1/2}$$

Where:
X = depth of freezing or thawing (ft)
m = coefficient of proportionality (ice thickness $\boldsymbol{m}$-factor)
I_g = ground surface freezing (I_f) or thawing (I_t) index (°F-days)

12-8.2.2 Specific Solutions.

Equations 12-2 through 12-5 incorporate various assumptions that are useful for specific conditions:

- Equation 12-2 is the Stefan solution for a homogeneous material with a step change in surface temperature (see Appendix C, Example 1). Equation 12-2 is identical to Equation 12-1 except 12-1 uses empirical coefficients and 12-2 uses the values of the physical properties. Equation 12-2 overestimates the depth of freezing as a result.
- Equation 12-3 is a two-layer modification of the Stefan equation and is useful for calculations involving snow cover, a gravel pad, or a board of thermal insulation, in which the surface layer has no latent heat (see Appendix C, Example 2 and Example 3.
- Equation 12-4 is a close approximation of the Neumann solution when the ground temperatures are near freezing.
- Equation 12-5, the modified Berggren equation, is perhaps the most commonly used approach for determining thermal responses of soils. When the soil has a high moisture content the correction coefficient λ

approaches unity and the equation is identical to the Stefan approach (Equation 12-2).

- In climates where the mean annual temperature is near or below freezing, the thermal ratio approaches zero and the λ coefficient is greater than 0.9. In very dry soils, the soil warming or cooling can be significant, and should be included.

Equation 12-2. Depth of Freezing or Thawing (Stefan Solution)

$$X = \left(\frac{2kI_g}{L}\right)^{1/2}$$

Equation 12-3. Depth of Freezing or Thawing (Stefan Solution, Two-Layer)

$$X = \left(\left(\frac{k_2}{k_1}d_1\right)^2 + \frac{2k_2I_g - \frac{d_1^2L_1}{2k_1}}{L_2}\right)^{1/2} - \left(\frac{k_2}{k_1} - 1\right)d_1$$

Equation 12-4. Depth of Freezing or Thawing (Neumann Solution Approximation)

$$X = \left(\frac{2kI_g}{L}\right)^{1/2}\left(1 - \frac{CI_g}{8Lt}\right)$$

Equation 12-5. Depth of Freezing or Thawing (Modified Berggren Solution)

$$X = \lambda\left(\frac{2kI_g}{L}\right)^{1/2}$$

Where:

k = *thermal conductivity of the material above the freezing isotherm (Btu/hr·ft·°F). Subscripts f and t refer to freezing and thawing, and subscripts 1 and 2 refer to the surface layer and the underlying material (all symbols are also defined in Table 12-1).*

L = *volumetric latent heat of the material undergoing phase change (Btu/ft^3). For water L = (144 Btu/lb)(62.4 pcf) = 8986 Btu/f^3*

C = *volumetric heat capacity of the material above the freezing isotherm.*

For thawed soil: $C_t = \gamma\,[C_{mS} + C_{mW}(w/100)]$

For frozen soil: $C_f = \gamma\,[C_{mS} + C_{mi}\,(w/100)]$

γ = *dry unit weight of soil (pcf)*

C_{mS} = *mass heat capacity of mineral matter in soil; assume a value of 0.2 Btu/lb*

C_{mW} = *mass heat capacity of water = 1.0 Btu/lb*

C_{mi} = *mass heat capacity of ice, assumed value of 0.5 Btu/lb*

w = *moisture content of soil (%)*
T_m = *mean annual site temperature (°F)*
t = *freezing or thawing period, consistent units*
T_0 = *freezing point, 32°F for water*
d = *thickness of layer of material (ft)*
λ = *a correction coefficient which takes into consideration the effect of temperature change in the soil and primarily accounts for the volumetric specific heat effects. It is a function of two parameters, the thermal ratio (a) and the fusion parameter (μ) that are calculated using Equation 12-6 and Equation 12-7. λ is determined from Figure 12-5.*

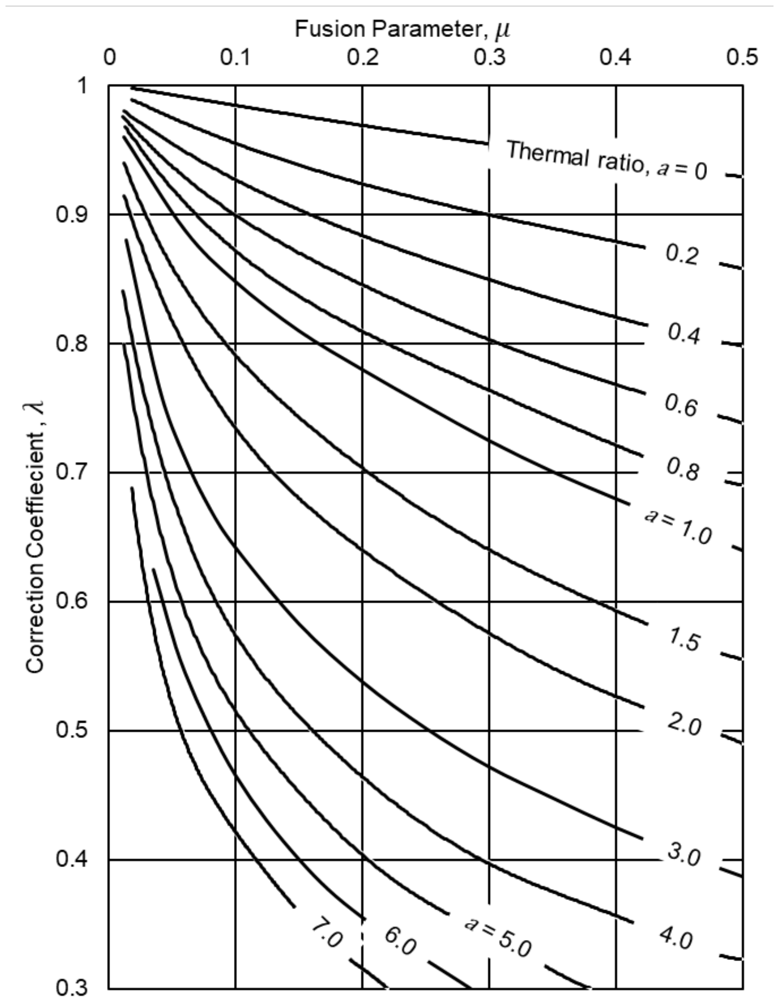
Equation 12-6. Thermal Ratio (*a*)

$$\mathrm{a} = \frac{(T_m - T_0)}{T_m} = \frac{(T_m - T_0)t}{I_g}$$

Equation 12-7. Fusion Parameter (*μ*)

$$\mu = \frac{CI_g}{Lt}$$

Figure 12-5 Correction Coefficient λ for use in Berggren Equation



12-8.2.3 Multi-layered Soil Systems.

Solve multilayered soil systems by determining that portion of the surface freezing or thawing index required to penetrate each layer. The sum of the thicknesses of the frozen or thawed layers, whose indices equal the total index, is equal to the depth of freeze or thaw. The partial freezing or thawing index to penetrate the n^{th} layer is calculated by Equation 12-8.

Equation 12-8. Partial Freezing or Thawing Index

$$I_n = \frac{L_n d_n}{\lambda^2} \sum_{1}^{n-1} \left(R + \frac{R_n}{2} \right)$$

Where:
I_n = *the partial freezing or thawing index required to penetrate the n^{th} layer (°F·hr)*
L_n = *volumetric latent heat in the n^{th} layer (Btu/ft^3)*
d_n = *thickness of the n^{th} layer (ft)*
λ = *the coefficient based on the weighted average values for µ down to and including the n^{th} layer*
$\sum_1^{n-1}\left(R + \frac{R_n}{2}\right)$ = *the sum of the thermal resistances of the layers above the n^{th} layer*
R_n = d_n/k_n, *the thermal resistance to the n^{th} layer (h ft °F/Btu)*

The solution for multilayered systems is facilitated by tabular arrangement of the intermediate values. The penetration into the last layer must be solved by trial and error to match the total freezing or thawing index at the site. It is necessary to determine the temperature condition at the ground surface to determine subsurface thermal effects, including the depth of freezing and thawing. Since air temperatures are readily available, but surface temperatures are not, a correlation factor which combines the effects of radiation with convective and conductive heat exchange at the air-ground surface is used:

Equation 12-9. Ground Surface Freezing or Thawing Index

$$I_g = nI_A$$

Where:
I_A = *air freezing or thawing index*
n = *n-factor, ratio of the surface and air temperature indices*

The n-factor is very significant in analytical ground thermal considerations. It is surface and site specific, highly variable, and usually estimated from published observations such as the values listed in Table 12-3.

12-8.2.4 Ice Thickness.

Estimate ice thickness on water bodies from the previous depth of freezing equations or from Equation 12-1 with the m values in Table 12-4 (see Appendix C, Example 1). Snow cover has a significant insulating effect and can significantly reduce the maximum ice thickness (see Appendix C, Example 2). The ice formation can be greater than calculated if the weight of snow or the lowering of the water level causes cracks in the ice and water overflows onto the surface. This water is drawn into the snow, and the mixture refreezes and bonds to the original ice.

Table 12-3 Typical Values of the n-factor of Air Temperature with Surface Temperature of Various Materials

Surface	n-factors		
	Thawing	Freezing	
Snow	—	1.0	General application
Pavement free of snow and ice	—	0.9	General application
Sand and gravel	2.0	0.9	General application
Turf	1.0	0.5	General application
Spruce	0.35 to 0.53	0.55 to 0.9	Thompson, Manitoba
Spruce trees, brush	0.37 to 0.41	0.28	Fairbanks, Alaska
Above site, cleared, moss surface	0.73 to 0.78	0.25	Fairbanks, Alaska
Stripped, mineral soil surface	1.72 to 1.26	0.33	Fairbanks, Alaska
Spruce	0.76	—	Inuvik, Northwest Territories (NWT)
Willows	0.82	—	Inuvik, NWT
Weeds	0.86	—	Inuvik, NWT
Gravel fill slope	1.38	0.7	Fairbanks, Alaska
Gravel road	1.99	—	Fairbanks, Alaska
Concrete road	2.03	—	Fairbanks, Alaska
Asphalt road	1.74 to 2.70	—	Fairbanks, Alaska
White painted surface	0.76 to 1.25	—	Fairbanks, Alaska
Peat bales on road	1.44 to 2.28	—	Fairbanks, Alaska
Dark gravel	1.15 to 1.73	—	Fairbanks, Alaska

Table 12-4 Example m-factors for Ice Thickness

m-factor inch /(°F-days)$^{1/2}$	Conditions
0.90–0.95	Practical maximum for ice not covered with snow
0.8	Windy lakes with no snow
0.7–0.8	Medium-sized lakes with moderate snow cover
0.6–0.65	Rivers with moderate flow
0.4–0.5	River with snow
0.2–0.4	Small river with rapid flow

APPENDIX A BEST PRACTICES

A-1 INTRODUCTION.

The Best Practices Appendix is considered to be guidance and not requirements. Its main purpose is to communicate proven facility solutions, systems, and lessons learned, but may not be the only solution to meet the requirement. It identifies additional background information and practices for accomplishing utilities design and construction in the Arctic and Subarctic. The DoR must review and interpret this guidance as it conforms to criteria and contract requirements and apply the information according to the needs of the project. If a Best Practices document guideline differs from any UFC, the UFC takes precedence. For Best Practices guidelines not discussed in a UFC, the DoR must submit a list of the guidelines or requirements being used for the project to the Government Project Manager with documentation sufficient for review and approval prior to completing the design.

A-2 WHOLE BUILDING DESIGN GUIDE.

The Whole Building Design Guide (WBDG) provides additional information and discussion on practice and facility design, including a holistic approach to integrated design of facilities. The WBDG provides access to all Construction Criteria Base criteria, standards and codes for the DoD Military Departments, and other agencies. These standards include UFC, UFGS, Performance Technical Specifications, design manuals, and specifications. For approved government employees, it also provides access to nongovernment standards.

A-3 CANADIAN EXPERIENCE.

The Government of the Northwest Territories (GNWT) *Good Engineering Practice for Northern Water and Sewer Systems* contains performance guidelines, preferred materials and methods, and logistical considerations developed from decades of Canadian experience with the design and construction of water and sewer systems in the far north. Over time, certain products and approaches to constructing water and sewer systems have proven successful and have been adopted by design consultants and builders working in the Northwest Territories. These guidelines should be reviewed as they document both failures and successes in cold regions utilities construction and durability.

A-4 PLANNING AND DESIGN CONSIDERATIONS.

Military Installations in cold regions may have their own heating or power plants, water source and treatment facilities, and wastewater treatment facilities. Alternatively, Installations may be connected to local utility providers. Virtually all Installations have existing overhead and underground distribution systems that have been in service for many years. Utility systems at some Installations are provided by public utility companies or have been privatized. Work for these systems must follow the standards of the utility owner or current utility contractor. Other Installations still own, operate, and maintain their utility systems. For those Installations, direction from the Installation staff, often in the form of Installation Facilities Standards (IFS), should be solicited and followed. IFS are available on the WBDG website at https://wbdg.org/airforce/ifs. New Installations may benefit from the guidance used at existing military Installations or local municipalities if differing design conditions are considered, especially climatic conditions. Revegetation after construction should follow IFS guidance and local requirements, such as Eielson AFB *Design Guidelines 04—Establishing Vegetation.*

Modular construction, where the entire facility or a major component is preassembled and shipped via barge to the point of use, has been used at oil field developments on the northern coast of Alaska. It is advantageous in these locations since large barges can be used, the construction season is short, and labor is very expensive. Barges can usually begin to arrive in Utiqiagvik (formerly Barrow), Alaska and the Eastern Arctic around the first of September. This means the nonmodular construction materials must be shipped a year in advance and stockpiled for the next construction season. The stick-built approach, where all fabrication is done on-site, and the prefabrication approach, where some components are preassembled at the point of manufacture, are more common at interior locations where transport is limited to air or small rivers. Prefabrication of insulating piping units has been shown to be cost effective for remote locations.

A-5 WATER SOURCE DEVELOPMENT.

The ADEC Standard 18 AAC 80 *Drinking Water* provides additional guidance for water wells. ADEC is the utilities permitting authority for the State of Alaska and all military Installations therein.

A-6 WATER TREATMENT.

See ADEC 18 AAC 80 *Drinking Water* standard.

UFC 3-230 series provides additional water treatment Best Practices. ADEC 18 AAC 80 *Drinking Water* is the regulatory standard document for water systems in Alaska.

A-7 WATER STORAGE AND DISTRIBUTION.

A-7.1 GENERAL.

UFC 3-230-01 provides general Best Practices for water storage and distribution. ADEC 18 AAC 80 *Drinking Water* is the regulatory standard for water systems in Alaska. Local municipalities and utility companies also publish standards that include minimum burial depth at specific locations, lists of materials that have performed well in their jurisdiction, and example detail drawings of pipes and appurtenances. Examples of such documentation are as follows:

- Anchorage Water and Wastewater Utility, *Design and Construction Practices Manual*

- Utility Services of Alaska, *Standards of Design and Construction* (Fairbanks, AK)
- City of North Pole, *Utility Standards of Construction*
- City of North Pole, *Service Line Requirements for Water and Wastewater—Commercial and Residential Structures*
- Doyon Utilities, *Water, Wastewater, Steam, & Utilidor Systems* (Fort Wainwright and Fort Greely)
- Doyon Utilities, *Division 60 Water Distribution Systems* (Joint Base Elmendorf-Richardson)

A-7.2 MATERIALS.

Unless otherwise approved by the Installation, Command, or District engineering staff, direct bury waterlines should be HDPE as this material can typically survive freeze expansion without rupturing.

A-7.3 MAINS.

Locating mains in the rear of buildings or in areas that retain their snow cover provides greater thermal protection, results in less risk of damage to manholes and other appurtenances, and allows shorter, less costly service connections to the buildings. There are special advantages to this approach for barracks and family housing areas where large numbers of similar structures tend to be laid out in a regular pattern.

A-7.4 HYDRANTS.

Comply with any specific requirements of the Installation, or for privatized systems, the utility contractor. It is best to avoid any kind of nonemergency operation of hydrants during the winter months.

A-8 WASTEWATER COLLECTION AND TREATMENT.

UFC 3-240-01 provides Best Practices for wastewater collection and treatment; paragraph A-6.6 provides guidance specific to cold regions. ADEC 18 AAC 72 *Wastewater Disposal* is the regulatory standards document for wastewater systems in Alaska, including required minimum separation distances between water and sewer mains (including manholes) and the criteria for obtaining a waiver if the required separation distances cannot be achieved. Local municipalities and utility companies also publish standards that include lists of material that have performed well in their jurisdiction, and example detail drawings of pipes and appurtenances. Contractors for Installations with privatized utilities system, or the Installation itself, may have specific design standards that must also be considered. Examples of such documentation are as follows:

- Anchorage Water and Wastewater Utility, *Design and Construction Practices Manual*
- Utility Services of Alaska, *Standards of Design and Construction* (Fairbanks, AK)
- City of North Pole, *Utility Standards of Construction*
- City of North Pole, *Service Line Requirements for Water and Wastewater—Commercial and Residential Structures*
- Doyon Utilities, *Water, Wastewater, Steam, & Utilidor Systems* (Fort Wainwright and Fort Greely)
- Doyon Utilities, *Division 50 Wastewater Collection Systems* (Joint Base Elmendorf-Richardson)

"Chatfield Wastewater Treatment Facility Improvements: A Design and Operational Review, Focused on Cold Weather Issues," by Wedin, provides a discussion of wastewater treatment facilities issues specific to cold regions operations.

A-9 UTILIDORS.

ADEC is the permitting authority for utilidors in the State of Alaska, and all utilidor designs must comply with ADEC standards or have an appropriate waiver. Follow the Eielson AFB *Design Guidelines 10—Utilidors*, generated by the 354th Civil Engineer Squadron, Operations Engineering Flight (354 CES/CEO), where applicable. Privatized utilities systems may have specific design standards that must be considered. An example of this would be Doyon Utilities, *Water, Wastewater, Steam, & Utilidor Systems.*

A-10 FIRE PROTECTION.

Follow Installation guidance such as the Eielson AFB *Design Guidelines 17—Fire Alarm Systems Standards* and Eielson AFB *Design Guidelines 71—Fire Protection* where applicable.

A-11 POWER DISTRIBUTION AND COMMUNICATIONS SYSTEMS.

A-11.1 GENERAL

Follow UFC 3-530-01 for exterior lighting, such as street and parking lot lighting.

Follow the Eielson AFB *Design Guidelines 14—Electrical Standards*, where applicable. Privatized utilities systems may have specific design standards that must be considered. An example of this would be Doyon Utilities, *Electrical System.*

A-11.2 GROUNDING

The GNWT *Good Building Practice for Northern Facilities* provides the following recommendations, in their order of preference, for obtaining the best possible electrical grounding in cold regions:

1. Exothermic (cad) weld to a minimum of four steel pipe piles
2. Minimum 9.5 mm (3/8 inch) bolts (copper, bronze, or brass) tapped and threaded to a minimum of four steel pipe piles

   Rationale: The large surface area of a steel pile or foundation system that is in contact with the ground can provide the best ground possible in northern areas. Cad welding provides a permanent connection.

3. A minimum of three steel rod electrodes
4. Ufer ground (concrete incased electrode)
5. Plate electrodes
6. Municipal piped water system

GNWT suggests the use of additives where obtaining low ground resistance is critical and standard methods are insufficient. GNWT notes: “Additives will degrade over time, reducing the effectiveness of the grounding system, however they may be warranted in some situations.” Additionally, they recommend designers avoid using dissimilar metals to protect from galvanic action, which may occur under certain soil conditions. All grounding measures must comply with UFC 3-550-01.

A-12 UTILITIES ENGINEERING RELATED GUIDANCE.

The following documents provide guidance on the specific topics indicated.

APPENDIX C EXAMPLE PROBLEMS

Appendix C gives example problems. EPA-600/8-79-027, Section 15.10 and the ASCE *Cold Regions Utilities Monograph*, Section 4.7 provide additional example problems.

C-1 EXAMPLE 1

Estimate the ice thickness on a water reservoir with no snow cover when the annual air freezing index (I_g) is 3000°F-days.

Use Equation 12-1:

$$X = m\left(I_g\right)^{1/2}$$

From Table 12-4: m = 0.80 inch/(°F-days)$^{1/2}$

X = 0.80(3000)^{½} = 43.82 inches = 3.65 ft

The Equation 12-2 can also be used. However, Equation 12-1 uses empirical values from observations, and Equation 12-2 uses only the values of the physical properties of water. It is expected that Equation 12-2 overestimates the ice thickness compared to Equation 12-1.

$$X = \left(\frac{2kI_g}{L}\right)^{1/2}$$

Where:

k = thermal conductivity of material above the freezing isotherm, ice in this case, so from Table 12-2:

k_{ice} = 1.28 Btu/ft hr °F

L = volumetric latent heat of material undergoing phase change, in this case water, so:

Latent heat of water at 32°F = 144 Btu/lb

Density of water at 32°F = 62.4 lb/ft^3

L = (144 Btu/lb)(62.4 lb/ft^3) = 8985.6 Btu/ft^3

I_g = (3000°F-days)(24 hr/day) = 72,000°F hr

Solving for the practical maximum ice thickness:

$$X = \left(\frac{2(1.28 Btu/ft\ hr\ °F)(72{,}000\ °F\ hr)}{8986\ Btu/ft^3}\right)^{1/2} = 4.5 \text{ ft}$$

C-2 EXAMPLE 2

Estimate the ice thickness on the reservoir in Example 1 when there is an 8-inch snow cover on top of the ice and I_g is 3000°F-days.

From Equation 12-1, and Table 12-4:

$$X = m(I_g)^{1/2}$$

$$X = 0.7(3000)^{1/2} = 38 \text{ inch} = 3.2 \text{ ft}$$

Or use the Stefan equation (Equation 12-2) for a two-layer soil system:

$$X = \left(\left(\frac{k_2}{k_1}d_1\right)^2 + \frac{2k_2 I_g - \frac{d_1^2 L_1}{2k_1}}{L_2}\right)^{1/2} - (\frac{k_2}{k_1} - 1)d_1$$

The first layer is snow, d_1 = 8 inch = 0.667 ft, assumed to be drifted and compact. From Table 12-2, k_1 = 0.4 Btu/ft hr °F. Since no phase change occurs in the snow, L_1 = 0.

For Ice: k_2 = 1.28 Btu/ft hr °F

L_2 = (144)(62.4) = 8986 Btu/ft^3

$$X = \left(\left(\left(\frac{1.28}{0.4}\right)(0.667)\right)^2 + \frac{2(1.28)(3000)(24)}{8986}\right)^{1/2} - (\frac{1.28}{0.4} - 1)(0.667)$$

$= (4.55 + 20.5)^{1/2} - 1.47 = 3.5$ ft (includes the 8 inch snow)

C-3 EXAMPLE 3

The Equation 12-3 can be used to estimate the depth of frost penetration beneath a gravel pad or an insulation board. The L_1 in either case would be zero. The L_2 in this example would be the latent heat of fusion for the soil and would be dependent on the moisture content in the soil.

Assume: sandy soil, dry density 125 pcf, moisture content 6%, and a freezing index (I_g) of 3000°F-days.

Find depth of frost penetration under 3-inch thick polystyrene board. From Table 12-2:

k_1 = 0.020 Btu/ft °F hr (for polystyrene)

k_2 = 1.0 Btu/ft °F hr (for sand), and thus
d_1 = 3/12 = 0.25 ft

The moisture content in the soil = (0.06)(125 pcf) = 7.5 lb water/ft^3 soil.

Latent heat of water = 144 Btu/lb

L_2 = (144 Btu/lb)(7.5 lb/ft^3) = 1080 Btu/ft^3 of soil

L_1 = 0

$$X = \left(\left(\frac{k_2}{k_1}d_1\right)^2 + \frac{2k_2 I_g}{L_2}\right)^{1/2} - (\frac{k_2}{k_1} - 1)d_1$$

$$X = \left(\left(\frac{1.00}{0.02}(0.25)\right)^2 + \frac{2(1.00)(3000)(24)}{1080}\right)^{1/2} - (\frac{1.00}{0.020} - 1)(0.25)$$

$$X = (156 + 133)^{1/2} = 4.75 \text{ ft}$$

The depth of frost penetration would be 11.5 ft in the same soil, under the same conditions, if the insulation board were not in place.

C-4 EXAMPLE 4

Determine the rate of heat loss per linear foot of aboveground pipe from a 5-inch interior diameter (wall thickness ½ inch) plastic pipe encased in 2-inch thick polyurethane insulation. Water inside the pipe is maintained at 40°F, ambient air temperature is −40°F, and wind speed is 15 mph. Thermal conductivity of pipe material (k_P) is 0.208 Btu/°F ft hr and thermal conductivity of the insulation material (k_I) is 0.0133 Btu/°F ft hr.

Use equations from columns (a) and (b) of Figure 12-2:

Thermal resistance of pipe $R_P = \frac{ln(r_P/r_W)}{2\pi k_P}$

Inside pipe radius = r_w = 2.5 inch

Outside pipe radius = r_P = 2.5 + 0.5 = 3.0 inch

$$R_P = \frac{ln(3.0 - 2.5)}{2(3.14)0.208} = \frac{0.182}{1.307}$$

R_P = 0.139 hr ft °F/Btu

Thermal resistance of insulation: $R_I = \frac{ln(r_I/r_P)}{2\pi k_I}$

Outside pipe radius, r_P = 3 inch

Insulation radius, r_I = 5 inch

$$R_I = \frac{ln(5/3)}{2(3.14)0.0133}$$

= 6.115 hr ft °F/Btu

The total resistance of the pipe, R_C, is found as

$R_C = R_I + R_p$ = (6.115 + 0.139) = 6.254 hr ft °F/Btu

To determine the thermal resistance of the air film (R_A) it is necessary to estimate the surface heat transfer coefficient (h_a). From Figure 12-2 column (a):

$$h_A = N\left(\frac{T_S - T_A}{r_S}\right)^{0.25} W(V)$$

Where T_s is the outer surface temperature of the insulated pipe. (Note that in Figure 12-2 column (a) it was assumed that the thermal resistance of the pipe wall was negligible so that $T_s = T_w$. In the present case the pipe is insulated, and that assumption cannot hold.) From Figure 12-2 column (a), N = 0.23 and $W(V) = (12.5V + 1)^{1/2}$ where V is the wind speed (mph):

$$W(V) = ((12.5)(15)+1)^{1/2} = 13.73$$

In this case, R_P is to the outer surface of the insulation, 5 inches or 0.417 ft. For the first iteration one must assume a surface temperature (Ts). This is close to air temperature. Assuming Ts is −39°F, then:

$$h_a = 0.23\left(\frac{-39-(-40)}{0.417}\right)^{0.25} (13.73)$$

= 3.930 Btu/hr °F ft

Then, to calculate thermal resistance of air film:

$$R_A = \frac{1}{2(\pi)r_p h_a}$$

$$\mathrm{R_A} = \frac{1}{2(3.14)(0.417)(3.930)} = 0.0971 \text{ hr ft °F/Btu}$$

Then, check the assumed air film temperature:

$$T_S = T_A + (T_W - T_A)(\frac{R_A}{R_A + R_I + R_P})$$

$$T_S = -40 + (40 - (-40))(\frac{0.0971}{0.0971 + 6.116 + 0.1396})$$

= -40 + (80)(0.0153)

= −38.78°F (versus assumed −39.0°F, which is close enough).

If the values did not check, it would be necessary to repeat the calculation with another assumed T_S until a reasonable check is attained. The combined thermal resistance (R_C) is:

$$R_C = R_A + R_I + R_P$$

= 0.0971 + 6.116 + 0.139 = 6.352 hr ft °F/Btu

The rate of heat loss (Q) is:

$$Q = \frac{(T_W + T_A)}{R_C}$$

$$Q = \frac{(40 + (-40))}{6.352}$$

= 12.59 Btu/hr linear ft of pipe.

C-5 EXAMPLE 5

Compare the heat losses for the water pipe in Example 4 if installed at Utqiagvik, Alaska, aboveground or at a depth of 4 ft. Assume the minimum air temperature is −58°F, and the minimum mean daily soil temperature at a depth of 4 ft is 1.4°F. The thermal conductivity of the soil is 1.2 Btu/ft hr °F.

(1) Aboveground installation. Assume a 5-inch interior diameter plastic pipe with 2 inches of polyurethane insulation:

R_C = 6.254 hr ft °F/Btu (from Example 4).

The water inside the pipe will be maintained at 40°F so that the maximum rate of heat loss:

$$Q = \frac{(T_W - T_A)}{R_C}$$

$$Q = \frac{(40 - (-58))}{6.254}$$

= 15.5 Btu/hr linear ft of pipe.

(2) *Buried installation*. Assume that the top of the pipe is 4 ft below the surface, and the radius to the outer surface is 5 inches (0.416 ft). The depth to center of the pipe H_P is 4.416 ft, and the radius of pipe r_P is 0.416 ft, therefore the condition H_p is greater than $2r_p$ is true. So, from Figure 12-3 column (a), the thermal resistance of the soil (R_S) is:

$$R_S = \frac{ln(2\,H_P/r_P)}{2\pi k_S}$$

$$R_S = \frac{ln[2(4.416/0.416)]}{2(3.14)(1.2)}$$

= 0.405 hr ft °F/Btu

The air film is not a factor for a buried pipe of this type, so the combined resistance R_C equals:

$R_c = R_P + R_I + R_S$

= 0.1396 + 6.116 + 0.405
(R_P and R_I from the previous example)

= 6.661 hr ft °F/Btu

So, the heat loss Q equals: $Q = \frac{(T_W - T_G)}{R_C}$

T_G in this case is soil temperature 1.4°F

$$Q = \frac{(40 - 1.4)}{6.661}$$

= 5.79 Btu/hr linear ft of pipe.

This is about one-third the heat loss rate calculated for an above

ground installation in the same location. The responsible factor is the attenuation of the extreme surface temperature at the 4-ft depth.

C-6 EXAMPLE 6

Determine the mean size of the thaw zone and the average rate of heat loss from a 6-inch steel pipe buried 4 ft below the surface in a clay soil, where the soil thermal conductivities are as follows: k_t (thawed) = 0.60 Btu/hr ft °F, and k_f (frozen) = 1.0 Btu/hr ft °F. Mean soil temperature at the ground surface is 27.5°F, and the water in the pipe is maintained at 45 °F. (See Figure 12-3 column (b) for schematic, symbols, and equations). A bare steel pipe has negligible thermal resistance, so:

R_P = 0

Outer pipe radius r_P = 6 inch/(2)(12) = 0.25 ft

Depth to center of pipe H_P = 4.0 ft

$$T'_W = \frac{k_t}{k_f}(T_W - T_0) + T_0$$

Where:

T_W = water temperature inside pipe

T_0 = soil temperature at interface of the thawed zone

= 32°F

$$T'_W = \frac{0.6}{1.0}(45 - 32) + 32 = 39.8\ °\mathrm{F}$$

$$T' = \frac{T_0 - T_G}{T'_W - T_G}$$

T_G = temperature at ground surface

$$T' = \frac{32 - 27.5}{39.8 - 27.5} = \frac{4.5}{12.3} = 0.366\ °\mathrm{F}$$

Depth to center of thawed zone, H_Z = *(c)(coth A)*

Radius of thawed zone, r_Z = *(c)(csch A)*

$$c = (H_P^2 - r_P^2)^{1/2} = (4^2 - 0.25^2)^{1/2} = 3.99\ \mathrm{ft}$$

$$A = T' \operatorname{arcosh}(H_P / r_P)$$

If $H_P \geq 2r_P$

$$A \cong T' \ln(2H_P / r_P) = (0.366)(3.466) = 1.268$$

H_Z = *(3.99)(coth 1.268)* = (3.99)(1.172) = 4.68 ft

r_Z = *(3.99)(csch 1.268)* = (3.99)(0.5215) = 2.08 ft

The thaw zone, under steady state conditions, will be a cylinder of soil enclosing and parallel to the pipe. The radius of this zone will be 2.08 ft, and the axis will be about 5.2 inches below the bottom of the pipe:

The axis = $H_Z - (H_P + r_P)$ = 4.68 − 4.25 = 0.43 ft = 5.2 inches below pipe

The heat loss (Q) from this pipe would be:

$$Q = \frac{T'_W - T_G}{R'_S}$$

$$R'_S = \frac{\text{arcosh}(H_P/r_P)}{2\pi k_f}$$

If $H_P \geq 2r_P$:

$$R'_S = \frac{\ln(2\,H_P/r_P)}{2\pi k_f}$$

$$R'_S = \frac{\ln[2(4.0/0.25)]}{2(3.14)(1.0)} = 0.552 \text{ hr ft °F/Btu}$$

$$Q = \frac{(39.8 - 27.5)}{0.552} = 22.3\ \frac{\text{Btu}}{\text{hr}}\text{LF of pipe}$$

C-7 EXAMPLE 7

Determine the design time, the safety factor time and the complete freezing time for the pipe designed in Example 4 if the water stopped flowing. From Example 4, assume a 5-inch interior diameter plastic pipe with 2-inches of polyurethane insulation, constructed aboveground. The temperature of the water flowing into the pipe (T_1) is 40°F, the ambient air temperature (T_A) is −40°F, and the wind speed is15 mph. Use equations from Figure 12-1.

Design time equals the time for water in pipe to drop to freezing temperature (32°F); see Figure 12-2 for definition of terms.

$$t_D = \pi r_W^2 RC \, ln\left[\frac{T_1 - T_A}{T_0 - T_A}\right]$$

$$t_D = (3.14)(0.2080)^2(6.306)(62.4)\, ln\left[\frac{40-(-40)}{32-(-40)}\right] = 5.6 \text{ hr}$$

Safety factor time equals the time for water in the pipe to reach nucleation temperature for ice formation. Assume 27°F.

Substitute 27°F for T_2 in previous equation:

$$T_{SF} = (3.14)(0.208)^2(6.306)(62.4)\, ln\left[\frac{40-(-40)}{27-(-40)}\right] = 9.5 \text{ hr}$$

Complete freezing time equals the time for water at 32°F in pipe to freeze completely solid.

$$T_F = \frac{\pi r_W^2 RL}{T_0 - T_A}$$

Where:

L = volumetric latent heat of water

= (144 Btu/lb)(62.4 lb/ft^3)

= 8986 Btu/ft^3

Other factors are as defined above.

Therefore:

$$T_F = \frac{(3.14)\pi(0.208)^2(6.306)(8986)}{32-(-40)} = 107 \text{ hrs}$$

This UFC supersedes UFC 3-190-06, dated 16 January 2004.

FOREWORD

The Unified Facilities Criteria (UFC) system is prescribed by MIL-STD 3007 and provides planning, design, construction, sustainment, restoration, and modernization criteria, and applies to the Military Departments, the Defense Agencies, and the DoD Field Activities in accordance with USD (AT&L) Memorandum dated 29 May 2002. UFC will be used for all DoD projects and work for other customers where appropriate. All construction outside of the United States is also governed by Status of Forces Agreements (SOFA), Host Nation Funded Construction Agreements (HNFA), and in some instances, Bilateral Infrastructure Agreements (BIA). Therefore, the acquisition team must ensure compliance with the most stringent of the UFC, the SOFA, the HNFA, and the BIA, as applicable.

UFC are living documents and will be periodically reviewed, updated, and made available to users as part of the Services' responsibility for providing technical criteria for military construction. Headquarters, U.S. Army Corps of Engineers (HQUSACE), Naval Facilities Engineering Systems Command (NAVFAC), and Air Force Civil Engineer Center (AFCEC) are responsible for administration of the UFC system. Defense agencies should contact the preparing service for document interpretation and improvements. Technical content of UFC is the responsibility of the cognizant DoD working group. Recommended changes with supporting rationale may be sent to the respective DoD working group by submitting a Criteria Change Request (CCR) via the Internet site listed below.

UFC are effective upon issuance and are distributed only in electronic media from the following source:

- Whole Building Design Guide web site http://www.wbdg.org/ffc/dod.

Refer to UFC 1-200-01 for implementation of new issuances on projects.

UNIFIED FACILITIES CRITERIA (UFC)
REVISION SUMMARY SHEET

Document: UFC 3-190-06, *Protective Coatings and Paints*

Superseding: UFC 3-190-06, dated 16 January 2004

Description: This UFC provides requirements and technical guidance for the effective use of paint-type coatings to protect metal, concrete, gypsum board, and wooden structures at military activities from deterioration. This UFC applies to all Navy, Air Force, and Army service elements and contractors.

Reasons for Document:

- This version updates the current UFC documents from a MIL-HDBK to the current requirements for a UFC and updates technologies to the latest industry standards for surface preparation and coatings.

Impact:

- The requirements in this version should not impact initial cost for coatings and paints; however, the requirements should have a positive impact on life cycle costs through extended life of the coatings.

Unification Issues

In addition to OSHA standards for these topics, the Navy adheres to an additional set of OPNAVINST policies for safety and health issues.

TABLE OF CONTENTS

TABLES

CHAPTER 1 INTRODUCTION

1-1 PURPOSE AND SCOPE.

UFC 3-190-06 provides requirements and technical guidance for the effective use of paint-type coatings to protect common materials such as metal, concrete, pavements, gypsum board and wooden structures at military activities from deterioration. The words "paint" and "coating" are used interchangeably in this UFC. In the industry, the word "paint" is sometimes used to describe an architectural coating material while “coating” describes a protective “industrial” coating material.

1-2 APPLICABILITY.

This UFC applies to all Navy, Air Force, and Army service elements and contractors. All other DoD and Government agencies may also use this UFC unless explicitly directed otherwise. This UFC does not cover painting of ships, aircraft, or motor vehicles.

1-3 GENERAL BUILDING REQUIREMENTS.

Comply with UFC 1-200-01. UFC 1-200-01 provides applicability of model building codes and government unique criteria for typical design disciplines and building systems, as well as for accessibility, antiterrorism, security, high performance, and sustainability requirements, and safety. Use this UFC in addition to UFC 1-200-01 and the UFCs and government criteria referenced therein.

1-3.1 Environmental Severity Classifications and Humid Locations.

Provide paints and coatings that are durable and minimize the need for preventative and corrective maintenance over the expected service life of the component or system. Different materials will be used based on local environmental conditions. UFC 1-200-01, section titled “Corrosion Prone Locations” identifies corrosive environments and humid locations requiring special attention. Corrosive environments, which require additional corrosion protection, are those project locations which have an Environmental Severity Classification (ESC) of C3, C4 or C5. To determine ESC for specific project locations, refer to UFC 1-200-01 Appendix titled “Environmental Severity Classifications (ESC) for DoD Locations”. Humid locations are those in ASHRAE climate zones 0A, 1A, 2A, 3A, 3C, 4C, and 5C (as identified in ASHRAE 90.1).

1-4 GLOSSARY.

Appendix B includes acronyms and definitions of terms used in this document.

1-5 REFERENCES.

Appendix C contains a list of references used in this document. The publication date of the code or standard is not included in this document. Unless otherwise specified, the most recent edition of the referenced publication applies.

This Page Intentionally Left Blank

CHAPTER 2 SURFACE PREPARATION

2-1 INTRODUCTION.

Prior to coating application, prepare the surface as required by the project UFGS and as recommended by the coating manufacturer. In case of conflict between the two, use the more stringent requirement. Surface preparation includes:

- Treat and repair surface irregularities including cracks, holes, sharp edges, weld spatter, and other defects that may lead to premature coating failure.
- Remove visible and non-visible surface contaminants (such as mill scale, oil, grease, salts and dirt) and deteriorated substrate surface layers (such as rust, chalk, and sunlight-degraded wood) that hinder coating adhesion.
- Produce a surface profile (texture) that promotes tight adhesion of the primer to the substrate.

2-1.1 Selection Factors.

Determine the type and degree of surface preparation based on these factors:

- Type of substrate
- Surface condition
- Type of exposure (service conditions)
- Desired life of the coating or structure
- Coating to be applied
- Environmental constraints
- Aesthetic requirements
- Desired finish
- Life-cycle cost considerations

2-1.2 Specification Procedure.

Use an industry surface preparation standard applicable to and compatible with the material, existing surface condition, and the selected coating. If an industry standard is not available, provide a performance-based requirement to achieve an acceptable level of surface preparation for the applied coating. Surface preparation methods and associated standards are summarized in Table 2-1.

Table 2-1 Commonly Used Methods of Surface Preparation for Coatings

(IMPORTANT NOTE: Methods may require modification or special control when existing paint or coating contains lead, cadmium, chromium, or other hazardous materials. For Navy projects, refer to UFC 3-810-01N Navy and Marine Corps Environmental Engineering for Facility Construction.)

Cleaning Method	Equipment/Standard	Comments
Organic solvent	Solvents and applicators such as mineral spirits, sprayers, and rags SSPC-SP 1	Removes oil and grease not readily removed by other methods. Take precautions to avoid fires and environmental contamination. Local VOC regulations may restrict use.
Water cleaning with or without detergent or emulsion type cleaners / power washing	Pumps, chemicals, sprayers, brushes SSPC-SP 1	At pressures not exceeding 2,000 psi (14MPa), removes soil, chalk, mildew, grease, and oil, depending upon composition. Good for smoke, stain, chalk, and dirt removal.
Acid	Chemicals, sprayers, and brushes SSPC-SP 1	Removes residual efflorescence and laitance from concrete after dry brushing. Thoroughly rinse to remove acid cleaners.
Chemical paint strippers	Chemicals, sprayers, scrapers, washing equipment No standard	Remove coatings from most substrates, but can be slow, messy, and expensive. May degrade surface of wood substrates. Refer to SSPC-TU 6, Chemical Stripping of Organic Coatings from Steel Structures.
Steam	Heating system pump, lines, and nozzles SSPC-SP 1	Removes heavy oil, grease, and chalk. Usually used prior to other methods.
Low-pressure water cleaning	Low pressure water pumps, lines, and nozzles SSPC-SP 1	At pressures of 2,000 psi to 5,000 psi (14 MPa to 34 MPa), may remove loose paint from steel, concrete, and wood. Can damage wood or masonry unless care is taken. Flash rusting of steel may occur.

High-pressure water cleaning	High pressure water pumps, lines, and nozzles SSPC-SP 1	At pressures of 5,000 psi to 10,000 psi (34 MPa to 70 MPa), removes loose paint from steel, concrete and wood. Can damage wood or masonry unless care is taken. Flash rusting of steel may occur.
Hand tool	Wire brushes, chipping hammers, and scrapers SSPC-SP 2	Removes only loosely adhering contaminants. Used mostly for spot repair. Slow and inconsistent.
Power tool	Wire brushes, grinders, sanders, needle guns, and rotary peeners SSPC-SP 3 SSPC-SP 15 SSPC-SP-11	Faster and more thorough than hand tools because tightly adhering contaminants can be removed. Some tools give a near-white condition on steel but not an angular profile. Slower than abrasive blasting. Some tools are fitted with vacuum collection devices.
Heat	Electric heat guns No standard	Can be used to soften coatings on wood, masonry, or steel. Softened coatings are scraped away. DO NOT use torches.
Shot blasting	Metal shot propelled onto concrete floor by centrifugal force SSPC-SP 13 / NACE No. 6	Can be used to prepare concrete floors for coating. Used to remove laitance and other unsound cementitious material and to provide appropriate surface profile.
Waterjetting	High and Ultra High pressure water pumps, lines, and nozzles SSPC-SP WJ-1 / NACE WJ-1 SSPC-SP WJ-2 / NACE WJ-2 SSPC-SP WJ-3 / NACE WJ-3 SSPC-SP WJ-4 / NACE WJ-4	At pressures above 10,000 psi (70 MPa), removes all oil, grease, and paint. Generally used to remove paint and prepare steel and concrete surfaces. Specify allowable degree of steel flash rusting.

Abrasive blasting	Sand, metal shot, and metal or synthetic grit propelled onto metal by pressurized air, with or without water or centrifugal force SSPC-SP 5 / NACE No. 1 SSPC-SP 6 / NACE No. 3 SSPC-SP 7 / NACE No. 4 SSPC-SP 10 / NACE No. 2 SSPC-SP 16 SSPC-SP 17 SSPC-SP 5 (WAB) / NACE WAB-1 SSPC-SP 6 (WAB) / NACE WAB-3 SSPC-SP 7 (WAB) / NACE WAB-4 SSPC-SP 10 (WAB) / NACE WAB-2 SSPC-SP CAB-1 SSPC-SP CAB-2 SSPC-SP CAB-3	Typically used on metal and, with care, on masonry and soft metals such as aluminum, copper, and galvanizing. Recyclable abrasives can be used. Special precautions are needed when removing lead containing paint. Water may be added to control dust but may require use of inhibitors. Vacuum blasting reduces dust but is slower. Centrifugal blasting is a closed cycle system in which abrasive is thrown by a spinning vane wheel but is typically limited to shop application. Softer, lower density abrasives such as corn cobs, walnut shells, sodium bicarbonate, and plastics may be used but they do not produce a profile. They are primarily used for cleaning purposes such as decal removal from painted surfaces, paint removal from soft metals, or smoke cleanup after a fire.

2-2 TREATMENT AND REPAIR OF SURFACE IRREGULARITIES.

Repair surfaces before recoating. Replace or repair rotten wood, broken siding, and other deteriorated substrates prior to maintenance painting. Repair water-associated problems, such as deteriorated roofs and nonfunctioning drainage systems, and spaces with inadequate ventilation prior to coating. Repair cracks, holes, and other defects prior to painting.

Areas in need of repair can sometimes be identified by associated, localized paint failures. For example, localized peeling paint confined to a wall external to a bathroom may be due to inadequate venting of the bathroom.

2-2.1 Joints, Cracks, Holes, or Other Surface Defects.

Fill joints, cracks, holes, and other surface defects to create a sound substrate with an acceptable texture. Use materials which are compatible with the specified coatings.

Use caulks and sealants to fill joints and cracks in wood, metal and, in some cases, in concrete and masonry. Use putty to fill holes in wood. Use specially formulated Portland cement materials in cracks and over spalled areas in concrete. Some of these contain organic polymers to improve adhesion and flexibility. Use patching plaster to repair large areas of interior plaster, spackle to repair cracks and small holes in wallboard, and joint cement to fill joints between wallboards and repair mortar. Before application of these repair materials, ensure surfaces are clean, dry, free of loose material, and primed according to the written instructions of the material manufacturer.

2-2.2 Cementitious Surfaces.

For concrete repair, use epoxy resin systems that meet ASTM C 881. Select the appropriate material based on application and working temperature.

2-2.3 Steel.

Require removal of accumulated dirt, trash, rust scale, pack rust ,and debris prior to or in conjunction with cleaning and surface preparation operations. Use NACE SP0178 to specify degree of surface imperfection repair for critical applications. This may include removal of slag, flux deposits, weld spatter, and burrs. Use SSPC-Guide 11 to specify edge treatment for critical applications. This may include rounding sharp edges such as those created by flame cutting and shearing by grinding. The rolled edges of angles, channels, and wide flange beams do not normally require further rounding unless specifically required.

2-3 SURFACE PREPARATION.

Select the proper surface preparation method based on the substrate to be coated, condition of the substrate, and the coating to be applied. Appendix A-1 identifies best practices associated with methods of surface preparation. Grease and oil are usually removed by solvent cleaning or steam cleaning, and mildew is killed and removed with a hypochlorite (bleach) solution, as described in Appendix A.

2-3.1 Wood.

Ensure wood surfaces are dry and clean before painting. New treated lumber may require an extended time to dry. Do not expose bare wood to direct sunlight for more than two weeks before priming. Sunlight causes photodegradation of surface wood-cell walls. This results in a cohesively weak layer on the wood surface which may fail when painted. If exposed, remove this layer by sanding prior to painting. Failure of paint caused by a degraded-wood surface is suspected when wood fibers are detected on the backside of peeling paint chips.

2-3.1.1 Existing Intact Paint.

When the existing paint is intact, clean the surface with water, detergent, and bleach as needed to remove surface contaminants, such as soil, chalk, and mildew. Remove loose paint by hand scraping when the existing paint is peeling and does not contain lead. Feather paint edges by sanding. Power sanding may damage the wood if improperly done. Water and abrasive blasting are not recommended for wood, because these techniques can damage the wood. When lead paint is present, use special precautions such as wet scraping.

2-3.1.2 Removal of Existing Paint.

Remove paint from wood when failure is by cross-grain cracking (that is, cracking perpendicular to the wood grain). This failure occurs when the total paint thickness is too thick or the paint is too inflexible. Painting over this condition almost always results in early failure of the maintenance paint layer. Paint removal from wood is difficult and may not always be feasible. Chemical strippers can be used, but the alkaline types may damage (chemically degrade) the surface of the wood and cause a future peeling-paint failure. Failure caused by a stripper-degraded wood surface is more likely for exterior exposures than for interior exposures. This is because the greater expansion and contraction of wood in exterior exposures requires that the surface wood have a greater mechanical strength.

2-3.2 Concrete/Masonry.

Prepare concrete and masonry surfaces to an appropriate class of surface preparation as described in SSPC-SP CAB-1, SSPC-SP CAB-2, SSPC-SP CAB-3, or SSPC-SP 13/NACE No. 6. Bare concrete and masonry surfaces, as well as painted surfaces, are usually best cleaned with water and detergent. Use low-pressure washing (less than 2,000 psi [14MPa]) or steam cleaning (ASTM D4258) to remove loose surface contaminants from surfaces. Use low-pressure water cleaning (2,000 psi to 5,000 psi [14 MPa to 34 MPa]) (ASTM D4259) to remove loose old coatings, other more tightly held contaminants, or chalk. If existing paints contain lead, special worker safety and environmental controls will be needed.

Abrasive blasting (ASTM D4259 and ASTM D4261) or acid etching of bare surfaces (ASTM D4260) may also be used to obtain a surface profile as well as to clean surfaces for coating. Avoid damaging surfaces with high-pressure water or abrasives. Remove grease and oil with detergents or steam before abrasive blasting or acid etching. First, remove any efflorescence present by dry wire brushing or acid washing. Special worker safety and environmental controls may be needed.

2-3.2.1 Testing for Moisture Content.

Concrete surfaces must be free of standing water prior to paint application. Concrete that appears dry can absorb and transfer ground moisture. Moisture vapor emissions can cause failures in non-permeable coatings and flooring systems. For these coatings, perform a moisture vapor emission test at a representative location prior to installing the coating or flooring system.

The plastic sheet method (ASTM D4263) can be used to detect the presence of moisture in concrete. The method involves taping a piece of plastic sheet to the surface and looking for condensed moisture under the sheet after 24 hours. The inside of the sheet should be dry if the moisture content is acceptable. The anhydrous calcium chloride test (ASTM F1869) can be used to determine the Moisture Vapor Emission Rate (MVER) at a point in time and at a specific location.

2-3.3 Steel.

Prepare steel for coating by solvent cleaning as described in SSPC-SP 1. Cleaning methods described in SSPC-SP 1 include organic solvents, vapor degreasing, immersion in appropriate solvent, use of emulsion or alkaline cleaners, and steam cleaning with or without detergents. SSPC-SP 1 is specifically included as the first step in the SSPC surface preparation procedures.

Remove mill scale, rust, and existing coatings by abrasive blasting (SSPC-SP 7, SSPC-SP 6, SSPC-SP 10, SSPC-SP 5) when installing a new coating system on a steel substrate. These methods can both clean the surface and produce a surface profile. The specific abrasive method selected depends upon the conditions of the steel, the desired coating life, the environment, and the coating to be applied. If lead paint is present, take special precautions to protect workers and the environment. Allow high-pressure and ultra-high pressure water jetting, with or without injected abrasives. Prepare the surface using hand tool cleaning (SSPC-SP 2) or power tool cleaning (SSPC-SP 3 or SSPC-SP 11) for localized repair or touch-up of existing coatings.

2-3.3.1 Specific Surface Preparation Requirements for Coatings for Steel.

Different types of coatings require different levels of cleaning. Use the more stringent (highest degree of cleanliness) of manufacturer's written instructions (tech data sheets) or contract specification requirements. Table 2-2 provides typical requirements for use where other guidance is unavailable. In each cell, the surface preparation methods are listed in order of decreasing cleanliness (the highest degree of cleanliness is at the top of the list). For immersion service or ESC C3, C4 and C5 environments, use the higher degree of cleanliness where surface preparation alternatives are provided.

In Table 2-2, “New Coating System,” includes coatings applied to new surfaces and existing uncoated surfaces, and existing coated surfaces made bare by cleaning operations. “Maintenance or Touch-up” refers to work performed on existing coated surfaces or small areas of touch up which is incidental to a new coating system.

Table 2-2 Typical Steel Surface Preparation Requirements for Coatings

Coating	Minimum Surface Preparation	
	New Coating System	Maintenance or Touch-up
Drying Oil	SSPC-SP 3 SSPC-SP 2	SSPC-SP 3 SSPC-SP 2
Alkyd	SSPC-SP 6/NACE No. 3 SSPC-SP 6 (WAB)/NACE WAB-3 SSPC-SP WJ-3 / NACE WJ-3 SSPC-SP 11 SSPC-SP 15	SSPC-SP 3 SSPC-SP 2 SSPC-SP WJ-4 / NACE WJ-4
Asphaltic	SSPC-SP 6/NACE No. 3 SSPC-SP 6 (WAB)/NACE WAB-3 SSPC-SP WJ-3 / NACE WJ-3 SSPC-SP 11 SSPC-SP 15	SSPC-SP 11 SSPC-SP 15 SSPC-SP 3 SSPC-SP WJ-4 / NACE WJ-4
Latex	SSPC-SP 6/NACE No. 3 SSPC-SP 6 (WAB)/NACE WAB-3 SSPC-SP WJ-3 / NACE WJ-3 SSPC-SP 11 SSPC-SP 15	SSPC-SP 11 SSPC-SP 15 SSPC-SP 3 SSPC-SP WJ-4 / NACE WJ-4
Epoxy	SSPC-SP 10/NACE No. 2 SSPC-SP 10 (WAB)/NACE WAB-2 SSPC-SP WJ-2 / NACE WJ-2 SSPC-SP 6/NACE No. 3 SSPC-SP 6 (WAB)/NACE WAB-3 SSPC-SP WJ-3 / NACE WJ-3	SSPC-SP 11 SSPC-SP 15 SSPC-SP 3 SSPC-SP WJ-4 / NACE WJ-4
Polyurethane	SSPC-SP 10/NACE No. 2 SSPC-SP 10 (WAB)/NACE WAB-2 SSPC-SP WJ-2 / NACE WJ-2	SSPC-SP 11 SSPC-SP 15 SSPC-SP WJ-4 / NACE WJ-4
Organic Zinc	SSPC-SP 10/NACE No. 2 SSPC-SP 10 (WAB)/NACE WAB-2 SSPC-SP WJ-2 / NACE WJ-2 SSPC-SP 6/NACE No. 3 SSPC-SP 6 (WAB)/NACE WAB-3 SSPC-SP WJ-3 / NACE WJ-3	SSPC-SP 11 SSPC-SP 15 SSPC-SP WJ-4 / NACE WJ-4
Inorganic Zinc	SSPC-SP 5/NACE No. 1 SSPC-SP 5 (WAB)/NACE WAB-1 SSPC-SP 10/NACE No. 2 SSPC-SP 10 (WAB)/NACE WAB-2	SSPC-SP 11
Metalizing	SSPC-SP 5/NACE No. 1 SSPC-SP 5 (WAB)/NACE WAB-1	SSPC-SP 11

2-3.4 Galvanized Steel or Inorganic Zinc Rich Coated Surfaces.

Clean these surfaces in accordance with SSPC-SP 16.

2-3.5 Aluminum and Other Soft Metals.

Clean aluminum and other soft metals by solvent cleaning (SSPC-SP 1). Use detergents, if necessary, for removal of dirt or loose corrosion products. Abrasive blasting with plastic beads or other soft abrasives may be necessary to remove old coatings. Use SSPC-SP 16 for brush-off blast cleaning of coated and uncoated aluminum and other soft metals. Use SSPC-SP 17 for thorough abrasive blasting of aluminum and other soft metals.

2-3.6 Mildew Removal.

Remove mildew from surfaces prior to painting. Additional requirements can be found in EPA 402-K-01-001.

2-3.7 Job Specific Demonstration.

If a project includes a complex coating system or procedure, require a job-specific mock-up or test patch representative of the completed coating system. The demonstration must represent the quality of work required, use the specified products for the project, and be approved prior to initiating production-scale effort.

2-3.8 Existing Coated Surfaces.

When the surface to be painted is an old weathered coating film (that is, surface preparation will not include removal of the old coating), use ASTM visual standards to evaluate chalk, mildew, and dirt removal. A minimum chalk rating (ASTM D 4214) of 8 is required for chalk removal, a minimum mildew removal rating (ASTM D 3274) of 8 (preferably 10) is required for mildew removal, and an ASTM D 3274 rating of 10 is required for dirt removal. Consider requiring preparation of a job-specific demonstration (as described in 2-3.7) for large jobs. This demonstration will cover removal of loose material, chalk, and mildew, as well as feathering of edges, and other requirements of the contract specification.

2-4 PROCEDURES FOR PAINT REMOVAL.

It is often necessary to remove old coatings that are peeling, checking, cracking, or the like. General recommendations for removal of paint from a variety of substrates are provided in Table 2-3. More detailed Best Practices are provided in Appendix A.

Table 2-3 Procedures for Coating Removal

(IMPORTANT NOTE – Use environmental and worker safety controls when existing paint or coating contains lead, cadmium, chromium, or other hazardous materials. For Navy projects, refer to UFC 3-810-01N Navy and Marine Corps Environmental Engineering for Facility Construction.)

Substrate	Methods
Wood	Chemical paint strippers, low- or high-pressure water cleaning, heat guns or hot plates along with scraping, or power sanding (perform with caution to avoid damaging wood).
Masonry	Acid cleaners, low- and high-pressure water cleaning, waterjetting, shot blasting, brush-off abrasive blast cleaning and power tool cleaning. Exercise caution to avoid undesirable damage to the masonry.
Steel	Abrasive blast cleaning (see Table 2-1), low- and high-pressure water cleaning, water jetting, power tool cleaning, or chemical paint strippers.
Miscellaneous metals	Chemical paint strippers, brush-off abrasive blast cleaning, low- and high-pressure water cleaning, water jetting, and power tool cleaning. Exercise caution to avoid substrate damage.

2-5 PERSONNEL AND CONTRACTOR CERTIFICATION.

Require minimum personnel and company certification requirements for DoD projects. Select more stringent requirements for high performance or complex coating systems, coatings subjected to exceptional service conditions, or installations with an exceptional consequence of failure. In these instances, require personnel meeting the requirements of SSPC-ACS 1/NACE No. 13, and performing contractors with an appropriate Corporate Certification, such as SSPC Painting Contractor Certification Programs (PCCP) or NACE International Institute Contractor Accreditation Program (NIICAP).

CHAPTER 3 SELECTION OF COATINGS

3-1 GENERAL.

Provide paints and coatings that are durable and minimize the need for preventative and corrective maintenance over the expected service life of the component or system. Identify the appropriate coating to be used based on UFC, UFGS, and Master Painters Institute (MPI) requirements. Where conflicts exist, the UFC and UFGS requirements take precedence over MPI. Select appropriate durability and coating system based on the ESC and service environment. Appendix A-2 identifies best practices for selection of coating systems for common substrates. Include surface preparation as a part of the coating system because of its importance in system performance.

3-1.1 Environmental Requirements.

Comply with all applicable Federal, State and local laws and regulations that may pertain to surface preparation and coatings projects. Use MPI products meeting environmental limits for lead, chromate, asbestos, crystalline free silica, and other hazardous materials. Select products with VOC levels that meet Federal, State and local requirements ,as well as UFC 1-200-02. When there is a conflict between Federal, State and local requirements, the more stringent applies; however, at a minimum all coatings must meet the requirements of UFC 1-200-02.

3-1.2 New Surfaces.

Use coating systems that are compatible with the surfaces to which they are applied. Coating incompatibility eventually leads to premature coating failures. Select a coating system based on life-cycle costs. Life-cycle costs include surface preparation, materials, application, necessary maintenance throughout the life of the coating system, disposal costs (waste streams), and environmental impacts. Include costs associated with containment during the removal of old paints and the subsequent disposal of debris that is often considered to be hazardous waste.

3-1.3 Existing Surfaces.

This section applies to existing coated surfaces, existing uncoated surfaces and existing coated surfaces made bare by cleaning operations. Use coating systems that are compatible with the surfaces (substrate and existing coating) to which they are applied. Coating incompatibility eventually leads to premature coating failures. A coating condition survey (CCS) must be accomplished for maintenance coating designs, or to determine if maintenance overcoating is appropriate. At a minimum, the CCS must identify existing coating conditions, analysis of remaining coating life, suitability of overcoating, technical requirements for overcoating, and any other information of interest to the coating system maintenance. Appendix A-3 contains additional information on coating condition surveys.

Select a maintenance approach based on life-cycle costs. Complete replacement of a coating system is typically more expensive than maintenance painting but may provide a substantially longer service life. Life-cycle costs include surface preparation, materials, application, necessary maintenance throughout the life of the coating system, disposal costs (waste streams), and environmental impacts. Include costs associated with containment during the removal of old paints and the subsequent disposal of debris that is often considered to be hazardous waste.

3-2 ARCHITECTURAL FINISHES.

Select durable materials for painting of new and existing, interior and exterior substrates, including masonry, concrete, metal, wood, and other miscellaneous materials from those listed in UFGS 09 90 00.

A Decision Tree that can be used as a guide in selecting Architectural Finishes is available on the MPI website (http://www.specifypaint.com/demo/demo_wbdg.html). Appendix A provides general guidance on coating system selection. Consult with an Army, Navy, or Air Force coatings specialist for applications where the coating will be subjected to exceptional service conditions or there is an exceptional consequence of failure. Note that not all coatings and systems available in MPI are included in the guide specifications. In the event of conflicts between MPI resources and DoD guide specifications, use the paint materials included in the DoD guide specifications.

3-2.1 Coating Selection for Corrosive and Humid Locations

Where available, select more durable coatings for projects located in corrosive environments and humid locations. Some of the coating systems listed in the guide specifications are explicitly for aggressive environments. Corrosive locations are defined in UFC 1-200-01, section titled "Corrosion Prone Locations". For exterior painting of metallic surfaces, corrosive locations include project locations with Environmental Severity Classifications (ESC) of C3 thru C5, or humid locations. For exterior painting of nonmetallic surfaces, corrosive locations are project locations with ESC of C4 and C5, or humid locations. Humid locations are those in ASHRAE climate zones 0A, 1A, 2A, 3A, 3C, 4C and 5C (as identified in ASHRAE 90.1). Interior high humidity areas such as bathrooms, locker rooms, laundry rooms, pools, and trainers are also considered as corrosive locations and require more durable coatings.

When using the MPI resources, such as the MPI Decision Tree, MPI designates systems for “Normal” or Aggressive” service and identifies the coating performance level which the specifier may find helpful when selecting from coating system options. When using the MPI resources, select “Normal” for locations defined as noncorrosive and select “Aggressive” for corrosive locations.

3-2.2 Wooden Floors.

Use the UFGS for paints and coatings for surface preparation (scraping and sanding) and coating of general use wooden floors. Use the appropriate UFGS for gymnasium flooring and other special purpose athletic hardwood floors.

3-3 COATING SYSTEMS FOR SPECIFIC USES.

Use coating systems specifically designed for metal storage tanks, pipelines, towers, waterfront structures, siding, fences, hot surfaces, concrete storage tanks, swimming pools, catchment basins, pavements, concrete floors, and surfaces particularly susceptible to mold and mildew.

3-3.1 Steel Storage Tanks

3-3.1.1 Fuel Storage Tanks.

Use coatings on steel fuel tanks to keep the fuel clean and help prevent leaks resulting from corrosion. Specify internal lining of welded steel petroleum tanks and exterior coating of steel structures as required by UFC 3-460-01. Specify interior cleaning prior to condition assessment of in-service tanks in accordance with applicable UFGS. Specify cathodic protection of fuel storage tanks as required by UFC 3-570-01.

3-3.1.2 Steel Water Tanks.

Specify internal and external coating of welded steel water tanks as required by UFC 3-230-01. Specify cathodic protection of water storage tanks as required by UFC 3-570-01 to supplement the protection afforded by the coatings.

3-3.1.3 Other Steel Tanks.

Use a suitable corrosion-resistant lining (such as fiberglass-reinforced polyester) to protect the interiors of steel tanks containing wastewater, chemicals, or other corrosive liquids from corrosion. Since there are no Federal specifications for such products, consult with protective coating specialists and specialty coating suppliers. Specify exterior coating of steel structures using applicable UFGS. Cathodic protection should be considered for these tanks, but the tanks must be evaluated by a certified Cathodic Protection expert.

3-3.2 Steel Distribution Lines.

Use protective coatings on steel distribution lines containing water, fuel, or other liquids to prevent loss of product from corrosion and contamination of soils and groundwater.

3-3.2.1 Steel Fuel Lines

Protect buried and immersed steel fuel lines using coatings and cathodic protection as required by UFC 3-460-01. Use UFGS 33 52 80 for interior and exterior coating of aboveground and buried, carbon steel, liquid fuel pipelines. Specify cathodic protection as required by UFC 3-570-01 to supplement the protection afforded by the coatings.

3-3.2.2 Steel Water Distribution Lines.

Protect aboveground and buried, carbon steel, steel water distribution lines as required by UFC 3-230-01.

3-3.3 Communication Towers and Other Tall Structures.

Use the UFGS for maintenance, repair, and coating of tall antenna towers. Use marking requirements in Federal Aviation Administration (FAA) Advisory Circular 70/7460-1L.

3-3.4 Waterfront Structures.

Use the UFGS for coating of steel waterfront structures for new construction and maintenance of steel waterfront structures such as “H” piles and sheet piles.

3-3.5 Hydraulic Structures and Appurtenant Works.

Use the UFGS for hydraulic structures for coating items such as locks, gates,and associated pipelines and equipment. Specify cathodic protection when appropriate.

3-3.6 Factory Finished Metal Siding.

Factory-finishing of steel, galvanized steel, or aluminum siding is accomplished by specialized procedures (such as coil coating) using commercial products. Follow the manufacturer recommended coating repair methods.

3-3.7 Hot Steel Surfaces.

Conventional coatings cannot protect mufflers, stacks, and other hot steel. Use specialty coatings selected by the equipment manufacturer for new construction and maintenance.

3-3.8 Concrete Fuel Tanks.

Consult a DoD coatings specialist for maintaining coatings on existing concrete fuel tanks.

3-3.9 Concrete Swimming Pools.

Consult swimming pool operations and maintenance manuals for maintenance painting of interior and exterior swimming pools.

3-3.10 Chemically Resistant Finishes for Concrete Floors.

Use the UFGS for fuel resistive coatings to install chemically resistant coating systems (resistant to fuels and hydraulic fluids). Consult the activity industrial hygienist for coatings on floors where chemicals or hazardous waste is stored.

3-3.11 Fouling-Resistant Coatings.

Antifouling coatings may be used on immersed portions of marker buoys and water cooling pipelines. For marker buoys, follow NAVSEA practices for ship hull antifoulant in NAVSEA Standard Item 009-32, Table One. For water cooling exchange pipelines, follow current industrial practices.

3-3.12 Mildew Resistant Coatings.

Mildewcides in paints are used to control mildew growth in the can and on the paint after application. Abate mildew growth on painted or unpainted surfaces of buildings, repair damaged areas, and clean substrates prior to applying a new or maintenance coating.

3-3.13 Pavement Markings.

Use the UFGS for pavement markings to install markings and applicable products on airfield and road pavements.

This Page Intentionally Left Blank

CHAPTER 4 APPLICATION

4-1 GENERAL.

Review coating suppliers Technical Data Sheets (TDS) or Product Data Sheets (PDS) and Safety Data Sheets (SDS) for each product to be used. Unless otherwise specified, comply with the storage requirements, application instructions, environmental parameters, mixing, curing time, thinning, and film thickness shown on the TDS/PDS.

If thinning is necessary, require a thinner product recommended by the coating manufacturer. Do not exceed the thinner volume recommended by the coating manufacturer or allowed by VOC regulations. Job site tinting is not allowed. The coating manufacturer or certified agent must tint all coatings.

4-1.1 Safety and Environmental Restrictions.

Comply with all applicable Federal, State, and local laws and regulations that may pertain to surface preparation and coatings projects. For Navy projects, refer to UFC 3-810-01N. Air Force components must comply with Air Force Manual (AFMAN) 91-203; in addition, always check with the local Bioenvironmental Department for local requirements. For Army projects, utilize EM 385-1-1 in addition to installation environmental requirements.

4-2 WEATHER CONDITIONS AFFECTING APPLICATION OF PAINTS.

Review the coating manufacturer's technical data sheets to determine if the environmental limits as well as other constraints on application of the paint are readily achieved. Include any extraordinary requirements in the project specifications.

4-3 METHODS OF APPLICATION.

Review the coating manufacturer's technical data sheets to determine if the methods of application are readily achieved. Include any extraordinary requirements in the project specifications.

4-4 PERSONNEL AND CONTRACTOR CERTIFICATION.

UFGS have minimum Contractor certification levels and may have more stringent requirements based on project specifics. Select more stringent requirements for high performance coating systems, complex coating systems, coatings subjected to exceptional service conditions, or installations with an exceptional consequence of failure. In these instances, require personnel meeting the requirements of SSPC-ACS 1/NACE No. 13, and performing contractors with an appropriate Corporate Certification: SSPC Painting Contractor Certification Programs (PCCP) or NACE International Institute Contractor Accreditation Program (NIICAP).

This Page Intentionally Left Blank

CHAPTER 5 INSPECTION OF PAINTING OPERATIONS

5-1 GENERAL.

Inspect painting operations to ensure conformance with the specification requirements. Depending upon the job and the contract requirements, quality-control inspectors may be contractor-supplied (that is, contractor quality control - CQC) or Government personnel. Include clear quality-control technical requirements, reporting requirements, and adjudication processes.

5-2 CONTRACTOR QUALITY CONTROL INSPECTION.

UFGS documents contain minimum quality-control requirements for DOD projects, which may be monitored by the contractor. Require a qualified third-party inspector for high performance or complex coating systems, coatings subjected to exceptional service conditions, or installations with an exceptional consequence of failure.

5-2.1 Duties of an Inspector.

The duties of an inspector include understanding the contract specification requirements, documenting performance of the contract in accordance with the specification, reporting rework requirements, and documenting rework. Keep records during all phases of the job. Records form an important part of the permanent record on each building and provide key information in the case of warranty claims and contract disputes.

5-3 WARRANTY INSPECTION.

Include a warranty inspection requirement for coatings that will be subjected to exceptional service conditions or with an exceptional consequence of failure. The warranty inspection includes a visual inspection of the film, and may involve chalk, film thickness, and adhesion measurements. Any defects found during the warranty inspection must be corrected by the Contractor.

This Page Intentionally Left Blank

APPENDIX A BEST PRACTICES

The Best Practices Appendix is considered guidance and not requirements. Its main purpose is to communicate proven facility solutions, systems, and lessons learned, but may not be the only solution to meet the requirement.

A-1 METHODS OF SURFACE PREPARATION.

Information on surface preparation methods and procedures is presented to help select appropriate general procedures and to inspect surface preparation jobs. It is not intended to be a complete source of information for those doing the work.

A-1.1 Abrasive Blasting.

Abrasive blast cleaning is most often associated with cleaning painted and unpainted steel. It may also be used with care to prepare concrete and masonry surfaces and to clean and roughen existing coatings for painting. Abrasive blasting is an impact cleaning method. High-velocity abrasive particles—driven by air, water, or centrifugal force—impact the surface to remove rust, mill scale, and old paint from the surfaces. Abrasive cleaning does not remove oil or grease. If the surface to be abrasive blasted is painted with lead paint, employ additional controls to minimize hazards to workers and the surrounding environment.

There are five degrees of cleanliness of blast cleaning designated by the SSPC/NACE standards for steel substrates. These designations are white metal, near-white metal, commercial, brush-off, and industrial. Note: Industrial is NOT an acceptable method for DoD components. Acceptable methods are summarized in Chapter 2. The degree of cleanliness obtained in abrasive blasting depends on the type of abrasive, the force with which the abrasive particles hits the surface, and the dwell time.

A-1.1.1 Air (Conventional).

In conventional abrasive blasting, dry abrasive is propelled against the surface to be cleaned so that rust, contaminants, and old paint are removed by the impact of the abrasive particles. Clean the surface of blasting residue before painting. This is usually done by vacuuming the surface. In the past, blowing clean air across the surface was used and termed “blow down”. However, this approach has the side effect of pushing the abrasive media into the substrate. This is especially noticeable in high profile requirements, where a tape test is used to verify the substrate is free of embedded grit and dust. Uncontrolled abrasive blasting is restricted in most locations because of environmental regulations. Consult the local industrial hygiene or environmental office for regulations governing local actions. Procedures for containment of blasting debris are being used for paint removal from industrial and other structures. SSPC has developed a guide (SSPC-Guide 6) for selecting containment procedures depending upon the degree of containment desired. Recycling the abrasive can reduce the amount of debris generated. Recycling systems separate the paint waste from the abrasive.

A-1.1.2 Wet Abrasive Blasting.

Wet-abrasive blasting is used to control the amount of airborne dust. It may be considered when dry abrasive blasting cannot be used due to environmental or worker safety restrictions. There are two general types of wet abrasive blasting. In one, water is injected near the nozzle exit into the stream of abrasive. In the other, water is added to the abrasive at the control unit upstream of the nozzle and the mixture of air, water, and sand is propelled through the hose to the nozzle. For both types of wet blasting, the blasting and rinsing water may contain a corrosion inhibitor if approved by the coating manufacturer. After wet blasting, rinse the surface free of spent abrasive. The surface must be completely dry before coating. When lead paint is present, the water and other debris must be contained and disposed of properly. This waste may be classified as a hazardous waste under Federal and local regulations and must be handled accordingly.

A-1.2 Ultra High Pressure Waterjetting

Waterjetting is an alternative method of removing coating systems or other materials from surfaces prior to the application of a protective coating or lining system. Waterjetting can be effective in removing water-soluble surface contaminants that may not be removed by dry abrasive blasting alone, specifically, those contaminants found at the bottom of pits of severely corroded metallic substrates. Waterjetting also helps to remove surface grease and oil, rust, shotcreting spatter, and existing coatings and linings. Waterjetting is also used in areas where abrasive blasting is not a feasible method of surface preparation.

Waterjetting does not provide the primary anchor pattern on steel known to the coatings industry as “profile.” The coatings industry uses waterjetting primarily for recoating or relining projects in which there is an adequate preexisting profile. Waterjetting has application in a broad spectrum of industries. It is used when high-performance coatings require extensive surface preparation or surface decontamination.

A-1.3 Acid Cleaning.

Acid cleaning is used for cleaning efflorescence and laitance from concrete. Remove heavy efflorescence and laitance from concrete surfaces by dry brushing or cleaning prior to acid cleaning. This is to prevent dissolution of the efflorescence and subsequent movement of the salts into the concrete. Prior to application of an acid solution, remove heavy oil, grease, and soil deposits. Oily dirty deposits can be removed by solvent or detergent washing.

A-1.4 Chemical Removal of Paint.

SSPC-TU 6 (Chemical Stripping of Organic Coatings from Steel Structures) outlines the selection and use of chemical strippers to remove paint. Paint strippers can be used when complete paint removal is necessary; other removal methods cannot be used due to environmental restraints, operational restraints or potential damage to the substrate or surrounding equipment. Removers are selected according to the type and condition of the old coating as well as the nature of the substrate. They are available as flammable or nonflammable types and in liquid or semi-paste types. If paint being removed contains lead, additional environmental and worker safety precautions will be needed. Removers are usually toxic and may be fire hazards. Management of the waste associated with the procedure will also be necessary. Consult the local environmental and safety offices for further information.

A-1.5 Solvent Cleaning.

SSPC-SP 1, Solvent Cleaning, defines solvent cleaning in surface preparation. This standard is included as a first step to other surface preparation standards. This standard defines the end-condition of a metal surface from which visible deposits of oil, grease, and other visible contaminants have been removed in preparation for subsequent application of protective coatings or for the use of additional methods to prepare the surface for the application of coatings. The standard also includes requirements for materials and procedures necessary to achieve and verify the end condition. A “solvent” is defined as any liquid or vapor that will dissolve or emulsify visible deposits of soluble contaminants on the surface. Examples of solvents include water, emulsion, or alkaline cleaners, and hydrocarbons.

A-1.6 Hand Tool Cleaning.

SSPC-SP 2, Hand Tool Cleaning, defines hand cleaning. It is primarily used to remove loose mill scale, loose rust, loose paint, and other loose detrimental material. This approach is more applicable to spot repairs in areas where deterioration is not a serious factor or in areas inaccessible to power tools. Remove grease or oil (SSPC-SP 1) prior to hand tool cleaning. Since hand cleaning removes only the loosest contaminants, select primers that are capable of thoroughly wetting the surface. Paint applied to hand-cleaned, steel surfaces has been shown to reduce longevity when compared to application on better-prepared substrates.

A-1.7 Power Tool Cleaning.

SSPC-SP 3, Power Tool Cleaning, defines power tool cleaning. It is primarily used to remove loose mill scale, loose rust, loose paint, and other loose detrimental material. This approach is more applicable to spot repairs in areas where deterioration is not a serious factor. This approach can be used to remove more tightly adhering contaminants and existing paint than hand tool cleaning. SSPC-SP 11 defines a cleanliness level comparable to SSPC-SP 10/NACE No. 2. Some power tools can be used to achieve an anchor profile comparable to abrasive blasting but not as deep. As with other surface preparation methods, remove grease, oil and other contaminants prior to power tool cleaning.

A-1.8 Non-Standard / Non-Traditional Surface Preparation Methods.

Surface preparation methods may be used on substrates not intended by a standard or design of the method. A SSPC Protective Coatings Specialist must be involved in the selection and use for industrial type substrates. For commercial / architectural applications consult MPI Level Two A for new construction or MPI Level Two B for repainting / maintenance.

A-1.9 Mildew Removal.

When a surface is to be cleaned for repainting, scrub with a solution of 2/3 cup (0.16 L) of trisodium phosphate (TSP), 1 liquid ounce of household detergent, 1 quart (0.95L) of 5-1/4 percent sodium hypochlorite (available as household bleach), and 3 quarts (2.8L) of warm water. Use rubber gloves with this caustic solution and rinse it from the surface with water after scrubbing. It will degrade alkyd and other oil-based coatings, but this will be no problem if the surface is to be repainted. An alternate procedure is to remove all the visible mildew by water cleaning at about 700 psi (5 MPa) at the nozzle and kill the rest by rinsing with a solution of 1 quart (0.95L) of 5-1/4 percent sodium hypochlorite and 3 quarts (2.8L) of warm water. If a painted surface is to be merely cleaned without repainting, apply the scrubbing solution without the TSP to avoid damage to the paint. Apply it first to a small test area to see if the hypochlorite bleaches the paint. If the TSP solution causes any damage, clean with detergent and water only.

Mildew on field structures can be distinguished from dirt with bleach. Common household hypochlorite bleach will cause mildew, but not dirt, to whiten.

A-1.10 Methods for Repairing Surface Defects.

A-1.10.1 Caulking and Sealant Compounds.

Caulking and sealant compounds are resin-based ,viscous materials. These compounds tend to dry on the surface but stay soft and tacky underneath. Sealants have application properties similar to caulking materials but tend to be more flexible and have greater extendibility than caulks. Sealants are often considered more durable than caulks and may be more expensive. Commonly available generic types of caulks and sealants include oil-based, butyl rubber, acrylic latex, silicone, polysulfide, and polyurethane. The oil-based and butyl-rubber type are continually oxidized by exposure to sunlight and become brittle on aging. Thus, their service life is limited. Acrylic-latex and silicone caulks tend to be more stable and have longer service lives. NOTE: Unless formulated for painting, silicone caulks will not hold paint. Applications are usually made with a caulking gun. However, some of these materials may also be available as putties or in preformed extruded beads that can be pressed in place.

A-1.10.2 Putty and Glazing Compounds.

Putty and glazing compounds are supplied in bulk and applied with a putty knife. Do not use putties for joints and crevices that require flexible fillers. Glazing compounds set firmly, but not hard, and thus retain some flexibility. Use acrylic-latex paints, such as MPI’s “Exterior Latex” series (MPI 10 – flat, MPI 11 – semigloss or MPI 119 – gloss) over flexible caulking, sealing, and glazing compounds.

A-2 COATING SYSTEMS FOR COMMON SUBSTRATES.

This section provides general recommendations for wood, concrete and masonry, steel, galvanized steel, and aluminum surfaces. A decision tree that can be used as a guide in selecting architectural finishes is available on the Whole Building Design Guide (WBDG) website (http://www.specifypaint.com/demo/demo_wbdg.html).

A-2.1 Recommendations for Wood.

Oil-based coatings (alkyds), waterborne coatings (acrylic emulsions and latex), and stains perform well on wood. A two-coat system consisting of either a paint or stain is typically sufficient. However, as overcoats are applied to resurface or repair weathered paint, the system’s film thickness may become too thick, resulting in the disbonding of the total paint system. Generally, no more than three or four overcoats of new paint will be applied to an existing system. Once this build-up occurs, remove some or all of the existing system prior to application of a new coating system.

Surface preparation of new wood generally consists of a light sanding with special care taken to not damage the wood. Sanding is also appropriate for preparing weathered surfaces for refinishing and for spot repairing areas of localized damage.

A-2.1.1 Oil-Based Paints.

Wood has been successfully painted with oil-based products that penetrate the surface well. These coatings are very easy to apply.

A-2.1.2 Water-Emulsion Paints.

Latex coatings are very effective in providing attractive, protective finishes. They are also less affected by moisture than are oil-based finishes and are generally more flexible and thus less susceptible to cracking as the wood swells and contracts with moisture changes.

A problem sometimes arises when repairing or top coating existing smooth alkyd coatings with latex paints. To obtain good intercoat adhesion, it may be necessary to lightly abrade the existing paint, wipe down, and apply a suitable primer (sometimes called a “transition” or “universal” primer) before applying the first coat of latex paint.

A-2.1.3 Semi-Transparent Stains.

Because oil-based and waterborne paints form continuous films, they may form blisters or disbond because of moisture in the wood attempting to escape. Semi-transparent stains do not form continuous films on wood and so do not have this problem. Thus, they are a good alternative on new wood. However, additional coats applied over the years or heavy-bodied stains will form continuous films.

A-2.1.4 Clear Floor Finishes.

Varieties of clear floor finishes are available for hardwood floors. UFGS documents contain detailed requirements for hardwood floors used in gymnasiums and other applications.

A-2.2 Recommendations for Concrete and Masonry Surfaces.

Concrete and masonry surfaces, as well as those of stucco, plaster, wallboard, and brick, can be coated with a variety of systems depending upon the desired purpose and appearance.

Surface preparation is usually accomplished by power washing with an aqueous detergent solution to remove dirt and other loose materials. Remove any oil or grease by solvent or steam cleaning; any mildew, by scrubbing with bleach; and any efflorescence or laitance, by brushing followed by acid treatment.

A-2.2.1 Waterborne Coatings.

A two-coat waterborne (latex) system provides an attractive breathing film that is normally less affected by moisture in the concrete than non-breathing systems. The latex material is a self-primer in this service, unless otherwise stated. Do not apply alkyd and other oil-based coatings directly to concrete or masonry surfaces, because the alkalinity in the concrete will hydrolyze (breakdown) the binder and cause the coating to peel. However, they can be applied over concrete or masonry surfaces primed with waterborne coatings to produce a tougher, more washable finish.

A-2.2.2 Elastomeric Coatings.

Elastomeric, waterborne acrylic coating systems perform well to seal and protect concrete/masonry surfaces and are normally very low in VOCs. They can successfully bridge fine or larger caulked cracks.

A-2.2.3 Textured Coatings.

Textured coating systems can bridge fine cracks and waterproof from wind-driven rain. They are normally applied over a primer recommended by the supplier to ensure good adhesion. They are available in a variety of textures and may be waterborne, oil or rubber-based products with a VOC limit of 250 grams per liter.

A-2.2.4 Epoxy Coatings.

A two-coat epoxy system will seal and protect concrete/masonry surfaces well. An aliphatic urethane finish coat should be used rather than the second epoxy coat on exterior surfaces to improve the weatherability.

A-2.2.5 Linseed Oil

Linseed oil is effective for sealing, waterproofing and anti-spall protection of concrete where freezing temperatures may cause damage. It is used on roads, bridge decks, sidewalks, curbs, parking ramps, floors, walkways, and other such concrete construction.

A-2.3 Recommendations for Steel.

High-performance coating systems are recommended to prolong the service life of steel structures before it becomes necessary to remove and replace it. Costs for coating maintenance on existing structures can be very high, especially where there are restrictions on abrasive blasting.

Abrasive blasting is always preferred to alternative methods of preparing steel surfaces for painting. It cleans the steel and provides a textured surface to promote good primer adhesion. A commercial blast (SSPC-SP 6/NACE No. 3) is normally adequate for alkyd and epoxy primers for a moderate environment such as interior exposures. A near-white blast (SSPC-SP 10/NACE No. 2) is required for epoxies, including zinc-rich epoxies, exposed to a severe environment such as exterior, marine atmospheric or water or fuel immersion. Some manufacturers may specify a white metal blast (SSPC-SP 5/NACE No. 1) for particular coatings for special applications. It is important that a contract specification does not conflict with the coating manufacturer's written directions. Inorganic zinc-rich primers require a white metal surface with a sharp angular surface profile. Few power tools provide this type of surface. If abrasive blasting cannot be done, then power tool cleaning to bare metal (SSPC-SP 11) can be specified with the additional requirement for an angular profile having a depth meeting the requirements of the coating manufacturer. Hand tool cleaning (SSPC-SP 2) or power tool cleaning (SSPC-SP 3) should not be specified for inorganic zinc primers.

A-2.3.1 Alkyd Systems.

In the past, most military steel structures with atmospheric exposures were coated with an alkyd or other oil-based system. On new painting, they are being replaced in significant part by epoxy systems that provide longer protection. Alkyd systems, however, might still be used for repairing old deteriorated alkyd systems. Alkyd coatings must never be applied directly to concrete or zinc-rich surfaces such as zinc-rich coatings, galvanizing, or zinc containing alloys (to name a few).

A-2.3.2 Epoxy Coating Systems.

A three-coat epoxy system provides good interior service in harsh and moderate environments. An aliphatic urethane finish system is used in place of the third epoxy coat in exterior service to provide greater resistance to deterioration by ultraviolet light. Newer topcoats include Fluorinated Aliphatic Polyurethanes, which provide much better resistance to UV and promise to at least double the life of previous systems. Several different epoxy mastic systems, some aluminum-filled, have been used successfully on steel structures.

A-2.3.3 Zinc-Rich Coatings.

Organic and inorganic zinc-rich coatings can provide good protection from corrosion and abrasion. Inorganic zinc-rich coatings perform well without topcoats in a variety of environments except acidic or alkaline. Inorganic zinc-rich coatings may be topcoated with an acrylic latex finish coat to provide a variety of color finishes or a color pigmented coating of the inorganic zinc-rich coating without the zinc. Epoxy (for interior) or epoxy and aliphatic urethane (for exterior) topcoats may also be used for both types. Localized repair of inorganic zinc systems is usually accomplished with a zinc-rich organic coating to permit good bonding to any exposed steel, inorganic coating, or organic topcoats.

A-2.4 Recommendations for Galvanized Steel.

Galvanized steel corrodes very slowly in moderate environments but may be painted with organic coating systems to provide color or additional corrosion protection, particularly in severe environments. It should never be coated directly with an alkyd paint because the alkalinity on the surface of the galvanizing will hydrolyze the oil in the binder, degrading the binder, and cause paint peeling.

New galvanized steel should be solvent- or steam-cleaned (SSPC-SP 1, Solvent Cleaning) to remove all grease and oil before coating. Older, untopcoated galvanizing should be power-washed to remove any dirt or loose zinc corrosion products. Remove loose coatings by power-washing or scraping and sanding to produce a clean, sound surface. Remove rust by waterjet cleaning to SSPC-SP WJ-2/NACE WJ-2 or SSPC-SP WJ-1/NACE WJ-1 per coating manufacturer requirements or by careful abrasive blasting in accordance with SSPC-SP 16 to limit the removal of galvanizing.

A-2.4.1 Epoxy Systems.

Two coats of epoxy will provide long-term protection to galvanizing in interior service, as will one coat of epoxy and one coat of aliphatic urethane in exterior service. NOTE: Avoid abrasive blasting or waterjet cleaning of light gauge metals / substrates such as sheet metal. The high velocity behind these methods can warp the substrate.

A-2.4.2 Waterborne System.

Two coats of latex paint will provide a pleasing appearance and good protection to galvanized steel in moderate environments.

A-2.5 Recommendations for Aluminum.

Aluminum surfaces corrode very slowly in moderate environments. They may be coated to provide color or additional protection, particularly in severe environments. Epoxy and epoxy/urethane systems perform well in interior or exterior service, respectively. Alkyd systems usually require surface pretreatments containing toxic materials.

Because aluminum surfaces are relatively soft, they should not be cleaned by blasting with conventional abrasives or grinding to avoid damage. Remove grease or oil by solvent or steam cleaning (SSPC-SP 1). Remove dirt and other loose contaminants by power washing. Existing coatings are best removed by careful abrasive blasting in accordance with SSPC-SP 16. Alkaline strippers must never be used; they will attack the aluminum.

A-2.5.1 Epoxy Systems.

Two coats of epoxy will provide long-term protection to aluminum in interior service, as will one coat of epoxy and one coat of aliphatic urethane in exterior service. NOTE: Avoid abrasive blasting or waterjet cleaning of light gauge metals / substrates such as sheet metal. The high velocity behind these methods can warp the substrate.

A-2.5.2 Waterborne System.

Two coats of latex paint will provide a pleasing appearance and good protection to aluminum in moderate environments.

A-3 COATING CONDITION SURVEYS (CCS).

A-3.1 Purpose.

The term "maintenance coating" may include overcoating of existing coated surfaces or coating of existing coated surfaces made bare by cleaning operations. The risks of overcoating can usually be avoided by designing project to remove all existing coatings to bare metal, then providing appropriate surface preparation and coating application. However, the extra costs of the coating removal, especially if containing hazardous material, along with the cost of surface preparation to SSPC-SP 10 Abrasive Blast to Near-White Metal, may be exorbitant compared to the costs of maintenance overcoating where the existing coating system is in fair-to-good condition. For maintenance coating design, or to determine if overcoating is appropriate, a coating condition survey should be accomplished.

Note that the aesthetic features of a coating do not define the coating condition; they only describe how the coating looks. Many coating systems have been replaced when only the topcoat needs "refurbishment." Likewise, many structures such as water tanks and fuel tanks have had complete coating replacement when only the roof coating needed replacement. A CCS can identify the weak components as well as the satisfactory components and propose solutions to make maximum use of existing resources.

A-3.2 Scope of Survey.

The scope of the CCS should be tailored to the specific project, and it should be recognized that while multiple coating failures or deficiencies may look similar, the risks of generalizing to save evaluation costs are potentially very high. The cost of large-scale overcoating failure and subsequent replacement of the coating system is far more than the cost of a CCS for all but the smallest projects.

The CCS should be accomplished by personnel from a business that routinely performs coating evaluations, and the individual investigator should be certified by SSPC as a

Protective Coatings Specialist. The CCS should be sufficiently detailed to provide all technical information about the coatings, and structures to be coated, required to properly design the project. At a minimum, the CCS should provide a detailed report of:

- Existing coating conditions, including condition of coating film, and the existence of potentially hazardous substances that may impact coating management (such as lead, cadmium, chromium);
- Analysis of remaining coating life, suitability of overcoating, and technical requirements for overcoating;
- Technical recommendations for the most cost-effective maintenance of existing coating systems, including any hazardous materials present in paint film; and
- Any other information of interest to the coating system maintenance that should be identifiable by an individual trained and experienced in the field of coating analysis, coating failure analysis, and coating design.

A-3.3 Lead and Other Hazardous Materials.

The requirements for removal and disposal of coatings which contain lead are provided in UFGS 02 83 00 and UFGS 09 97 02. Additional guidance is provided in SSPC-Guide 6 and SSPC-Guide 7.

A-3.4 Other CCS Uses.

Activities should consider an annual CCS to survey all structures to be authorized for design in the coming year. When accomplished for multiple projects, the per-structure cost will decrease. By accomplishing this survey prior to design, the basis for design is fully identified.

The CCS can also be a very useful tool when used to screen structures for maintenance painting requirements. A CCS can be scoped to provide a general inspection of many structures to screen for near-term overcoating or recoating requirements. If necessary, a subsequent investigation can provide appropriate details for project planning and design.

A-3.5 CCS Guidance Document.

SSPC Technology Update SSPC-TU 3 Maintenance Overcoating should be used as a guide for scoping the CCS, for accomplishing the CCS, and for designing the coating work.

A-4 LIFE CYCLE COST CONSIDERATIONS FOR COATINGS.

A-4.1.1 Opportunity When Coating New Structures.

The designer of the first coating system for a new fuel tank, pipeline or other constructed facility has the unique opportunity to specify a system that can provide the best life-cycle performance service. Often the coating system—surface preparation, priming and in some cases application of the complete coating system—can be carried out in a shop environment where the environmental and application parameters can be controlled. Whether shop- or field-applied, by controlling the various coating task application conditions, the surface can be very well prepared and the film properties obtained after curing are optimum. Since the cost difference of the "best" materials may not be much greater than the cost of "poor" materials, the use of these materials must be evaluated on a life-cycle performance basis when selecting the coating system if lower cost coating systems are being considered. Maintenance painting is always more difficult and costlier than shop painting ,and frequent maintenance painting on constructed facilities may interfere unacceptably with the mission of the structure. Thus, high-performance systems provide the optimum life-cycle performance and the appropriate high-performance system must always be specified on new construction or maintenance applications.

B-2 DEFINITION OF TERMS

Coating: (1) A liquid, liquefiable, or mastic composition that is converted to a solid protective, decorative, or functional adherent film after application as a thin layer [ASTM D 16]; (2) Generic term for paint, lacquer, and enamel (from SSPC Glossary)

Corrosion: The deterioration of a material or its properties due to a reaction of that material with its chemical environment. (from 10 USC §2228(f))

Corrosion prone locations: Locations with one or more of the following characteristics (1) Exterior exposed metallic elements at a location with an ESC of C3, C4, or C5, (2) Exterior exposed nonmetallic elements at a location with an ESC of C4 or C5, (3) Locations where microenvironmental factors (for example, prevailing winds, ventilation, waterfront environments, industrial emissions, deicing salt application, possible chemical splash/spillage, adverse weather events such as flooding or wind-driven rain, and penetrations of the building envelope) may create a locally corrosive environment regardless of ESC, (4) Humid locations identified in ANSI/ASHRAE/IES 90.1 as climate zones 0A, 1A, 2A, 3A, 3C, 4C, and 5C, and (5) High humidity interior areas (for example, bathrooms, locker rooms, laundry rooms, pools, and trainers).

Environmental Severity. Describes the corrosivity of the local environment of a given location or region.

Environmental Severity Classification (ESC): A classification of geographical macro environments developed by DoD based on the International Standards Organization Corrosivity Classification Method. Additional details are available at https://www.wbdg.org/ffc/dod/cpc-source/environmental-severity-classification.

Paint: (1) Any pigmented liquid, liquefiable, or mastic composition designed for application to a substrate in a thin layer that is converted to an opaque solid film after application. Used for protection, decoration, identification, or to serve some other functional purposes; (2) Application of a coating material. (from SSPC Glossary)

FOREWORD

The Unified Facilities Criteria (UFC) system is prescribed by MIL-STD 3007 and provides planning, design, construction, sustainment, restoration, and modernization criteria, and applies to the Military Departments, the Defense Agencies, and the DoD Field Activities in accordance with USD (AT&L) Memorandum dated 29 May 2002. UFC will be used for all DoD projects and work for other customers where appropriate. All construction outside of the United States is also governed by Status of Forces Agreements (SOFA), Host Nation Funded Construction Agreements (HNFA), and in some instances, Bilateral Infrastructure Agreements (BIA). Therefore, the acquisition team must ensure compliance with the most stringent of the UFC, the SOFA, the HNFA, and the BIA, as applicable.

UFC are living documents and will be periodically reviewed, updated, and made available to users as part of the Services' responsibility for providing technical criteria for military construction. Headquarters, U.S. Army Corps of Engineers (HQUSACE), Naval Facilities Engineering Systems Command (NAVFAC), and Air Force Civil Engineer Center (AFCEC) are responsible for administration of the UFC system. Defense agencies should contact the preparing service for document interpretation and improvements. Technical content of UFC is the responsibility of the cognizant DoD working group. Recommended changes with supporting rationale may be sent to the respective DoD working group by submitting a Criteria Change Request (CCR) via the Internet site listed below.

UFC are effective upon issuance and are distributed only in electronic media from the following source:

- Whole Building Design Guide web site http://www.wbdg.org/ffc/dod.

Refer to UFC 1-200-01, *DoD Building Code*, for implementation of new issuances on projects.

TABLE OF CONTENTS

FIGURES

TABLES

CHAPTER 1 INTRODUCTION

1-1 REISSUES AND CANCELS.

This UFC supersedes UFC 3-201-01 with Change 5 dated 1 April 2021.

1-2 PURPOSE AND SCOPE.

This UFC provides civil engineering requirements for all new and renovated Government facilities for the Department of Defense (DoD). Where other criteria, statutory or regulatory requirements, are referenced, the more stringent requirement must be met.

1-3 APPLICABILITY.

This UFC applies to all service elements and contractors involved in the planning, design and construction of permanent DoD facilities worldwide. It is applicable to all methods of project delivery and levels of construction.

1-3.1 Foreign Countries.

All design and construction outside of the United States and United States territories is governed by international agreements, such as the Status of Forces Agreements (SOFA), Host Nation-Funded Construction Agreements (HNFA), and in some instances, Bilateral Infrastructure Agreements (BIA), and country-specific Final Environmental Governing Standards (FGS) or DoDI 4715.05. DoDI 4715.05 is commonly referred to as the Overseas Environmental Baseline Guidance Document (OEBGD). The OEBGD applies when there are no international agreements in place. Therefore, in foreign countries this UFC will be used for DoD projects to the extent that it is allowed by and does not conflict with the applicable international agreements.

1-4 GENERAL BUILDING REQUIREMENTS.

Comply with UFC 1-200-01, *DoD Building Code*. UFC 1-200-01 provides applicability of model building codes and government unique criteria for typical design disciplines and building systems, as well as for accessibility, antiterrorism, security, high performance and sustainability requirements, and safety. Use this UFC in addition to UFC 1-200-01 and the UFCs and government criteria referenced therein.

1-4.1 Low Impact Development.

Use UFC 3-210-10 for Low Impact Development (LID) criteria. UFC 3-210-10 was developed to comply with the DoD Memorandum implementing Section 438 of the Energy Independence and Security Act (EISA).

1-5 CYBERSECURITY.

All control systems (including systems separate from an energy management control system) must be planned, designed, acquired, executed, and maintained in accordance with UFC 4-010-06, and as required by individual Service Implementation Policy.

1-6 BEST PRACTICES.

APPENDIX A provides guidance for accomplishing certain civil design and engineering services. The Designer of Record (DoR) is expected to review and interpret this guidance as it conforms to criteria and contract requirements and apply the information according to the needs of the project. If a Best Practices document has guidelines or requirements that differ from any UFC or the Unified Facilities Guide Specifications (UFGS), the UFC and the UFGS must be given a higher order of precedence.

1-7 GLOSSARY.

APPENDIX B contains acronyms, abbreviations, and terms.

1-8 REFERENCES.

APPENDIX C contains a list of references used in this document. The publication date of the code or standard is not included in this document. Unless otherwise specified, the most recent edition of the referenced publication applies.

1-9 COMMENTARY.

Limited commentary has been added to the chapters. Section designations for such commentary are preceded by a “[C]” and the commentary narrative is highlighted with light gray.

CHAPTER 2 SITE DESIGN

2-1 PLANNING.

Site selection and planning require knowledge of environmental requirements, land use restrictions, building setbacks, flood hazard areas, utility connections, utility offsets, vehicle circulation, buffers from natural and manmade features and other similar requirements. Use this UFC prior to starting design to determine specific project requirements including but not limited to demolition, site development, water distribution, and wastewater collection.

2-1.1 Wetlands.

Executive Order (EO) 11990 directs all Federal agencies to avoid wetlands development wherever there is a practicable alternative.

2-1.2 Flood Hazard Planning.

EO 11988 directs all Federal agencies to comply with the minimum requirements of the National Flood Insurance Program. DTM 22-003 directs DoD to avoid development within a flood hazard area to the maximum extent practicable. When mission needs require siting a building within or partially within a flood hazard area, evaluate alternative site locations to avoid or minimize adverse impacts to the floodplain. When no practicable alternative exists, use section 2-1.2.3 to develop a flood risk reduction plan and use section 2-8 to determine the appropriate flood risk reduction criteria.

2-1.2.1 Assessment of Flood Vulnerability.

Provide an assessment of flood vulnerability that integrates: current flood hazard mapping; increases in projected sea level rise; when available, the climate-informed science approach; and future forecasted land use changes over the service life of the facility.

2-1.2.1.1 Non-Tidally Influenced Locations.

Use paragraph 2-8.1.1 Flood Hazard Areas.

2-1.2.1.2 Tidally Influenced Locations.

Use paragraph 2-8.2.1 DoD Regional Sea Level Database.

2-1.2.2 Design Flood Event.

The design flood event is the 100 year or greater flood event used to establish the design flood. The design flood event may include events that exceed the 100-year event, such as areas that may be impacted by projected sea level rise over the service life of the facility, the 500-year flood event, or when available, the Climate-Informed Science Approach.

2-1.2.3 Flood Risk Reduction Plan.

A project-specific Basis for Flood Risk Reduction is required for all facilities sited within a flood hazard area. When developing the Basis for Flood Risk Reduction, fully consider all flood risk reduction measures included in ASCE 24-14 such as breakaway walls, non-engineered and engineered openings, dry proofing and wet proofing. The Basis for Flood Risk Reduction may include temporary flood protection systems.

2-1.2.3.1 Department of Defense Form 1391 Disclosure Requirements.

When mission needs require siting a building within or partially within a flood hazard area, indicate the following information on DoD Form 1391:

1. Identify the type of flood hazard area: 1 percent annual chance event (ACE), 0.2 percent ACE, Climate-Informed Science Approach; or projected sea level rise over the service life of the facility; and
2. For the Climate-Informed Science Approach, the climate informed science flood elevation as the base flood elevation (BFE) and the design flood elevation (DFE);
3. For the Freeboard Approach, the design flood event, BFE and the DFE; or
4. For the DRSL Approach, sea level rise scenario and timeframe used to establish the DFE.

2-1.2.3.2 Flood Risk Reduction Documentation.

In accordance with PL 115-232, Section 2805(a)(3), as amended by PL 116-92, evaluate all applicable flood risk reduction measures and document in the Basis for Flood Risk Reduction. Store the Basis for Flood Risk Reduction in project file during the 1391 development process and retain the Basis for Flood Risk Reduction in the project historical file. In tidally influenced locations, the Basis for Flood Risk Reduction must incorporate DoD component direction, when available. DoD component direction may include scenarios and timeframes that are less than or greater than the default values shown in the DRSL Approach column in Table 2-1. The Basis for Flood Risk Reduction must include:

- A description of the site location and rationale for the project's site selection, including if the site is non-tidally or tidally influenced;
- Information concerning alternative sites that were considered and an explanation of why those sites did not satisfy mission requirements;
- A description of the flood hazard area, such as a high velocity V zone, coastal A zone, X zone, area inundated by projected sea level rise, or the Climate-Informed Science Approach, and an assessment of the flood vulnerability;

- A description of the design flood event, such as the 1 percent ACE, 0.2 percent ACE, Climate-Informed Science Approach, or the projected sea level rise scenario and timeframe;
- If using the Climate–Informed Science Approach, the climate-informed science flood elevation, an assessment of the flood vulnerability (risk of flooding), the BFE and the DFE;
- If the project is in a non-tidally influenced location, an assessment of the flood vulnerability (risk of flooding), the BFE and the DFE;
- If the project is in a tidally influenced location, a description of the approach used, Freeboard Approach or DRSL Approach; whichever is more stringent. For the Freeboard Approach, include an assessment of the flood vulnerability (risk of flooding), BFE and the DFE. For the DRSL Approach, include an assessment of the flood vulnerability (risk of flooding), and the sea level rise scenario and timeframe used to establish the DFE; and
- A description of planned flood risk reduction measures.

2-2 NATIONAL ENVIRONMENTAL POLICY ACT.

National Environmental Policy Act (NEPA) actions should be completed prior to starting design. Obtain NEPA documentation prepared for the project from the Installation environmental staff. Comply with the identified measures and include them as contract requirements.

2-3 PRELIMINARY SITE ANALYSIS.

Use UFC 2-100-01 to develop a preliminary approach appropriate to the site and adjacent facilities, integrate sustainable strategies, and utilizing a holistic design approach. Conduct a preliminary site visit and obtain photographs of the site. Research and obtain Installation’s master plan, utility maps, and as-built record drawings for information related to topography, utility, and storm drainage availability, including design approaches used in the project vicinity. Evaluate the potential for abandoned or unmapped utilities. Research and review available subsurface investigation data and reports in order to evaluate subsurface conditions. Identify flood hazard areas in accordance with the International Building Code (IBC) Section 1612 and sections 2-1.2 and 2-8 of this UFC. Research and obtain explosive safety requirements. Consult with the Government Project Manager to establish contact with the Installation’s Environmental personnel to determine if the site has environmental concerns, such as radon, pesticides, or known contamination. If required, provide radon mitigation system design in accordance with UFC 3-101-01. Evaluate the need for additional analysis based on project requirements and site conditions.

Conduct detailed consultations with the Government in order to clearly define requirements and preferences.

2-4 EXISTING CONDITIONS.

2-4.1 Geotechnical Site Investigation.

Obtain soil exploration, testing, and evaluation from a professional geotechnical engineer. Determine the extent of exploration and testing based on recommendations with the geotechnical engineer, structural engineer (for foundations), civil engineer (for site elements such as LID, pavements, wells, and septic systems), local stormwater permitting agency (for detention ponds), and Government reviewers. Soils investigation (sampling, testing, and evaluation) must be in accordance with UFC 3-220-01, UFC 3-250-01, and UFC 3-260-02.

Indicate the results of the subsurface investigation, including boring locations, boring logs, groundwater observations, a summary of laboratory test results, and any details required to convey requirements for site preparation on the contract documents.

2-4.1.1 Soil Corrosivity.

Require geotechnical site investigation for soil corrosivity, when existing operating records, visual observations, inspections, or testing indicate corrosive soil conditions. Provide an evaluation of existing soils at the proposed depths and locations of piping in accordance with AWWA M27, chapter titled *Evaluating the Potential for Corrosion*.

2-4.2 Surveying.

Unless provided by Government personnel, a licensed or certified professional must seal all surveys in accordance with the applicable requirements of the local regulatory agency or overseas equivalent having jurisdiction over the Installation. Where overseas equivalent requirements do not include an accuracy standard, provide surveys at a minimum third order in accordance with National Oceanic and Atmospheric Administration (NOAA), Federal Geodetic Control Committee, *Standards and Specifications for Geodetic Control Networks*.

Prior to entering property not owned by the Government, consult with the Government Project Manager to establish contact with the Installation’s real estate personnel. Notify and obtain authorization for a right of entry over, across, or through all lands public or private landowners necessary to perform required field survey work. Coordinate with the Installation’s Security section for approval to enter controlled or restricted areas including but not limited to airfields, ranges, and munition storage. Consult with Government Project Manager to establish contact with the Installation’s Environmental personnel before entering the area with regards to any restrictions such as cutting or clearing vegetation, natural resources, or species.

2-4.2.1 Topographic Surveys.

Provide a topographic survey of the project site in accordance with each service’s requirements as well as the requirements of the state or Host nation equivalent in which the site is located. If state or Host nation equivalent requirements are not available, use *Model Standards for Topographic Surveys*.

2-4.3 Environmental Considerations.

Coordinate with the Installation EV Staff during preliminary site investigation, review existing records and evaluate site for environmental concerns or known contamination such as soil or groundwater contamination. If known contamination or environmental concerns are identified, notify the Government Project Manager and evaluate impacts to project cost to ensure adequate funding for current project.

2-4.4 Existing Sewers.

Use WEF MOP FD-6 for guidance when evaluating and rehabilitating existing sewers.

2-5 APPROVALS AND PERMITS.

The DoR must identify, assist, and provide, as applicable, all permits, approvals, and fees required for the design and construction of the new project from Federal, state, and local regulatory authorities or overseas equivalent. The Civil Engineering DoR must be a Professional Civil Engineer experienced and licensed. Licensure in the location of the project may be required to obtain permits and approvals. In the United States and its territories and possessions the Government will review permits for acceptability. In locations outside of the United States and its territories and possessions with Host nation agreements, follow permit approval procedure as directed in project scope and by the Government Project Manager. In locations outside of the United States and its territories and possessions without Host nation agreements, the Government will review and approve site improvement plans for compliance.

Consult with the Government Project Manager to determine the appropriate signatories for permit applications.

2-6 CLEARING AND DEMOLITION.

Identify the following in the construction documents: limits of disturbance; limits of demolition; limits of clearing and grubbing; isolated trees and shrubs to remain or to be removed. Describe size, density, and type of trees to be cleared and grubbed, items to be salvaged or relocated, staging area, temporary storage area and location. Coordinate with the Installation concerning clearing options to remove merchantable timber from the project site.

During site demolition and preparation, remove existing and abandoned utilities under or within 10 feet (3.0 m) of the foundation of any new facility or building foundation. Reroute existing utilities to remain in accordance with paragraph titled “UTILITIES” in Chapter 2.

2-7 SITE DEVELOPMENT.

Location and orientation of facilities must be based on an analysis of activities to be accommodated and on specific requirements for each project, to include all functional, technical, and economic factors. Use UFC 3-101-01 for building function, size, and orientation criteria.

Incorporate the following into site design, as applicable:

a. Land use restrictions and setbacks (existing and future).

b. Circulation (vehicle and pedestrian).

c. Orientation and Location to integrate green space. Provide adequate grading and drainage while preserving natural topographic features to minimize cut and fill, impact on existing drainage patterns and tree removal.

d. Operational and natural constraints.

1. Maintain mandated buffers:

(a) Airfield and helipad clearances.

(b) Explosives safety clearances.

(c) Noise abatement.

(d) Antiterrorism and physical security clearances.

(e) Storage and handling hazardous material clearances.

(f) Separation of incompatible land use or functions.

(g) Building setbacks (if established).

(h) Fire separation zones per building and fire codes.

2. Eliminate or minimize construction activities requiring permits for areas such as archaeological sites, wetlands, utilities, and stormwater management.

3. Minimize site or utility maintenance and operating costs.

4. Accommodate site constructability and security requirements.

5. Minimize distance to existing utility connections.

2-7.1 Accessibility.

Use UFC 1-200-01 to determine accessibility requirements.

2-7.2 Petroleum, Oil and Lubrication (POL).

Use UFC 3-460-01 for POL criteria.

2-8 FLOOD RESISTANT DESIGN.

Facilities sited within or partially within a flood hazard area must be designed in accordance with UFC 1-200-01 and this UFC. For flood resistant design, UFC 1-200-01 implements the IBC and the IBC implements ASCE 24-14. This UFC modifies the IBC and ASCE 24-14. The term facilities applies to buildings and structures and the terms buildings and structures are used interchangeably for flood resistant design criteria. To minimize impacts to the existing floodplain, EO 11988 directs all Federal agencies to elevate buildings rather than filling in land, wherever practicable. Use UFC 4-152-01 for waterfront construction.

When mission needs require siting a building within or partially within a flood hazard area, obtain the project specific Basis for Flood Risk Reduction, when available. When the Basis for Flood Risk Reduction is not available, the DoR is responsible for preparing the Basis for Flood Risk Reduction, consistent with section 2-1.2. Use the Basis for Flood Risk Reduction and Table 2-1 when computing the minimum DFE. Table 2-1 modifies ASCE 24-14, Table 1-1 Flood Design Class of Buildings and Structures and provides DFEs. Ensure proper correlation between vertical datums and submit flood design calculations, including the governing criteria used, to the Government Civil Engineer.

Table 2-1 Design Flood Elevation (DFE)

ASCE 24-14 Flood Design Class	Freeboard Approach [1]	DRSL Approach [2,3,4]	Climate-Informed Science Approach
1 (minimal risk; non-essential facilities)	BFE	Lowest 2065	BFE
2 (moderate risk; non-essential facilities)	BFE + 2 ft (600 mm)	Low 2065	BFE +1 ft (300 mm)
3 Subcategory 3a (high risk; non-essential facilities)	BFE + 2 ft (600 mm)	Medium 2065	BFE +1 ft (300 mm)
3 Subcategory 3b[5] (high risk; essential facilities)	BFE + 3 ft (900 mm)	High 2065	BFE + 2 ft (600 mm)
4[6] (high risk; essential facilities)	BFE + 3 ft (900 mm)	Highest 2065	BFE + 2 ft (600 mm)

1. The freeboard approach complies with PL 115-232, Section 2805(a)(4)(A) and (B).
2. The default sea level rise scenario complies with USD (A&S) DTM 22-003, “Flood Hazard Area Management for DoD Installations,” dated June 7, 2022.
3. Use the site-specific value from the DoD Regional Sea Level (DRSL) database corresponding to the designated scenario (lowest/low/medium/high/highest) for the 1 percent ACE for year 2065. The DRSL database is publicly available at https://drsl.serdp-estcp.org/Site. The FOUO DRSL database is available at https://sealevelscenarios.serdp-estcp.org.
4. These are default values in the absence of a Basis for Flood Risk Reduction. When provided, use the component’s sea level rise scenario and timeframe in lieu of the value provided in this column.
5. Essential facilities that would not need to remain operational during the design flood event but would need to be fully operational immediately following a storm event.
6. Essential facilities that would need to remain operational during the design flood event.

2-8.1 Non-Tidally Influenced Locations.

2-8.1.1 Flood Hazard Areas.

The boundaries of the flood hazard area for the design flood event must be designated by:

a. When available, the Climate-Informed Science Approach,

b. The applicable Flood Insurance Study (FIS) with the accompanying Flood Insurance Rate Map (FIRM) or Flood Boundary and Floodway Map (FBFM) issued by Federal Emergency Management Agency (FEMA), when available,

c. Past flooding events, storm of significant impact,

d. A flood hazard map adopted by the Installation; or

e. A flood study performed to determine flood hazard areas in accordance with FEMA accepted hydrologic and hydraulic engineering practices used to define flood hazard areas.

When a new project site occupies two or more flood hazard areas, site the buildings or most vulnerable buildings to avoid the flood hazard area that presents the highest risk to the extent practicable.

2-8.1.1.1 Base Flood Elevation.

Determine the BFE for the design flood event in accordance with the following order of precedence:

1. When available, the Climate-Informed Science Approach;
2. As indicated on the applicable FIS and accompanying FIRM;
3. When regulation promulgated by a state or other government source is greater than the BFE identified in the Basis for Flood Risk Reduction, use the BFE established by the state or other government source;
4. A flood study performed to determine the BFE in accordance with FEMA; or
5. A flood elevation established by the Installation using documented historical flood data from previous extreme flood events.

When a building is sited within or partially within one or more flood hazard areas or BFE contours, use the flood hazard area or BFE that presents the highest risk to the buildings. In some cases, it may be acceptable to design portions of buildings that are structurally independent.

2-8.1.1.2 Design Flood Elevation.

Determine the DFE in accordance with the following order of precedence:

1. Use Table 2-1 to determine the DFE using the Freeboard Approach or, when available, the Climate-Informed Science Approach.
2. When regulation promulgated by a state or other government source is greater than the DFE computed in the first order of precedence, use the DFE established by the state or other government source.

2-8.2 Tidally Influenced Locations.

2-8.2.1 DoD Regional Sea Level Database.

The DRSL Database provides five global and site-specific sea level change scenarios for three discrete time periods, 2035, 2065, and 2100. These scenarios are bound by the lowest scenario which is based on the 95% confidence interval for sea level trends developed by NOAA and the highest scenario which is based on the highest projection from the United Nations Framework Convention on Climate Change produced by the Intergovernmental Panel on Climate Change. The three intermediate scenarios are based on equally proportional 0.5 m increment subdivisions of the upper bound for the 2100 time period which deviates from the United Nations Framework Convention on climate change scenarios. For the 2100 time period, the five global scenarios from the DRSL Database are lowest 0.7 ft (0.2 m), low 1.6 ft (0.5 m), medium 3.3 ft (1 m), high 4.9 ft (1.5 m), and highest 6.6 ft (2.0 m).

In accordance with PL 116-92, Section 2804 and DTM 22-003 on Flood Hazard Area Management for DoD Installations, use the DRSL Database to determine site-specific mean sea level rise when the tidal record is a minimum of 50 years or two National Tidal Datum Epochs. Use the following order of precedence to select the appropriate sea level rise scenario and timeframe:

1. Basis of Flood Risk Design retained in the project file.
2. The DRSL Approach column in Table 2-1.

For the lowest scenario, the NOAA relative sea level trend from the 95% confidence interval may be interpolated or extrapolated to estimate future sea level rise increases for time periods not provided in the DRSL Database. The low, medium, high and highest scenarios may be graphically interpolated to estimate sea level rise between the time periods provided in the DRSL Database. Do not extrapolate the low, medium, high and highest scenarios in the DRSL Database.

2-8.2.2 Flood Hazard Areas.

Determine the flood hazard area in accordance with the most stringent of the following requirements:

1. Paragraph 2-8.1.1, or

2. The 1 percent ACE EWL elevation from the DRSL Database.

2-8.2.3 Base Flood Elevation.

When using the DRSL approach, set the BFE equal to the EWL for the 1 percent ACE from the DRSL Database.

[C] 2-8.2.3 Base Flood Elevation

The EWL is the historical extreme water level value from the DRSL Database, not including wave height, having a 1 percent chance of being equal or exceeded in any given year. When using the DRSL Approach, the 1 percent ACE EWL from the DRSL Database is used as the 1 percent ACE flood event to consistently apply flood design criteria between the Freeboard Approach and the DRSL Approach.

2-8.2.4 Design Flood Elevation.

Use the following procedure to account for projected current and future mean sea level rise over the service life of the facility. Procedure for determining the DFE in tidally influenced locations:

1. Use paragraph 2-8.1.1.2 to determine $DFE_{freeboard}$.
2. Use paragraph 2-8.2.1 to determine the sea level rise scenario and timeframe.
3. Use Equation 2-1 to determine DFE_{SL}.
4. DFE equals $DFE_{freeboard}$ or DFE_{SL}, whichever is more stringent.

Equation 2-1. Design Flood Elevation

$$\boldsymbol{DFE_{SL} = EWL + SLR}$$

Where:
DFE_{SL} = Sea level rise impacted design flood elevation
EWL = 1 percent ACE EWL from the DRSL Database
SLR = Increases to site-specific mean sea level from the DRSL Database

[C] 2-8.2.4 Design Flood Elevation

Equation 2-1 is equivalent to using the combined tab in the DRSL Database.

2-8.3 Flood Resistant Design Options.

ASCE 24-14 does not require elevating all building types as a minimum standard. ASCE 24-14 allows additional flood resistant design standards to be used when constructing flood resistant buildings and minimizing damage from the design flood event. Flood resistant design standards include flood risk reduction measures such as:

- Design of openings (see ASCE 24-14, paragraph 2.7.2),
- Openings in breakaway walls (see ASCE 24-14, paragraph 2.7.1.1),
- Non-engineered openings (see ASCE 24-14, paragraph 2.7.2.1),
- Engineered openings (see ASCE 24-14, paragraph 2.7.2.2),
- Dry floodproofing (see ASCE 24-14, paragraph 6.2), or
- Wet floodproofing (see ASCE 24-14, paragraph 6.3).

Fully investigate flood resistant design standards, including temporary flood protection systems, and evaluate the impact of their use based on level of risk, non-essential or essential status, level of protection provided, user impacts and cost.

2-8.4 Flood Protection Systems.

When the design flood event cannot be mitigated using the flood risk reduction measures identified in ASCE 24-14, use a flood protection system to protect the building or buildings. A flood protection system may also be used when an engineering and cost analysis indicates that a flood protection system is advantageous to the intent of the project or master development plan. Flood protection systems may consist of dams, levees, floodwalls, and other types of flood protective works.

2-8.4.1 Establishing Flood Protection System Design Criteria.

Flood protection systems meeting the minimum design requirements in 44 CFR 65.10 may be accredited by FEMA for protection against the 1 percent ACE. FEMA accreditation of flood protection systems is encouraged but not required. Use 44 CFR Section 65.10 for the design of flood protection systems providing protection to the 1% ACE. Design flood protection systems to protect the building or buildings to the minimum DFE. When the design flood event exceeds the 1 percent ACE, the DoR must modify the minimum height of wall and associated criteria provided in 44 CFR Section 65.10 to account for the minimum DFE and submit the revised criteria to the Government Civil Engineer for review and approval prior to beginning design. In accordance with 44 CFR Section 65.10, the flood protection system is required to be certified by the DoR. Refer to FEMA GD34 for guidance on FEMA accreditation.

[C] 2-8.4.1 Establishing Flood Protection System Design Criteria

A registered professional engineer is responsible for certifying flood protection systems.

Flood protection system accreditation may be received from FEMA once a registered professional engineer has completed the certification process and all of the required documentation has been submitted to FEMA for review.

2-8.5 Mission Critical Roads.

Design mission critical roads and roads used for evacuation to be above the BFE plus freeboard or in accordance with the Installation's emergency management plan. Determine freeboard based on the reliability of available flood hazard area maps and supporting data, flood elevation and floodway data, increases in projected sea level rise, climate-informed science approach, or in accordance with FEMA accepted hydrologic and hydraulic engineering practices used to define flood hazard areas.

[C] 2-8.5 Mission Critical Roads

Mission critical roads provide at least one route of travel to mission critical buildings.

Freeboard is used to provide a factor of safety. A minimum freeboard of 1 foot (300 mm) is recommended.

2-9 GRADING.

UFC 1-200-01 implements grading requirements from the IBC and provides supplements to IBC criteria. Use UFC 1-200-01, paragraph titled "Soils and Foundations", to determine the appropriate requirements for site grading. Grading must direct water towards new or existing drainage features and away from impervious site features such as buildings, structures, runways, and roads. Grading must not result in low spots that hold water or that direct water towards new or existing site features. Conform to existing topography to the greatest extent possible.

Crowned sections are the standard cross sections for roads, runways, taxiways, and safety areas. Crowned sections are generally symmetrical and slope away from the center line of the pavement.

2-9.1 Transverse and Longitudinal Slopes.

Acceptable ranges of transverse and longitudinal slopes are indicated in Table 2-2. Grading criteria is also indicated in AASHTO GDHS.

Table 2-2 Grading

Item	Item Description	Requirement	Best Practices
1	Longitudinal grades of roads	Min. 0.3%	Min. 0.5%
2	Transverse grades of roads	Min. 2.0%	
3	Concrete pavement in parking areas	Min. 1.0%	Min. 1.5% Max. 5.0%
4	Curb & Gutter or Valley Gutter	Min. 0.3%	Min. 0.5%
5	Bituminous pavement in parking areas	Min. 1.5%	Min. 2.0% Max. 5.0%
6	Permeable Pavements in parking areas*	Min. 1.0%	Max. 5.0%
7	Walks, Transverse	Max. 2.0%	
8	Walks, Longitudinal		Max. 5.0%
9	Concrete Landings	Max. 2.0%	
10	Paved Concrete Ditches, longitudinal	Min. 0.3%	
11	Unpaved Ditches, longitudinal*	Min. 0.5%	
12	Pervious Surfaces (Grass, Turf, or Landscape)*	Min 2.0%	

* Regulatory agency's stormwater management criteria may govern for items used as stormwater management features.

2-9.2 Finished Floor Elevations.

Establish minimum finished floor elevations in accordance with this UFC, UFC 1-200-01 paragraph titled "Structural Design", or UFC 3-101-01, whichever is more stringent.

[C] 2-9.2 Finished Floor Elevations

The referenced criteria is included for projects that many or may not be in a flood hazard area. For example, if a project is not in a flood hazard area, UFC 3-101-01 may provide the more stringent criteria.

2-9.3 Airfields.

Use the airfield grading criteria in UFC 3-260-01.

2-10 VEHICLE CIRCULATION.

The DoR must address unique aspects of military facilities when designing roads and parking. For example, roads on military installations are typically designed for lower speeds while also addressing the movement of specialized military vehicles. Roads, parking areas and structures must conform to current antiterrorism and accessibility requirements.

2-10.1 Special Circulation Areas.

Circulation areas for vehicles other than normal passenger cars have special requirements to maintain traffic safety. These areas require additional space to accommodate unusual traffic patterns and greater turning radii for maneuverability. Special circulation areas include areas such as drop off areas, delivery and service zones, garbage collection areas (dumpsters), drive-in facilities, emergency vehicle access, and entry control facilities. The design must also address the turning and reverse movements for the largest vehicle including but not limited to deliveries, emergencies, and garbage collection that will use the facility and discourage through traffic.

2-10.1.1 Dumpster Pads.

Consider site circulation, building location, and distance to service doors. Coordinate the location of dumpster pads with Government personnel. Provide access to dumpster pads that is fully coordinated with the operation of the facility and facilities waste collection plan. When wheeled trash cans or carts are used as part of the facilities waste collection plan, provide sidewalks and ramps for access to and from the facility. Size dumpster pads in accordance with the Installation waste collection service. Provide site circulation and reverse turning area that allows dumpster trucks to maintain a forward movement to and from the dumpster pads. For frontloading dumpster trucks, provide a straight approach for dumpster trucks to access and align with the dumpster, reverse away, and exit forward. For rear-loading dumpster or roll off trucks, provide a reverse turning area that allows for a straight approach for dumpster trucks to access and align with the dumpster after reversing, and exit forward. For side-loading dumpster trucks, provide a straight approach for dumpster trucks to access and align with the dumpster, reverse away if needed, and exit forward. The concrete dumpster pad must be large enough to accommodate the:

- Front wheels of frontloading dumpster trucks;
- Rear wheels of rear-loading and roll-off dumpster trucks; or
- Front and rear wheels of side-loading dumpster trucks.

2-10.1.1.1 Airfields.

Locate dumpsters in locations approved by Airfield Operations (AIROPS) to avoid a Bird/Animal Aircraft Strike Hazard (BASH) issue.

2-10.2 Traffic Studies.

Provide traffic studies and analysis in accordance with Surface Deployment and Distribution Command Transportation Engineering Agency (SDDCTEA) Pamphlet 55-17 and SDDCTEA Pamphlet 55-8.

2-10.3 Design Vehicles.

Design vehicle types include:

a. Passenger car, truck, light-delivery truck, bus, and truck combinations are as defined by AASHTO (moving vans, refuse trucks and school buses, snow-clearing trucks).

b. Emergency vehicles.

c. Specialized military vehicles such as tracked vehicles.

Obtain design information for emergency vehicles and specialized military vehicles from the Government Project Manager.

2-10.4 Design Traffic.

Use ITE LP-674B to evaluate average daily traffic (ADT) and peak hourly traffic, as applicable. Adjust for vehicles other than passenger cars. In addition to the vehicles indicated in ITE LP-674B (trucks, RV's, buses), add specialized military vehicles as a vehicle type and determine the nearest equivalent AASHTO vehicle type.

2-10.5 Roads.

Design roads in accordance with SDDCTEA Pamphlet 55-17, AASHTO GDHS, AASHTO RSDG-4, and AASHTO VLVLR as applicable.

Single-lane roads may be provided for fire lanes and approach drives to buildings within built-up areas. Access roads to unmanned facilities may also be single-lane roads. Where shoulders are not sufficiently stable to permit all-weather use and the distance between intersections is greater than ½-mile (805 m), turnouts must be provided at 1/4-mile (402 m) intervals along single lane roads for use by occasional passing or meeting vehicles.

2-10.5.1 Fire Lane and Emergency Vehicle Access.

Fire lanes and emergency vehicle access must comply with UFC 3-600-01.

2-10.6 Parking Areas.

Design parking areas in accordance with SDDCTEA Pamphlet 55-17, Chapter titled "Parking". Parking areas include on-street parking, off-street parking lots, and parking structures. Refer to scope of work to determine the gross area or number of parking spaces. If the number of parking spaces is not identified in the project scope of work, use Table A-2 for guidance. Provide parking spaces primarily by off-street parking areas or structures.

For Flood Design Class IV facilities, design parking supporting essential personnel that would need to remain at the facility during the design flood event to be above the BFE plus freeboard. Determine freeboard based on the reliability of available flood hazard area maps and supporting data, flood elevation and floodway data, increases in projected sea level rise, climate-informed science approach, or in accordance with FEMA accepted hydrologic and hydraulic engineering practices used to define flood hazard areas.

[C] 2-10.6 Parking Areas

Freeboard is used to provide a factor of safety. A minimum freeboard of 1 foot (300 mm) is recommended.

2-10.6.1 On-Street Parking.

The use of on-street parking is discouraged. On-street parking will not be allowed within 20 feet (6.1 m) of an intersection. The minimum length for the first and last stall is 20 feet (6.1 m). The minimum length for each interior stall is 22 feet (6.7 m).

Exception to SDDCTEA Pamphlet 55-17: The minimum width for all passenger vehicle stalls is 8 feet (2.4 m).

2-10.6.2 Off-Street Parking.

Typically, 90 degree parking is preferred for off-street parking for ease of traffic flow. If 90 degree parking is not used, the designer must be able to justify by showing that the minimum functional and technical requirements are met while providing an economic benefit to the Government. Provide minimum 9 feet (2.7 m) wide and 18.5 feet (5.6 m) long parking spaces for 90 degree parking. The design must discourage through traffic.

Exception to SDDCTEA Pamphlet 55-17: In areas of limited space, provide a minimum buffer strip of 8 feet (2.4 m) when sufficient space is available.

2-10.6.3 Compact Cars.

Compact spaces may be used when there will be a consistent number of compact size vehicles accessing the facility on a regular basis. Do not use compact spaces when sufficient space is available for standard size passenger vehicles.

2-10.6.4 Motorcycles.

When motorcycle spaces are subtracted from the required regular spaces a parking study must be performed to determine the consistent number of motorcycles regularly parking at the facility throughout the year. When performing the traffic study, take into account adverse weather (winter in northern climates). Do not subtract motorcycle spaces from required regular spaces unless supported by a traffic study.

Motorcycle parking surfaces are typically designed as rigid pavements to prevent kickstands from penetrating bituminous pavement in warm weather. The minimum size for motorcycle spaces is 9 feet (2.7 m) long and 4.5 feet (1.3 m) wide.

2-10.6.5 Parking Areas Outside of the United States.

Use UFC 1-200-01 and refer to the “Forward” at the beginning of this UFC to determine accessibility requirements for areas outside of the United States. When standard passenger car dimensions, as indicated in SDDCTEA Pamphlet 55-17, are not used, a traffic engineering study (parking study, parking design vehicle study) must be performed to determine the predominant vehicle size and parking layout. Perform traffic engineering studies in accordance with SDDCTEA Pamphlet 55-8. The minimum parking size for all cars is 8 feet (2.4 m) x 16 feet (4.8 m).

During the parking study, take into account the following at a minimum:

- Requirements for each project.
- An analysis of activities to be accommodated.
- Government vehicle use.
- Standard vehicles from the United States.
- Current and future parking demand.
- Variety of parking areas needed.
- Truck traffic, including deliveries- and garbage collection.
- Emergency vehicles.
- Minimum entrance widths.
- Number of entrances.
- AT setbacks.
- Parking (on-street, off-street, parking orientation, aisle widths, minimum stall size and orientation, accessible spaces).

2-10.7 Bicycle Facilities.

Use AASHTO GDHS and SDDCTEA Pamphlet 55-17 for the design of bicycle facilities. Use Best Practices document, AASHTO GBF for additional design guidance.

2-11 SITE APPURTENANCES.

Provide site appurtenances in accordance with state or local standards where project is located.

2-11.1 Pedestrian Circulation.

Allow for pedestrian circulation between various new and existing facilities by providing a network of new sidewalks that connect new pedestrian circulation systems with existing pedestrian circulation systems. Use UFC 1-200-01 to determine accessibility requirements. Use AASHTO GDHS and SDDCTEA Pamphlet 55-17 for the design of pedestrian circulation systems. Use Best Practices document, AASHTO GPF for additional design guidance.

Sidewalks may consist of portland cement concrete, bituminous concrete (asphalt), solid pavers, permeable pavers, or pervious concrete. The minimum thickness of PCC concrete sidewalks is 4 inches (100 mm). Provide bituminous sidewalks with a minimum 4 inches (100 mm) thick base and a 1 inch (25 mm) thick bituminous surfacing. The minimum width for all sidewalks is 4 feet (1.2 m). In high volume or urban areas, the minimum width for sidewalks is 6 feet (1.8 m). Where the sidewalk is adjacent to the curb, increase the minimum width to account for obstacles such as signs and fire hydrants. Consult with the Government Project Manager for special sidewalk requirements for facilities with high pedestrian volumes such as barracks, medical facilities, where extra wide walks may be required.

2-11.2 Curb or Curb and Gutter.

Use concrete curb and gutter when overland flow cannot be achieved; to extend curb or curb and gutter from an adjacent facility; or to confine traffic. Asphalt-type curbs are only allowed in remote areas where approved by the Installation.

2-11.2.1 Airfields.

Curbs and gutters are not permitted to interrupt surface runoff along a runway, taxiway, heliport, or apron. The runoff must be allowed unimpeded travel transversely off the runway and then directed to the inlets.

2-11.3 Wheelstops.

Provide 6 feet (1.8 m) long wheelstops anchored to the pavement at parking spaces adjacent to sidewalks, buildings, stormwater management facilities, areas of extreme slope, and other areas without curb where a vehicle would likely cause property damage. Locate the front face of the wheelstop 30 inches (750 mm) from the edge of the pavement or sidewalk.

Where snow removal equipment is used, wheelstops may not be allowed by the Installation; coordinate with Government Project Manager.

2-11.4 Bollards.

2-11.4.1 Bollards around Structures.

Provide bollards around any structures subject to damage from vehicular traffic by incidental contact; such bollards must be at minimum 4 feet (1.2 m) high. For steel bollards, provide minimum 4 inch (100 mm) diameter filled with concrete and painted. Bollards on aircraft aprons protecting fire hydrants must not exceed 30 inches (750 mm) aboveground and 24 inches (600 mm) above load bearing paving.

2-11.4.2 Bollards for Security.

For vehicular barrier and crash rated applications, use UFC 4-022-02.

2-11.5 Signage and Markings.

Provide signs and associated pavement markings to facilitate proper utilization of the project site. Provide new traffic control devices such as signs and markings in accordance with SDDCTEA Pamphlet 55-17. Also use Manual on Uniform Traffic Control Devices, SHSM, and *Department of Defense Supplement to the National Manual on Uniform Traffic Control Devices*.

Provide non-reflectorized pavement markings for paved parking areas, reflectorized pavement markings for paved roads, and fire access markings in accordance with marking criteria and procedures recognized by the Department of Transportation (DOT) in the state in which the project is located or local governing authority's requirements.

2-11.6 Dumpster Enclosures.

Where dumpster pads are required on a project, provide a dumpster pad enclosure conforming to the Installation Appearance Plan.

2-12 UTILITIES.

New underground utilities such as water, sanitary sewer, electrical, telecommunications, and natural gas) must be at least 10 feet (3.0 m) from foundations for buildings and structures. For building connections, minimize the length of piping under the building by running the service piping around the outside of the building. Provide horizontal and vertical separation between new and existing utilities for rehabilitation, maintenance, repair or replacement. Minimize underground utilities located beneath pavements, except where crossings are required. Locate utilities to minimize connection costs and traffic interference with future maintenance.

Obstructions including signs and poles for overhead utilities must be located outside the limits of usable shoulder on roads designed without barrier curbs. Where practicable, roads designed with barrier curbs must have the desirable lateral clearances to obstructions as indicated in AASHTO GDHS except that fire hydrant clearances must be in accordance with UFC 3-600-01.

2-12.1 Water Distribution Systems.

Use UFC 3-230-01 for water distribution system criteria. Use UFC 3-230-03 to establish water demand.

2-12.2 Wastewater Collection Systems.

Use UFC 3-240-01 for wastewater collection and treatment criteria.

2-12.3 Lighting.

Use UFC 3-530-01 for lighting criteria.

2-13 STORM DRAINAGE SYSTEMS.

Refer to Chapter 3 of this UFC.

2-14 ENTRY CONTROL FACILITIES.

Use UFC 4-022-01 and SDDCTEA Pamphlet 55-15 for entry control facility criteria.

2-15 BRIDGES, OVERPASSES AND UNDERPASSES.

Where applicable, comply with AASHTO GDHS, AASHTO RSDG-4 and AASHTO LRFDBDS. Use Best Practices document USDA 0625 1808P as applicable.

For railroad bridges, also comply with UFC 4-860-01, the design manual of the relevant railroad company and use Best Practices document, the American Railway Engineering and Maintenance-of-Way Association (AREMA) publication *Manual for Railway Engineering*.

CHAPTER 3 STORM DRAINAGE SYSTEMS

3-1 DESIGN CRITERIA.

Design surface drainage, underground drainage systems, stormwater management facilities, and erosion and sediment control in accordance with the criteria noted in this UFC, UFC 3-210-10, HDS-5, state drainage manual, or the local regulatory agency with jurisdiction over the Installation; whichever is more stringent. Ensure that the stormwater runoff does not adversely affect the project site (building function, parking, roads) for the service life of the facility, the surrounding facilities for the service life of the surrounding facilities, and future forecasted land use changes. Submit calculations to the Government Civil Engineer and document the governing criteria used. For additional design guidance, consult Best Practices, as indicated in APPENDIX A and manufacturer’s data.

The design of the storm drainage system and stormwater management features must address the following:

- The storm drainage system and stormwater management plan must comply with Federal, state, and local regulatory requirements including regional or site-specific stormwater management agreements.
- Minimize grading to complement the features and functions of the natural drainage system and the existing contours.
- The siting and sizing of stormwater management facilities must take into account the high and seasonal groundwater table elevations.
- Utilize overland flow and natural site features where storm drainage will not impact site function or adversely affect surrounding sites. Drainage systems must prevent erosion of existing soils, ponding, and convey flow to a suitable outfall location.
- Culverts, ditches, and other drainage structures must be designed to minimize adverse environmental effects such as erosion, impacts to wetlands, and blocking fish passage.
- If a suitable point of discharge does not exist, one must be constructed.

3-1.1 Approved Methodologies.

Peak design flow must be calculated using the Rational Method for drainage areas smaller than 200 acres, Technical Release 55 (TR-55) curve number method or as approved by the Government Civil Engineer. Intensity-duration-frequency (IDF) curves are available in most state or local regulatory agency drainage manuals or from NOAA. If the IDF curves are not available, particularly in areas outside of the United States, the DOR needs to develop them on a project-by-project basis. Submit IDF curves with the calculations for approval from the Government Civil Engineer.

The TR-55 curve number methodology is approved and recommend for LID calculations required by UFC 3-210-10.

3-1.2 Design Storm Frequency.

For the design of surface and underground stormwater drainage systems, use a minimum 10-year storm frequency, the facility type minimum, or the minimum required by the state or local governing authority; whichever is more stringent.

3-1.2.1 Airfields.

Runways, taxiways, heliports, and aprons use the minimum required by the local governing authority for airfields and heliports or a minimum 5 year storm frequency. Retrofit projects on existing runways, taxiways, heliports, and aprons should be designed using a 5 year storm. Where an engineering and cost analysis indicates that it is advantageous to the project, a minimum 2 year storm frequency may be used for retrofit projects.

3-1.2.2 Principal Roads.

For principal roads, collector or local roads with speeds greater than 50 mph (80 kph) use the minimum storm frequency and intensity required in the state drainage manual or a minimum intensity of 4 in/hr (100 mm/hr); whichever is more stringent.

3-1.3 Maximum Spread.

The maximum spread for roads is ½ driving lane. For collector and local roads, use a minimum 5-year storm frequency. Roads with speeds greater than 50 mph must be designed in accordance with the state or local regulatory agency with jurisdiction over the Installation; whichever is more stringent.

3-1.3.1 Airfields.

The maximum spread for airfields must not include runways, taxiways and heliport pavements or paved shoulders using a 5 year storm frequency.

The maximum spread for airfields must not encroach on the center 50 percent, along the centerline, of runways, taxiways, or helipad surfaces using a 10 year storm frequency.

3-1.3.1.1 Aprons.

The maximum spread for aprons is a depth of 4 inches (100 mm) using a 5 year storm frequency.

The maximum ponding depth is 4 inches (100 mm) around apron inlets.

3-1.4 Inlet Design.

Size and locate drainage inlets to limit the spread of water. Use bicycle safe inlet grates where bicycle travel is possible.

For paved parking, storage, and similar areas, inlets must be provided in sag locations.

3-1.4.1 Airfields.

Avoid drainage patterns consisting of closely spaced interior inlets in pavements with intervening ridges for airfields. Such grading may cause taxiing problems, including bumping or scraping of wing tanks. For paved apron areas, inlets must be provided in sag locations.

If there is a long, gradually sloping swale between a runway and its parallel taxiway (in which the longitudinal grade is all in one direction), additional inlets should be placed at regular intervals down this swale. The area around these additional inlets may have ridges to protect the area around the inlet, prevent bypassing, and facilitate the entry of the water into the structure. The grades and grade changes for ridges must be provided in accordance with UFC 3-260-01.

3-1.5 Erosion and Sediment Control.

Design erosion and sediment controls that minimize the discharge of pollutants from earth disturbing activities in conformance with the applicable requirements of the regulatory agency with jurisdiction over the Installation regarding erosion and sediment control. Where requirements do not exist, provide an erosion and sediment control plan in accordance with the requirements of Environmental Protection Agency's (EPA) Construction General Permit.

3-1.6 Pollution Prevention.

Segregate stormwater from industrial processes that may introduce conventional pollutants, such as oil, grease or lubricants, or any toxic or non-conventional pollutant. When stormwater segregation is not possible, provide collection and treatment in accordance with UFC 3-240-01.

3-1.6.1 Petroleum Fuel Facilities.

Use UFC 3-460-01 for the design of stormwater collection systems associated with petroleum fuel facilities.

3-2 MATERIAL SELECTION FOR AIRFIELDS.

The use of plastic pipe is not approved for use under any type of airfield pavement except for subsurface water collection and disposal.

3-3 ROOF DRAINAGE.

Use UFC 3-420-01 to size underground roof drainage or use a minimum interior diameter of 6 inches (150 mm), whichever is greater. When using underground piping to collect roof drainage, provide an air break between the downspouts and underground piping. Connect a maximum of three downspouts to each underground roof drainage header and connect each underground roof drainage header to a storm drainage structure. Use a maximum length of 150 feet (45.7 m) from the most distant downspout to the storm drainage structure. Provide cleanouts for changes in direction and each downspout connection. Provide cleanouts for underground roof drainage piping to prevent cleanouts from being located more than 100 feet (30.4 m) apart.

Where roof drainage is discharged to grade, provide splash blocks or paved channels to direct the flow away from the structure. Eliminate safety hazards such as ice, ponding, and flooding in pedestrian and vehicular traffic areas.

3-4 SURFACE DRAINAGE.

Surface drainage must convey flow to a point of discharge capable of handling the stormwater flow from the design storm event.

3-4.1 Open Channels.

For channels with flows greater than 100 cfs (2.83 cms), provide 1 foot (300 mm) of freeboard or design for the 100 year storm event. Major channels with flows greater than 100 cfs (2.83 cms) are usually trapezoidal in cross section. Minor channels are usually V shaped in cross section.

3-4.1.1 Channel Characteristics.

Use the following channel characteristics for channels:

- Maximum side slopes of 2:1, horizontal to vertical, unless using steeper side slopes are supported by a geotechnical report.
- Use Manning’s Roughness Coefficient, “n”, of 0.030 for unmaintained earth channels. For other surface materials see state or local regulatory agency’s requirement.

3-4.1.2 Airfields.

Open channels or natural water courses are permitted only at the periphery of an airfield or heliport facility and must be well removed from the landing strips and traffic areas.

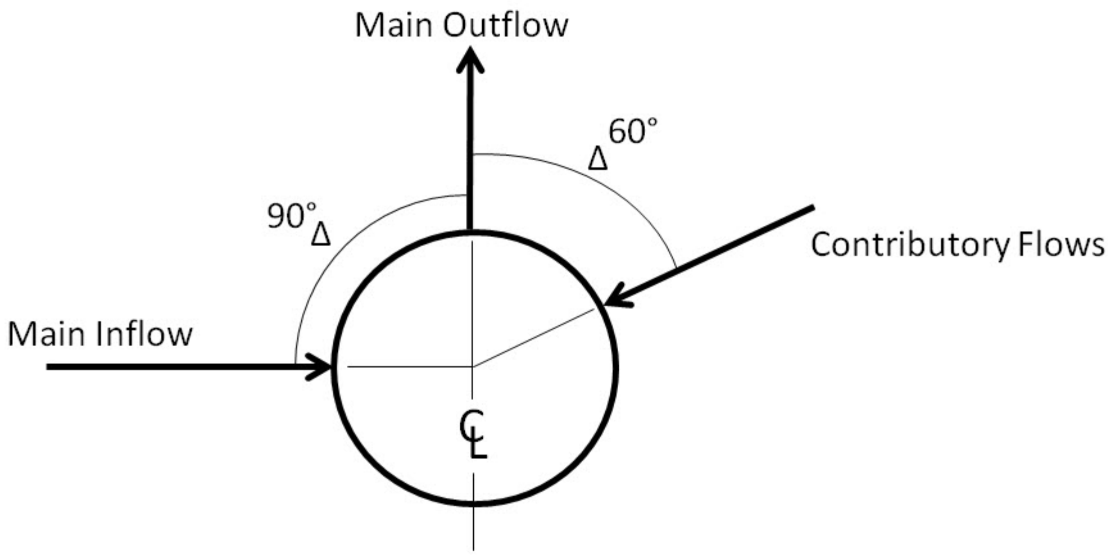
3-5 UNDERGROUND GRAVITY STORM DRAINAGE SYSTEM.

For underground storm drainage design comply with the documents referenced in the paragraph titled, “Design Criteria” in Chapter 3, or the following criteria, whichever is more stringent.

a. Provide straight alignments for piping between storm drainage structures. Use of curvilinear alignment is not allowed for pipes with a diameter of 48 inches (1200 mm) or less. For pipes with a diameter greater than 48 inches (1200 mm) use of curvilinear alignment may be allowed with explicit authorization by the Government.

b. Deflection at structures must not be less than 90 degrees for main line flows and not less than 60 degrees for contributory flows, as measured from the centerline of the mainline discharge. See Figure 3-1.

Figure 3-1 Deflection at Structures



c. Storm drainage piping must not pass under buildings and must be a parallel distance of at least 10 feet (3.0 m) from building foundations.

d. Avoid conflicts with other utilities.

e. Conflict structures will not be allowed without Government approval.

f. Comply with state or applicable regulatory agency's requirements for separation distances between utilities and other public health and safety issues.

g. Provide a structure at collection and inlet points, at changes in horizontal or vertical alignment, at pipe junctions and with minimum spacing of a pipe run according to Table 3-1. Provide a discharge structure wherever flow changes from piped to open channel flow.

Table 3-1 Storm Structure Spacing Criteria

Pipe Diameter		**Maximum Spacing**	
inches	mm	feet	meters
12 – 24	300 – 600	300	91.4
27 – 36	675 – 900	400	121.9
42 – 54	1050 – 1350	500	152.4
60 and up	1500 and up	1000	304.8

h. In the design of culverts and storm drains, account for headwater and tailwater and their effects on hydraulic grade line and capacity.

i. The following upstream controls limit headwater elevation:

   1. Not higher than an elevation that is 18 inches (450 mm) below the outer edge of the shoulder at its lowest point in the grade.

   2. Upstream property damage.

   3. Elevations established to delineate National Flood Insurance Program or other floodplain zoning.

   4. HW/D is at least 1.0 and not to exceed 1.5 or the local requirement. Where HW is the headwater depth from the culvert inlet invert and D is the height of the barrel.

   5. Low point in the road grade which is not necessarily at the culvert location.

   6. Elevation of terrain and ditches that will permit flow to divert around the culvert.

j. The tailwater elevation in the storm drain outfall must be either the average of the critical depth and the height of the storm drain conduit, (dc + D)/2, or the mean high tide if tidal conditions are present, whichever is greater. Storm drains must be designed for open channel flow. The hydraulic grade line for the storm sewer system must not exceed the pipe crown elevation unless the outfall is submerged. If the controlling tailwater elevation is above the crown elevation of the outfall, the hydraulic grade line for the storm sewer system must not exceed one foot (300 mm) above the crown, or one foot (300 mm) below the structure rim or gutter flow line at inlets, whichever is the lower elevation at each structure.

k. At structures, set the invert elevation of the inlet pipe equal to or greater than the invert elevation of the outlet pipe to minimize the hydraulic turbulence at the junction in accordance with Table 3-2.

m. The downstream pipe configuration, slope, and size must have capacity for the upstream hydraulic peak flow. The pipe size must not decrease downstream in the direction of flow.

n. Locate drainage structures out of paved areas wherever possible. Adjust structure locations to avoid primary wheel tracks when structures must be located in roads.

o. During design evaluate the potential for infiltration of fine soils into drainage pipe joints and coordinate with the Installation to see if it is a known maintenance issue. Specify watertight joints to mitigate the possibility.

Table 3-2 Minimum Invert Elevations

Item Description	Requirement	Best Practice
Main Flow Line[1] (change in grade or depth of pipe do not adversely affect design)	Match inverts[2]	Match crowns[3]
Main Flow Line or Contributory line (lateral) of same size diameter	Match inverts[2]	0.1 feet (30 mm)
Contributory line (lateral) of smaller diameter	0.1 feet (30 mm)	Match crowns[3]

1. Applicable for pipes that are the same size or smaller diameter.
2. In areas where the grade is relatively flat or significantly steep, matching invert elevations will reduce the depth of pipe and may increase headloss.
3. Matching crown line elevations may slightly reduce headloss; however, setting the invert elevation of the outflow pipe at least 0.1 feet (30 mm) lower than the lowest inflow pipe invert elevation is preferred.

3-5.2 Minimum Pipe Size.

Use a minimum inside diameter of 12 inches (300 mm) for storm drainage piping (not including roof drainage piping) for runs 50 feet (15.2 m) or less and where the existing downstream pipe is a 12-inch (300 mm) inside diameter with sufficient capacity; otherwise, use a minimum inside diameter of 15 inches (375 mm).

3-5.3 Minimum and Maximum Cover.

Use the paragraphs below, as applicable, or perform calculations to determine minimum and maximum cover, pipe material, pipe strength, and bedding requirements to accommodate the imposed dead and live loads during and after construction for all pipes. Minimum and maximum cover tables, for selected pipe material, may be used for single barrel applications with equivalent shapes and loadings. Refer to Chapter 9 of AC 150/5320-5 for additional design guidance on minimum and maximum cover. Account for loads from expected maintenance equipment in non-paved areas.

3-5.3.1 Minimum Cover.

Where the live load does not exceed H-20 Highway loading, the minimum cover for single barrel circular concrete pipe, reinforced concrete pipe, corrugated aluminum pipe, corrugated steel pipe, structural plate aluminum alloy pipe and structural plate steel pipe must be the most stringent of the following requirements:

- Equal to or greater than 24 inches (600 mm);
- Equal to or greater than one-half of the pipe diameter; or

- Equal to or greater than the frost penetration depth minus the inside diameter of the pipe. Best Practice: Equal to or greater than the frost penetration depth minus one-half of the pipe diameter.

[C] 3-5.3.1 Minimum Cover

Frost penetration depth minus the inside diameter is used to keep the invert of the pipe below the frost penetration depth.

Frost penetration depth minus the one-half of the inside diameter is used to keep the springline of the pipe below the frost penetration depth. The springline is the horizontal centerline of the pipe section.

Use UFC 3-301-01 to determine the minimum frost penetration depth. For pipe under a minimum 6 inch (150 mm) rigid pavement section, minimum cover may be reduced to 12 inches (300 mm) from the top of pipe to the bottom of the rigid pavement section if:

- Single barrel application;
- Live load does not exceed H-20;
- ASTM C76 or ASTM C76M, Class V, circular reinforced concrete pipe is used; and
- Design assumptions and calculations are approved by the Government Civil Engineer.

3-5.3.1.1 Airfields.

Use Tables 9-9 included in Chapter 9 of AC 150/5320-5 as applicable or determine minimum cover based on project specific loads and conditions.

3-5.3.2 Maximum Cover.

Use Tables 9-1 through 9-7 in Chapter 9 of AC 150/5320-5 as applicable or determine maximum cover based on project specific loads and conditions.

3-5.4 Design Velocity.

Provide a minimum full flow velocity as indicated in Table 3-3. Determine full flow velocity using the Manning equation, without surcharge.

Table 3-3 Design Velocity

Item Description	Requirement	Best Practice
Full Flow Velocity	Min. 2.5 ft/sec (0.76 m/sec)	Min. 3 ft/sec (0.91 m/sec)

For storm drain system constructability, a minimum slope of 0.2 percent is recommended. The minimum full flow velocity requirement must be met regardless of the pipe slope.

3-5.5 Manning's Roughness Coefficient.

Use Manning's roughness coefficient, "n" of 0.013 for smooth concrete pipe. For other drainage materials see state or local regulatory agency's requirement.

3-5.6 Material Selection.

Provide storm drain system materials in conformance with the UFGS to meet specific site conditions and soil characteristics. Consider thermal expansion of pipe material based on pipe location and temperatures of stormwater.

3-5.7 Culverts and Outfalls.

Culverts and outfalls must have headwalls, endwalls, wingwalls, flared end sections, or mitered end sections at free outlets. In areas of seasonal freezing, the structure must also be designed to preclude detrimental heave or lateral displacement caused by frost action. The most satisfactory method of preventing such damage is to restrict frost penetration beneath and behind the wall to non-frost-susceptible materials. Positive drainage behind the wall is also essential. Outlets and endwalls must be protected against undermining, bottom scour, damaging lateral erosion, and degradation of the downstream channel.

3-5.7.1 Security and Storm Drainage System Components.

Provide security barriers at all locations where security fences must cross drainage ditches or swales to ensure that intruders are prevented from passing under the fence. Use protective measures for pipes crossing under security fences with diameters larger than 10 inches (250 mm).

3-5.8 Storm Structures.

Storm structures for roads and site drainage must be in accordance with the UFGS, state DOT standards and specifications where the project is located or the requirements of the applicable local regulatory agency that governs stormwater management, whichever is more stringent. Structures must provide access for maintenance. Internal dimensions must not be less than 2 feet (0.6 m) in any one direction. Ensure that catch basins, curb inlets, and manholes are of adequate size to accommodate inlet and outlet pipes.

Provide structures of cast-in-place or precast concrete. Masonry structures are allowed for shallow installations less than 5 feet (1.5 m) in depth. Design structure frames, covers and grates to withstand traffic loadings and meet any additional requirements set forth in the using agency criteria for the particular application. Select grate type based on such factors as hydraulic efficiency, debris handling characteristics, pedestrian and bicycle safety, and loading conditions. Grates in traffic areas must be able to withstand traffic loads.

3-5.8.1 Airfields.

Use frames, covers, and grates capable of withstanding airfield traffic loadings and meeting any additional requirements set forth in the using agency's criteria. Isolate airfield structures from the pavement section. Provide structures of cast-in-place or precast concrete; do not use masonry structures in airfield construction. Watertight joints are recommended under airfield pavements.

Use ductile iron or steel frames, grates and covers. Frames, grates, and covers must be designed to withstand maximum aircraft wheel loads, considering the gear configuration, of the largest aircraft using or expected to use the facility. Provide hold-down devices to prevent grate displacement by aircraft traffic. Commercially manufactured frames and grates that have been designed specifically for aircraft loads may be used. When manufactured grates are used, the manufacturer must certify the design load capacity of each type of structure.

3-5.8.1.1 Diagonal Routes.

For structures that will be required to support both in-line and directional traffic lanes such as diagonal taxiways or apron taxi routes, do not consider load transfer at expansion joints in the design process; however, if specific knowledge about the long-term load transfer characteristics of a particular feature supports the use of load transfer in the design of a particular drainage structure, then an exception can be allowed and load transfer considered.

3-6 STORMWATER MANAGEMENT FACILITIES.

Design stormwater management facilities in accordance with the criteria referenced in the paragraph titled, "Design Criteria" in Chapter 3. The selected approach must conform to stormwater management regulations and applicable stormwater management agreements.

Include an overflow or bypass device for inflow volumes in excess of the treatment volume, or, if applicable, the peak attenuation volume. Ensure stormwater overflow does not adversely affect the stormwater management facility or pertinent site features such as building function, parking, and roads for the service life of the facility, surrounding sites over the service life of the surrounding facilities, and future forecasted land use changes.

3-6.1 Safety and Storm Drainage System Components.

Provide protective measures for stormwater management facilities such as detention and retention ponds in residential housing areas and other areas frequented by children in accordance with the applicable requirements of the locality, State or Host Nation equivalent. Protective measures include but are not limited to appropriate site selection for the storm water management facility or providing a fenced enclosure surrounding the facility. When provided, fence must be at a minimum of 4 feet (1.2 m) high with locking access gates.

3-6.2 Airfields.

Avoid stormwater management facilities with surface storage that attract wildlife to the facility; avoid a BASH issue.

3-7 STORMWATER PUMP STATIONS.

Use of stormwater pump stations is not allowed except with explicit authorization by the Government. Design stormwater pump stations in accordance with UFC 3-240-01. Use Best Practices documents Pumping Station Design and WEF MOP FD-4 for guidance.

3-7.1 Existing Pump Stations: Upgrades and Additional Flow.

Existing pump stations may be upgraded where a complete hydraulic analysis shows that the upgraded pump station can operate at the new capacity and in conformance with the jurisdictional requirements. Include effects on the existing force main to its point of discharge in the hydraulic analysis, and if networked, the effects on all other pump stations connected to the system. This analysis is required whenever additional flow is added to a pump station, even if physical changes to the station are not proposed.

This Page Intentionally Left Blank

CHAPTER 4 PAVEMENTS

4-1 SURFACED AND UNSURFACED ROADS AND SITE PAVEMENTS.

Provide geometric design of vehicular roads in accordance with Chapter 2 of this UFC. Unless specified otherwise in project specific requirements, design pavement based upon anticipated vehicles and loadings for a 25 year life; however, sections shall not be less than the minimums indicated below. Use pavement design criteria and procedures recognized by the DOT in the state in which the project is located or UFC 3-250-01. When state design criteria and procedures are used, the entire pavement section must conform in every detail to the applicable state criteria and materials must conform to the DOT material specifications.

Use UFC 3-250-01 for design of roads and parking areas trafficked by special military vehicles and in areas outside of the United States. Special military vehicles include, but are not limited to: cranes, aircraft tow tractors, forklifts, container handling vehicles, tracked vehicles, heavy military cargo trucks greater than 10,000 pounds (4535 kg) including but not limited to Heavy Expanded Mobility Tactical Truck, Heavy Equipment Transport Systems, Palletized Load Systems (M1074, or M1075), Mine-Resistant Ambush Protected, and Stryker vehicles.)

4-1.1 Frost Conditions.

The design must address seasonal frost conditions per State DOT. For overseas locations or locations where the State DOT does not address seasonal frost conditions use UFC 3-250-01.

4-1.2 Recycled Materials.

Limit recycled materials to limits in applicable UFGS sections. Recycled concrete and recycled asphalt affected by Alkali-Silica Reaction (ASR) must not be used as subbase or base course materials.

4-1.3 Flexible Pavements.

The minimum thickness of the flexible pavement section for roads and parking areas is 6 inches (150 mm). The typical flexible pavement section consists of an asphalt surface course, aggregate base course, and an optional subbase course.

4-1.3.1 Surface Course.

The minimum thickness of the surface course is 2 inches (50 mm).

4-1.3.2 Base and Subbase Courses.

The minimum thickness of the aggregate base course is 4 inches (100 mm). Provide a thicker aggregate base or subbase(s) if required to protect weak subgrade soils or to reduce frost penetration into the subgrade.

4-1.4 Rigid Pavements.

The minimum flexural strength for portland cement concrete pavements at 28 days is 650 psi (4.48 MPa). No reduction in thickness will be allowed for increased flexural strength. The minimum compressive strength for portland cement concrete sidewalks, curbs, and gutters is 3500 psi (25 MPa). Provide air entrainment in all exterior concrete pavements in areas subject to freezing temperatures. Use plain (non-reinforced) concrete for rigid pavements for roads and parking areas at military installations; use reinforced concrete for odd-shaped slabs or mismatched joints. An odd-shaped slab has a length to width ratio greater than 1.25:1. Clearly indicate on the drawings the specific individual slabs requiring reinforcement.

During design evaluate the potential for ASR and specify requirements for aggregates and cementitious materials to mitigate the possibility of ASR occurring in the concrete job mix formula for the project.

4-1.4.1 Concrete Pavement.

4-1.4.1.1 Plain Concrete.

The minimum thickness of plain concrete for roads and parking areas is 6 inches (150 mm).

4-1.4.2 Joints.

Provide joints in a manner to form a regular rectangular pattern and to prevent random or uncontrolled cracking. Do not allow the use of insertable forms for contraction joints. The use of keyed joints is discouraged, but may be used subject to evaluation of subgrade strength, loadings, pavement thickness, and details in UFC 3-250-01 and UFC 3-250-04. Dowels and tie-bars shall not be placed closer than 0.6 times the dowel or tie-bar length from the planned joint line.

4-1.5 Permeable Pavements.

Permeable pavements (such as permeable interlocking concrete pavers or pervious portland cement concrete) may be used on site pavements, such as parking lots, provided there is documented evidence of successful past performance for similar applications. Provide signage to indicate salting and sanding is not allowed for pervious portland cement concrete. Permeable pavements may not be used in areas where there is the potential to contaminate existing soils, such as fuel areas, industrial storage, marinas, vehicle maintenance or service areas. Porous asphalt pavement is not allowed. Compacted gravel is not considered permeable pavement.

Use Best Practices documents, Permeable Interlocking Concrete Pavements Manual - Design, Specification, Construction, Maintenance, from the Interlocking Concrete Pavement Institute and ACI 522R for additional design guidance.

4-1.6 Aggregate Pavements.

Minimum thickness for aggregate surfaced roads and parking areas is 8 inches (200 mm).

4-2 AIRFIELD PAVEMENTS AND MARKINGS.

Use UFC 3-260-01, UFC 3-260-02 and UFC 3-260-04 for the design of airfield pavements and airfield markings. Key joints for rigid pavements are not allowed for airfields.

This Page Intentionally Left Blank

APPENDIX A BEST PRACTICES

This appendix identifies background information and practices for accomplishing certain civil design and engineering services. The Designer of Record (DoR) is expected to review and interpret this guidance and apply the information according to the needs of the project. If a Best Practices document has guidelines or requirements that differ from the UFGS or UFC, the UFGS and the UFC must prevail. If a Best Practices document has guidelines or requirements that are not discussed in the UFGS or UFC, the DoR must submit a list of the guidelines or requirements being used for the project with sufficient documentation to the Government Civil Engineer for review and approval prior to completing design.

A-1 WHOLE BUILDING DESIGN GUIDE.

The Whole Building Design Guide (WBDG) (www.wbdg.org) provides additional information and discussion on practice and facility design, including a holistic approach to integrated design of facilities.

The WBDG provides access to criteria, standards, and codes for DoD Military Departments. The criteria includes UFC, UFGS, Performance Technical Specifications, design manuals, and specifications. For approved Government employees, it also provides access to non-government standards.

A-2 BEST PRACTICES CIVIL ENGINEERING RELATED GUIDANCE.

A-2.1 Building Location and Orientation.

Consider the following in regard to spacing between buildings:

- Functional relationships
- Operational efficiency
- Future expansion
- Open space – passive and active

A building's relationships to its support facilities and to other primary facilities influence its location. Proximity to access roads, existing utility lines, and other compatible functions (especially if they share facilities or have interdependent activities) also influence location. When a building is a shared facility, it should be centrally located and within a reasonable distance from all participating users. Buildings which depend upon a shared facility should orient either the front building face or a doorway area towards the shared facility.

A-2.2 Flood Hazard Areas.

A-2.2.1 National Defense Authorization Act for Fiscal Year 2019.

PL 115-232, Section 2805(a)(4) of The National Defense Authorization Act for Fiscal year 2019 requires a flood risk reduction plan or minimum building elevations for non-essential and essential buildings. The flood design classes found in Table A-1 can be used as guidance when evaluating a buildings essential or non-essential status.

Table A-1 Essential and Non-Essential Guidance

ASCE 24-14 Flood Design Class	NDAA Building Classification
1 (minimal risk; non-essential facilities)	No Impact to mission
2 (moderate risk; non-essential facilities)	Non-Essential
3 Subcategory 3a (high risk; non-essential facilities) Building types (1) through (9)	Non-Essential
3 Subcategory 3b (high risk; essential facilities) Building types (10) and (11)	Essential
4 (high risk; essential facilities)	Essential

A-2.2.2 National Defense Authorization Act for Fiscal Year 2020.

PL 116-92, Section 2804, required DoD to develop sea level rise projection criteria and provide criteria to project designers and master planners on how to use sea level rise projections.

PL 115-232, Section 2805 as amended by PL 116-92 requires DoD to include how projects will be impacted by projected mean sea level rise over the lifetime of the project.

A-2.2.3 National Defense Authorization Act for Fiscal Year 2022.

PL 115-232, Section 2805 as amended by PL 117-81 requires DoD to disclose if a project will be sited within or partially within a 500-year floodplain if outside a 100-year floodplain or be impacted by sea level rise projections and adopting hydrologic, hydraulic, and hydrodynamic data, methods, and analysis that integrate changes in flooding over the anticipated service life of the facility.

A-2.2.4 Executive Order 11988.

EO 11988 establishes key terms, sets the 1 percent ACE, also referred to as the 100-year flood, as the minimum flood requirement and identifies floodplain management concepts.

A-2.2.5 DoD Memorandum on Floodplain Management for DoD Installations.

DTM 22-003 canceled DoD Memorandum on Floodplain Management for DoD Installations dated 11 February 2014.

A-2.2.6 DoD Memorandum on Improving Defense Installation Resilience to Rising Sea Levels.

DTM 22-003 incorporates and supersedes DoD Memorandum on Improving Defense Installation Resilience to Rising Sea Levels dated 24 February June 2020.

A-2.2.7 DTM 22-003, Directive-type Memorandum “Flood Hazard Area Management for DoD Installations”

DTM 22-003 establishes policy, assigns responsibilities, and prescribes procedures to incorporate:

- The Climate-Informed Science Approach, when available;
- Flood hazard management practices stipulated by Section 2805 of Public Law 115-232 and Section 2806 of Public Law 116-92; and
- Implements flood hazard requirements in EO 11988, EO 13690, and EO 14030.

A-2.3 Flood Protection Systems.

In addition to 44 CFR 65.10, considered other design criteria for design of levees and floodwalls. Evaluate soil types, including but not limited to seepage, scour and erosion, structure type, embankment stability, foundation stability, settlement, and interior drainage. Levee and floodwall systems may include active and passive components such as gates, barriers and movable walls that would need to be closed prior to a flood. When addressing operation plans include appropriate warning systems and test in place. Best Practice documents may include EM 1110-2-1913, EM 1110-2-2104, EM 1110-2-2502, EM 1110-1-1904, EM 1110-2-2504, ETL 1110-2-583, EM 1110-2-1619, ER 1105-2-101, ER 1110-2-1150, and ETL 1110-2-299.

A-2.3.1 Buildings and Structures.

Based on an individual site analysis, it may be more advantageous to protect a facility or a group of facilities with a flood protection system. Flood protection systems meeting the minimum design requirements in 44 CFR 65.10 may be accredited by FEMA for protection against the 1 percent ACE. ASCE 24-14 requires flood protection systems to be shown on the community's flood hazard map prior to being considered as providing adequate protection.

A-2.4 Roads.

Roads and similar infrastructure do not need to be designed to the same standard as buildings and structures. An engineering analysis should be conducted to determine the DFE.

A-2.5 Vehicle Circulation.

Consider bicycle lanes and pedestrian corridors to reduce vehicle traffic.

A-2.5.1 Access and Service Drives.

Consider the following in locating access drives:

- Spacing.
- Corner Clearances.
- Sight Distances.
- Left Turns.
- Entrances.
- Grading and Drainage.
- Traffic Controls.

When a safe sight distance cannot be met, consider the following alternatives:

- Removal of sight obstructions.

- Relocation of the access drive to a more favorable location along the access road or an alternate access road.
- Prohibition of critical movements at the access drive.

A-2.6 Parking Areas.

Where slopes are steep consider providing more than one level of parking.

Table A-2 Parking Space Guidelines for Non-Organizational Vehicles

Facility	Number of Parking Spaces
Administration, Headquarters, and Office Buildings	60 percent of assigned personnel
Bakeries	75 percent of employees
Bank and Credit Union, when not included in a Community Shopping Center	2 percent of customers served
Cafeteria, Civilian, when not included in a Community Shopping Center	15 percent of seating capacity
Central Food Preparation Facilities	38 percent of employees
Chapels	30 percent of seating capacity
Child Development Centers (Staff Parking)	80 percent of staff
Child Development Centers (Patron Parking)	10 percent of children served
Commissary Stores, Food Sales, when not included in a Community Shopping Center	Contact DeCA for parking requirements
Community Shopping Center, including such elements as Main Exchange, Miscellaneous Shops, Restaurant, Commissary Stores, Food Sales, Bank, Theater, Post Office	4 percent of customers served
Dental Clinic Parking	3 spaces per treatment room
Dormitories, BEQ, Enlisted Unaccompanied Personnel Housing	70% of design capacity
Enlisted Personnel Dining Facilities (Staff Parking)	38 percent of employees
Enlisted Personnel Dining Facilities (Patron Parking)	8 percent of enlisted personnel served

Facility	Number of Parking Spaces
Exchanges, Main, when not included in a Community Shopping Center	25 percent of customers served
Family Housing	2.5 spaces per living unit
Field House, combined with Football and Baseball Facilities	1 percent of military strength served
Fire Stations	100% of largest shift
Guard Houses, Brigs, Military Police Stations	30 percent of guard and staff strength
Fitness Center	1 percent of military strength served
Laundry Plants and Dry Cleaning Plants	38 percent of employees
Central Libraries	1 space for each 500 ft^2 (46.5 m2) gross area of floor area
Branch Libraries	8 spaces
Maintenance Shops	40 percent of employees
Medical Facilities	Use UFC 4-510-01
Officers' Quarters, BOQ, Officer Unaccompanied Personnel Housing	100% of living suites
Schools, Dependent with Auditorium	2 spaces per classroom, plus 15 percent of auditorium seats
Schools, Dependent without Auditorium	2 spaces per classroom
Security Offices: Population served 100 to 2,000	5 spaces
Security Offices: Population served 2,001 to 4,000	10 spaces
Security Offices Population served 4,001 to 6,000	15 spaces

Facility	Number of Parking Spaces
Security Offices Population served 6,001 to 10,000	20 spaces
Security Offices Population served 10,001 and over	To be based on a special study
Service Clubs (Open Mess and Club Facility)	2 percent of military strength served
Swimming Pools	20 percent pool capacity
Temporary Lodging Facilities	90 percent of bedrooms
Theaters, when not included in a Community Shopping Center	25 percent of seating capacity
Training Buildings (Staff Parking)	70 percent of staff
Training Buildings (Student Parking)	60 percent of students
Warehouses	40 percent of employees

A-2.6.2 On-Street Parking.

Consider the width of the travel lane and the types of vehicles. A parking lane width of 10 feet (3.0 m) to 12 feet (3.6 m) is recommended for delivery vehicles.

A-2.6.3 Off-Street Parking.

Consider the following in the parking lot design:

a. Maintain two-way movement.
b. Avoid dead end parking lots.
c. Provide cross aisles every 20 to 30 spaces.
d. Provide curbs or painted lines at the ends of stalls for vehicle control.
e. Provide adequate walkway width to allow comfortable pedestrian movement in areas of bumper overhang.
f. Consider requirements for snow removal.

A-2.6.3.1 Islands and Medians.

Locate islands at the ends of parking stalls and at the intersections of parking aisles. The islands establish turning radii for vehicular movement and protect end stalls. Consider the height of driver's eye level when providing shrubs and small trees.

A-2.6.4 Compact Parking.

The use of compact space is limited for the following reasons:

- The potential for building function to change.
- They do not comply with accessible parking requirements.
- Compact spaces limit the amount of available parking for standard vehicles.

A-2.6.5 Motorcycle Parking.

- Locate parking close to building entrances.
- Locate parking in parking lot corners.
- Provide signage and pavement markings.

A-2.6.6 Buffers.

Provide a 20 feet (6.1 m) wide buffer strip to separate parking areas from adjacent roads.

A-2.6.7 Drop Off Areas.

Design considerations for drop-off areas include adequate width and length to accommodate the safe movement of vehicles in and out of the flow of traffic.

A-2.6.8 Delivery and Service Zones.

Delivery and service trucks need to access service doors in buildings. Delivery may require dock facilities, which need to accommodate the necessary maneuvering into and out of the dock. Design considerations for delivery zones include:

a. Separate service access drives from parking circulation because these functions are incompatible. Service access that is required through a parking area goes straight to and straight out of the service area.
b. On a dead-end service drive, provide the necessary turning movements.
c. Provide for visual screening with walls, fences, or plant material.

A-2.6.8.1 Garbage Collection Areas.

The design of garbage collection removal areas (dumpster pads) is controlled by the frequency of waste removal. Coordinate with the Installation to determine the frequency of waste removal and determine appropriate dumpster pad size. Consider screening solid waste removal areas with fences, walls, or plant material in accordance with the Installation Appearance Plan.

A-2.6.9 Facilities with Drive Thru Lanes.

Facilities with one or more drive thru lanes, such as banks, pharmacies, and fast–food restaurants, require careful and clear establishment of traffic patterns and a continuous traffic flow. The standard configuration for a single – or double-service position facility does not lend itself to a two–lane approach and departure design. It usually relies on some form of loop system. Average stacking distance is recommended as 180 feet (54.8 m). Stacking space is determined by subtracting the number served (serving time averages 2-3 minutes per customer) from the expected arrivals per 15-minute period (4-14 minutes is the average) and multiplying the difference times 20 feet (6.1 m). Recommended parking for facilities with drive thru lane(s) is 17.5 spaces per 1,000 sq. feet (93.0 square meters) of building area. Design considerations for facilities with drive thru lane(s) include:

- Maintain traffic lanes into and out of the drive thru windows while working with other on-site vehicular traffic flow including parking.
- Minimize interference with pedestrian traffic flow.
- Provide the recommended average stacking distance in the drive-thru lanes.
- Provide the recommended average stacking distance on-site to prevent traffic safety conflicts with access roads.
- Use curb and planting islands for vehicle control.
- Provide adequate pavement markings.

A-2.7 Rational Formula.

Use the Rational Formula to determine peak flow from small watersheds. The Rational Formula is based on the following assumptions:

- Peak flow occurs when the entire watershed is contributing runoff.
- The rainfall intensity is uniform over a period of time equal to or greater than the time of concentration.
- The frequency of the peak flow equals the frequency of the peak rainfall intensity. For example, the 10-year peak rainfall will produce the peak 10-year volume.

These assumptions are not fully valid in every case. However, if the Rational Formula is used on small watersheds, parking lots, or small developed areas, the errors will not be large.

The most common form of the Rational Formula is:

$$Q = c\,I\,A$$

Where:
Q = peak flow in cfs.
C = a dimensionless coefficient that is a function of the watershed characteristics.
I = rainfall intensity in inches per hour.
A = watershed area in acres.

A-2.8 Airfield Pavements.

For additional guidance on design and construction of airfield pavements see IPRF-01-G-002-1 and ACPA Document No. JP007P.

B-2 DEFINITION OF TERMS.

Climate-Informed Science Approach: The elevation and flood hazard area that result from using the best-available, actionable hydrologic and hydraulic data and methods that integrate current and future changes in flooding and tidally-influenced inundation based on climate science. This approach will also include an emphasis on whether the action is a critical action as one of the factors to be considered when conducting the analysis.

Non-Tidally Influenced Locations: Locations that are not subject to oceanic astronomical tidal influence.

Tidally Influenced Locations: Coastal and inland locations with oceanic astronomical tidal influence.

Use the following order of precedence for additional definitions:

1. The applicable legal definition.
2. The definitions provided in the applicable building code.
3. The definitions provided in the applicable standard.

Record of Changes (changes are indicated by **1**\ ... /**1**/)

Change No.	**Date**	**Location**
1	09 FEB 2021	1. Deleted references to American Society of Heating, Refrigeration, Air-conditioning Engineers (ASHRAE 189.1) in Chapter 2, paragraphs 2-3.2, 2-6.12, Appendix B, and Appendix C. 2. Revised Chapter 2, paragraphs 2-3.2 and 2-6.12 for tree requirements in parking areas to comply with International Green Construction Code (IgCC). 3. Added International Green Construction Code (IgCC) to Chapter 2, paragraphs 2-6.1, 2-6.12, 2-6.13, 2-7, Appendix B, and Appendix C.

This UFC supersedes UFC 3-201-02 Change 1, dated November 2009.

FOREWORD

The Unified Facilities Criteria (UFC) system is prescribed by MIL-STD 3007 and provides planning, design, construction, sustainment, restoration, and modernization criteria, and applies to the Military Departments, the Defense Agencies, and the DoD Field Activities in accordance with USD (AT&L) Memorandum dated 29 May 2002. UFC will be used for all DoD projects and work for other customers where appropriate. All construction outside of the United States is also governed by Status of Forces Agreements (SOFA), Host Nation Funded Construction Agreements (HNFA), and in some instances, Bilateral Infrastructure Agreements (BIA). Therefore, the acquisition team must ensure compliance with the most stringent of the UFC, the SOFA, the HNFA, and the BIA, as applicable.

UFC are living documents and will be periodically reviewed, updated, and made available to users as part of the Services' responsibility for providing technical criteria for military construction. Headquarters, U.S. Army Corps of Engineers (HQUSACE), Naval Facilities Engineering Command (NAVFAC), and Air Force Civil Engineer Center (AFCEC) are responsible for administration of the UFC system. Defense agencies should contact the preparing service for document interpretation and improvements. Technical content of UFC is the responsibility of the cognizant DoD working group. Recommended changes with supporting rationale may be sent to the respective DoD working group by submitting a Criteria Change Request (CCR) via the Internet site listed below.

UFC are effective upon issuance and are distributed only in electronic media from the following source:

- Whole Building Design Guide web site http://www.wbdg.org/ffc/dod.

Refer to UFC 1-200-01, *DoD Building Code*, for implementation of new issuances on projects.

UNIFIED FACILITIES CRITERIA (UFC)
REVISION SUMMARY SHEET

Document: UFC 3-201-02, *Landscape Architecture*, unifies the landscape architectural criteria for DoD.

Superseding: UFC 3-201-02, 23 February 2009, including change 1 November 2009

Description: This document assimilates and applies current policies, technology, and environmental planning critical to the long-term success of DoD facilities and projects. The integration of government and industry codes, practices, materials, and reference works ensure the contemporary relevance of the UFC Landscape Architecture document.

Reasons for Document:

- Improve the quality-of-life at DoD facilities through informed, user-centric input to planning, design, construction, and maintenance projects.
- Encourage innovation and alternatives to planning, design, construction, and maintenance projects across the DoD.
- Integrate the DoD commitment to sustainable practices and Low Impact Development (LID).

Impact:

The following direct impacts will result from revision of this UFC:

- Design and construction initial cost benefit
- Energy and water efficiency
- Life-cycle cost reduction
- Facility functionality, safety, and security

Unification Issues:

For **Army** projects, comply with the Assistant Secretary of the Army Installations, Energy and Environment (ASA IE&E) Water Use Memorandums:

- ASA IE&E Memorandum, January 13, 2017, “Energy and Water Goal Attainment Responsibility Policy,” which sets policy and assigns responsibilities to achieve federal water use goals.
- ASA IE&E Memorandum, January 17, 2017, “Sustainable Design and Development Policy,” Update 5, 3-b Outdoor Water Use.

For **Navy and Marine Corps** projects, comply with UFC 4-750-02N, which includes design requirements for a variety of outdoor sports and recreational facilities.

TABLE OF CONTENTS

FIGURES

TABLES

CHAPTER 1 INTRODUCTION

1-1 PURPOSE AND SCOPE.

This UFC establishes minimum landscape architectural requirements and best practices to promote consistent landscape architectural quality for DoD facilities worldwide. Where other criteria, statutory or regulatory requirements are referenced, comply with the more stringent requirement.

1-2 APPLICABILITY.

This UFC applies to all DoD agencies and contractors involved in landscape architectural design and implementation of projects with site improvements for permanent DoD facilities worldwide. Use the information in this document for the site analysis, development of plans, specifications, calculations, and deliverables.

1-3 PROFESSIONAL REQUIREMENTS.

Design of all site improvement features must be accomplished by a licensed professional. All DoD military construction (MILCON) projects with site improvement costs over $250,000, must include a landscape plan with supporting details and specifications prepared by a registered professional (Architect, Engineer, or Landscape Architect) as required by the Federal Acquisition Regulations (FAR) (Subpart 2.1). Additional professional requirements and/or certifications may be required based upon specific project needs as defined in the project Request for Proposal (RFP).

1-4 GENERAL BUILDING REQUIREMENTS.

UFC 1-200-01, *DOD Building Code* provides applicability of model building codes and government-unique criteria for design disciplines and building systems, as well as accessibility, antiterrorism, safety, security, high performance and sustainability requirements.

1-5 CYBERSECURITY.

All control systems (including systems separate from an energy management control system) must be planned, designed, acquired, executed, and maintained in accordance with UFC 4-010-06, and as required by Individual Service Implementation Policy.

1-6 BEST PRACTICES.

Appendix A identifies background information, lessons learned, and proven best practices for landscape architectural design services. The information is considered guidance and not criteria, and is not intended to address all possible design solutions.

1-7 GLOSSARY.

Appendix B contains a list of acronyms, abbreviations, and definitions.

1-8 REFERENCES.

Appendix C contains a list of references used in this document. The publication date of the code or standard is not included in this document. Unless otherwise specified, the most recent edition of the referenced publication applies.

CHAPTER 2 LANDSCAPE ARCHITECTURAL SITE CRITERIA

2-1 INTRODUCTION.

The following requirements address specific landscape architectural design practices, site elements, and materials. These requirements have been compiled from DoD policy and industry standards.

2-2 LANDSCAPE ARCHITECTURAL SITE DESIGN.

The focus of DoD landscape architecture is to support the users' mission. Landscape architecture combines ecology, hydrology, engineering, planning, and functional design to create successful DoD facilities that achieve the following goals:

- Protect the health, safety, and welfare of all users.
- Elevate Installation functionality and appearance to enhance the quality of life.
- Establish a sense of place and unique identity.
- Preserve cultural and historic landscapes.
- Provide spaces considering 'human factors'.
- Achieve environmentally sustainable development and operations.
- Protect natural communities of plants and wildlife.
- Meet DoD requirements for outdoor water use and management.
- Utilize operation and maintenance plans to ensure successful long-term viability of landscapes.

Effective integration of the landscape architectural discipline into DoD projects requires early involvement, including participation in DD1391 development and project programming, pre-design, and schematic design development.

2-3 WATER USE MANAGEMENT.

2-3.1 General.

Prepare a water management plan that identifies the minimal amount of water required to sustain the project landscape. Develop a plan for how the water can be most efficiently delivered. Include application of reuse water (also called reclaimed or recycled water), when available in conformance with applicable installation and local water reuse policies and guidelines.

2-3.2 Potable Water Reduction.

It is the Department of Defense's policy that DoD Components reduce or eliminate the use of potable/domestic water for purposes of landscape maintenance, consistent with existing legal and contractual obligations. Use water-efficient irrigation strategies that comply with UFC 1-200-02 for required DoD reduction in combined indoor and outdoor potable water use. **1**\ Refer to the International Green Construction Code (IgCC), Chapter 6 "Water Use Efficiency"./1/

For water use management criteria, comply with the “Water Use for Landscape Architecture on Department of Defense Installations/Sites” (March 10, 2017) memorandum from the Office of Assistant Secretary of Defense for Energy, Installations, and Environment (OASD EI&E). Ornamental water features and irrigation systems must comply with this policy.

For Army projects: comply with the Assistant Secretary of the Army Installations, Energy and Environment (ASA IE&E) Water Use Memorandums:

- ASA IE&E Memorandum, January 13, 2017, “Energy and Water Goal Attainment Responsibility Policy,” which sets policy and assigns responsibilities to achieve federal water use goals.
- ASA IE&E Memorandum, January 17, 2017, “Sustainable Design and Development Policy,” Update 5, 3-b Outdoor Water Use.

For Navy projects: comply with the “Guidance for Xeriscaping on CNIC Installations (11010, 04 April 2017) memorandums from the Commander, Navy Installations Command.

2-4 CONSERVATION AND RESOURCE PROTECTION.

2-4.1 Natural Resources.

Coordinate with the Installation Environmental (EV) staff to obtain the project NEPA documentation, as applicable, for project specific requirements. Comply with seasonal limitations for site impacts specific to the threatened and endangered species present on site, including all clearing, site disturbance, and tree mitigation requirements.

2-4.2 Cultural Resources.

Discuss the project with the Installation Cultural Resources Manager (CRM) prior to design initiation, to ensure compliance with federal laws and DoD policies for cultural resources, including Section 106 of National Historic Preservation Act (NHPA) and DoD Instructions 4715.16, 4710.02, and 4710.03, or equivalent Host Nation agreements, as applicable. Coordinate with the CRM to identify relevant documentation from the site assessment concerning cultural resources located on or adjacent to the project site. Obtain any additional information necessary to complete the Section 106 consultation process, including the Integrated Cultural Resource Management Plan. Coordinate with the Installation CRM to identify existing cultural resources or tribal consultation agreement documents, such as a Programmatic Agreement, Tribal Consultation Protocol, Comprehensive Agreement, or Memorandum of Agreement. Consult with the CRM to gather appropriate cultural resources information for the project site for purposes of Section 106 compliance, including CRs listed in or eligible for inclusion in the National Register of Historic Places. Engage the CRM to consult with federally recognized tribes and Native Hawaiian Organizations (NHO) with historical or cultural affiliations with Installation lands as required by DoDI 4710.02 and DoDI 4710.03. Include activities that may impact cultural resources of traditional religious and/or cultural importance to the tribe or NHO, including sacred sites, or other resources to which tribes may retain treaty rights.

Coordinate with the CRM, tribes, NHO, Tribal Historic Preservation Officers, and State Historic Preservation Officers to avoid and minimize effects to the cultural resources. If an adverse effect cannot be avoided, partner with the CRM and external stakeholders to develop a memorandum of agreement to mitigate adverse effects. Collaborate with Installation CRM on methods to reduce water use and remove invasive species from historic landscapes. Consider potential impacts of plantings and furnishings to historic properties.

2-4.3 Viewsheds.

Preserve significant viewsheds as a part of initial project planning and design. Identify significant or historic viewsheds in the project RFP. Historic viewsheds and their features are those that are listed in, or eligible for, inclusion in the National Register of Historic Places. Implement screening elements as appropriate to minimize and mitigate impacts to significant and historic viewsheds. Work with the Installation CRM to consider impacts to historic viewsheds and their historical features, as a part of the Section 106 and tribal consultation responsibilities listed in 2-4.2 Cultural Resources.

2-4.4 Tree Preservation Plan.

Prepare a Tree Preservation Plan to identify existing vegetation to be preserved. Coordinate the Tree Preservation Plan with the Civil Engineer and include it as part of the Erosion and Sediment Control Plan. Calculate the tree critical root zone (CRZ) using a 1.5-foot (0.45 m) protection radius for each 1 inch (3 cm) of tree diameter measured at breast height (DBH).

Figure 2-1 Critical Root Zone Diagram

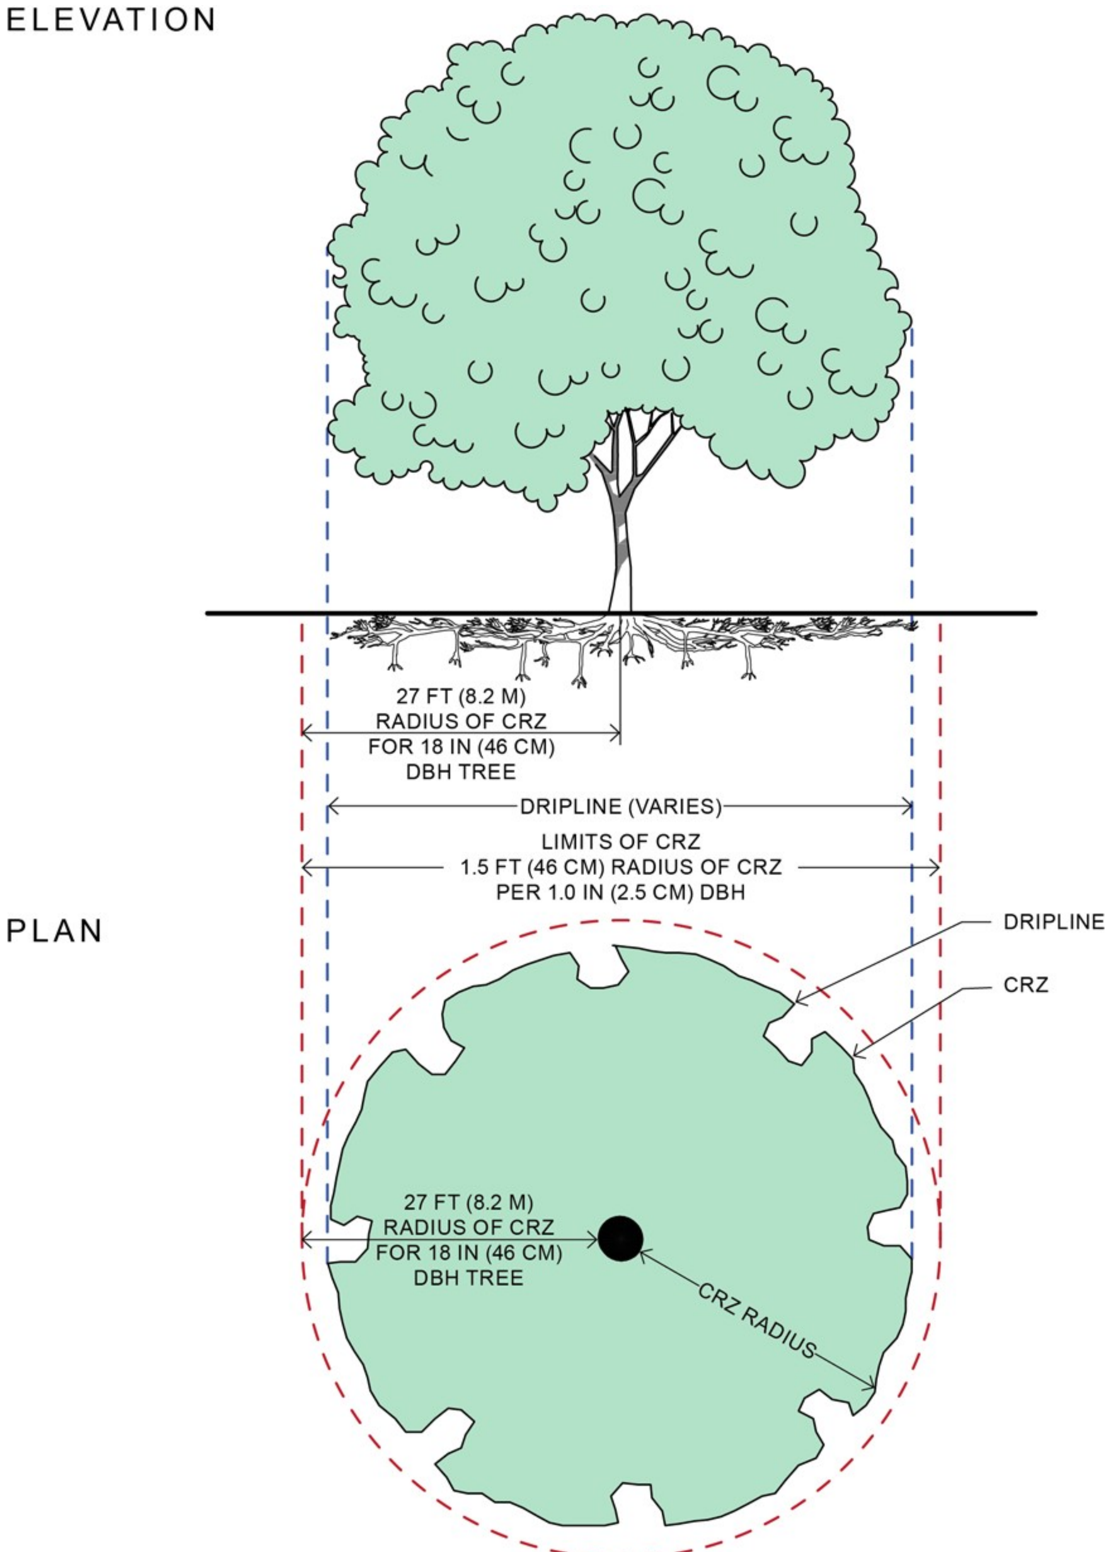

Figure 2-2 Sample Tree Protection Detail[1]

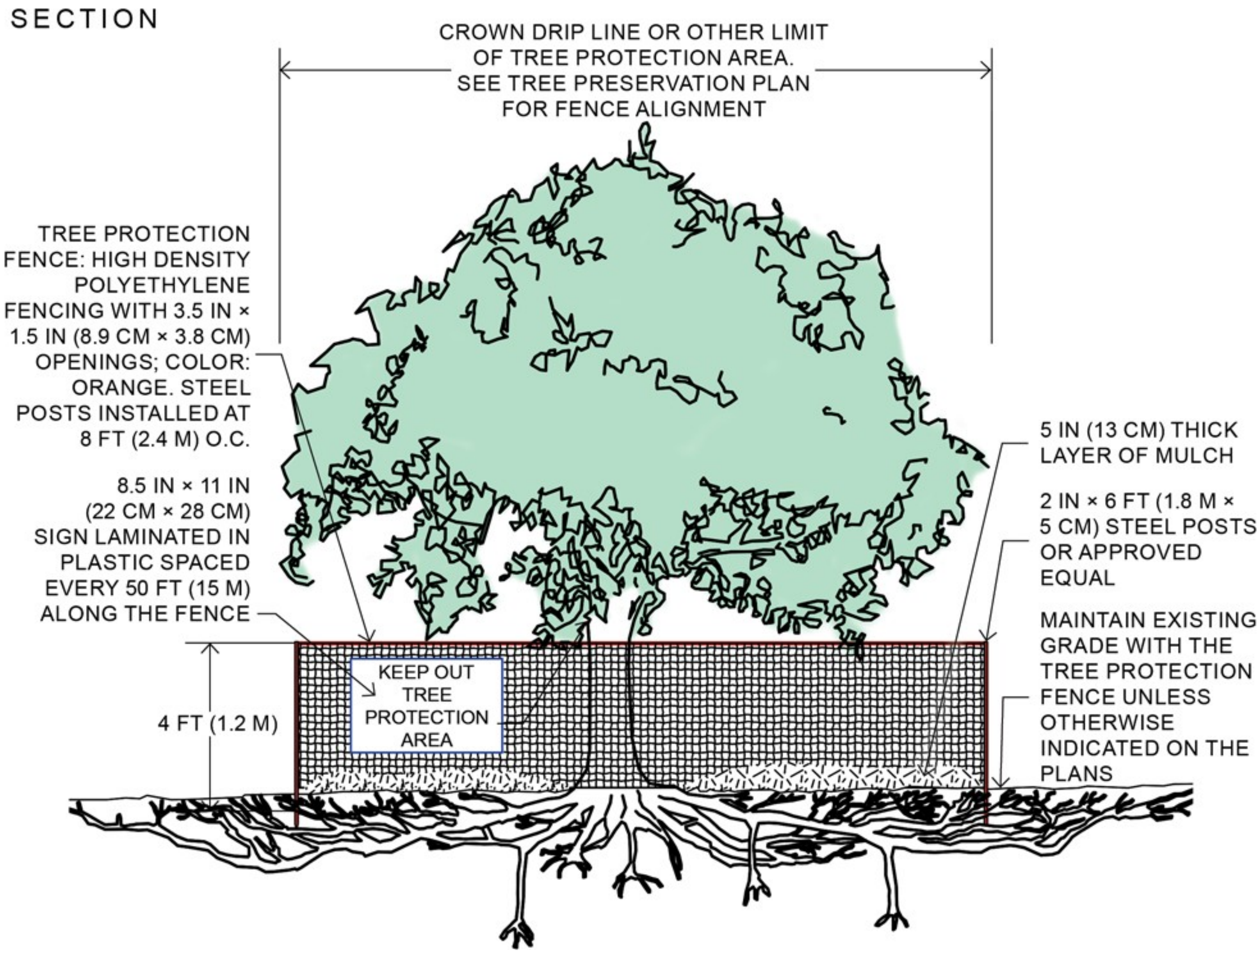


2-5 CIRCULATION AND ACCESSIBILITY.

2-5.1 General.

Employ a well-integrated circulation system with a network hierarchy that strengthens connectivity, reduces conflicts, and enhances the visual quality of the installation. Connect significant elements, destinations, and features. Promote design of streetscapes that balance vehicular traffic, pedestrian access, and safety of all users. Define goals with the end-user during conceptual design. Establish a comprehensive circulation network, hierarchy of uses, and times of day to optimize use.

Utilize UFC 3-201-01 for circulation requirements, including standards for street widths, sight lines, parking layouts, drop-off zones, and special areas.

[1] Adapted from Urban Tree Foundation, "Planting Details and Specifications," 2014, http://www.urbantree.org/details_specs.shtml.

2-5.2 Pedestrian Circulation.

Coordinate pedestrian circulation with the Transportation Component Plan for Installation Development Plans (IDP) and Area Development Plans (ADP).

Figure 2-3 Pedestrian Circulation[2]

2-5.3 Bicycle Facilities.

Utilize the American Association of State and Highway Transportation Officials (AASHTO) Guide for the Development of Bicycle Facilities for bicycle circulation design and multi-use trails.

2-6 PLANTING DESIGN.

2-6.1 Sustainable and Resilient Planting Design.

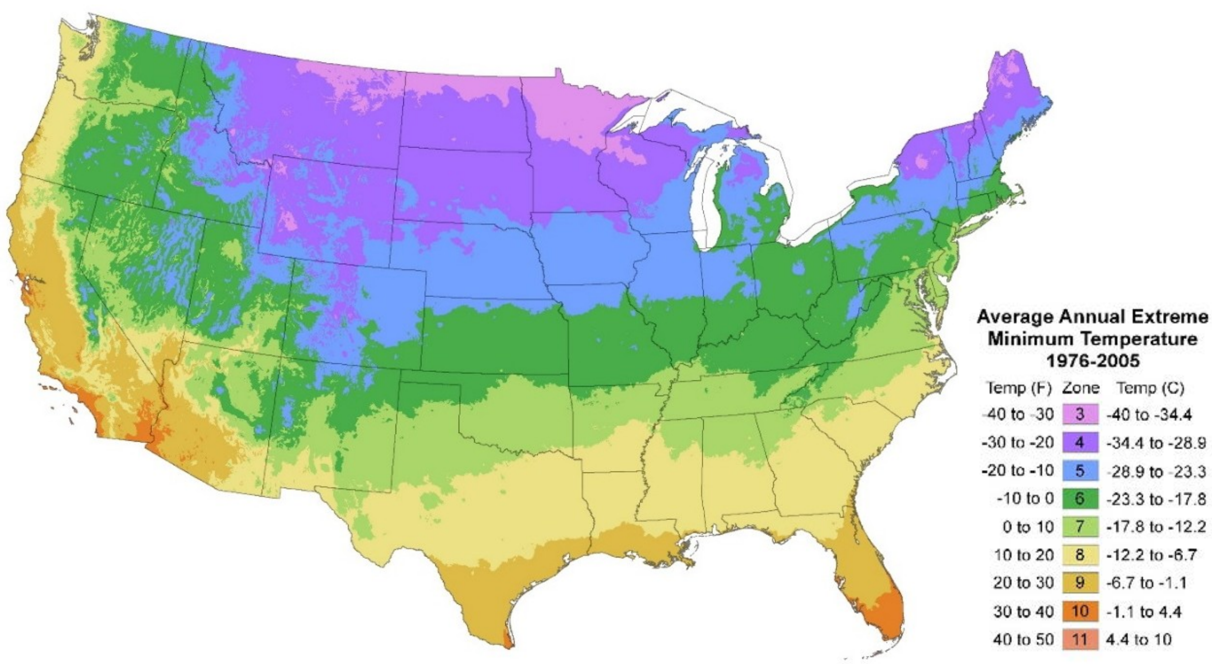
Design for water conservation and minimize maintenance requirements on all new and retrofitted landscape projects. Assess existing irrigated plant and turf areas for opportunities to reduce or eliminate existing irrigation systems. Use vegetation that does not require irrigation beyond the plant establishment period. Specify and install trees to provide shade for paving, vehicles, and pedestrians. Use only non-invasive vegetation; see Chapter 2-6.6 for requirements. \1\ Refer to the International Green Construction Code (IgCC), Chapter 6 “Water Use Efficiency”. /**1**/

[2] Image: CallisonRTKL, https://www.callisonrtkl.com/

Design plantings for climate resiliency and natural hazards:

- Select plant species and cultivars that can tolerate shifts in U.S. Department of Agriculture (USDA) plant hardiness zones. Recent shifts are reflected in the 2012 update to the USDA Plant Hardiness Zone Map (Figure 2-4). Future changes are projected. See Figure 2-5 for a composite model of future changes projected through 2040.
- Specify plant species and cultivars, based on regional conditions that will be resilient to extreme weather events.
- Specify plant materials to withstand flooding and saltwater intrusion from storm surge where those events are anticipated risks.
- Specify plant materials with high tolerance for wind strength along coastal areas.

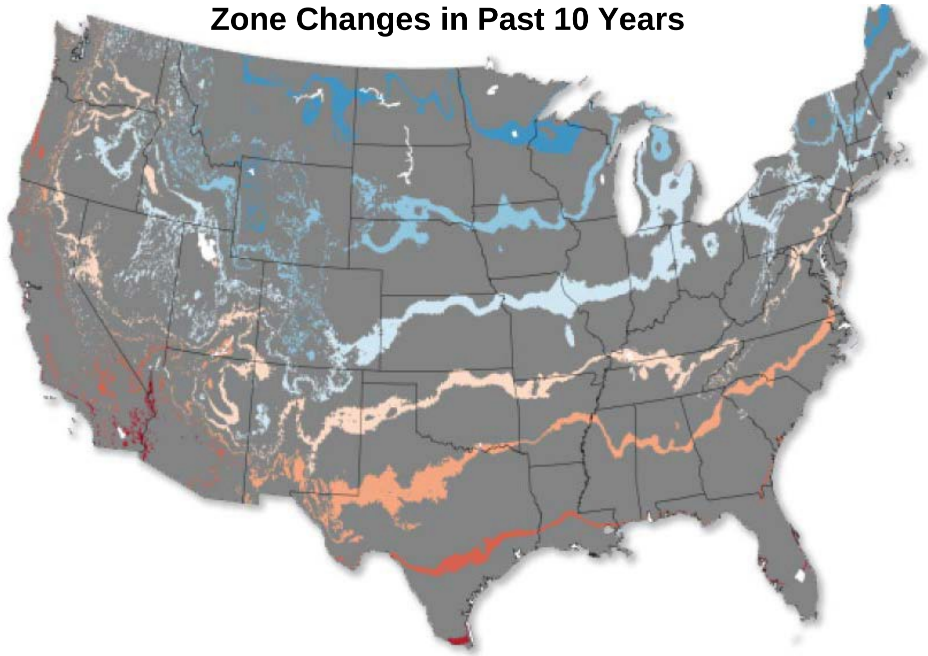
Figure 2-4 USDA Plant Hardiness Zone Map (2012)[3]



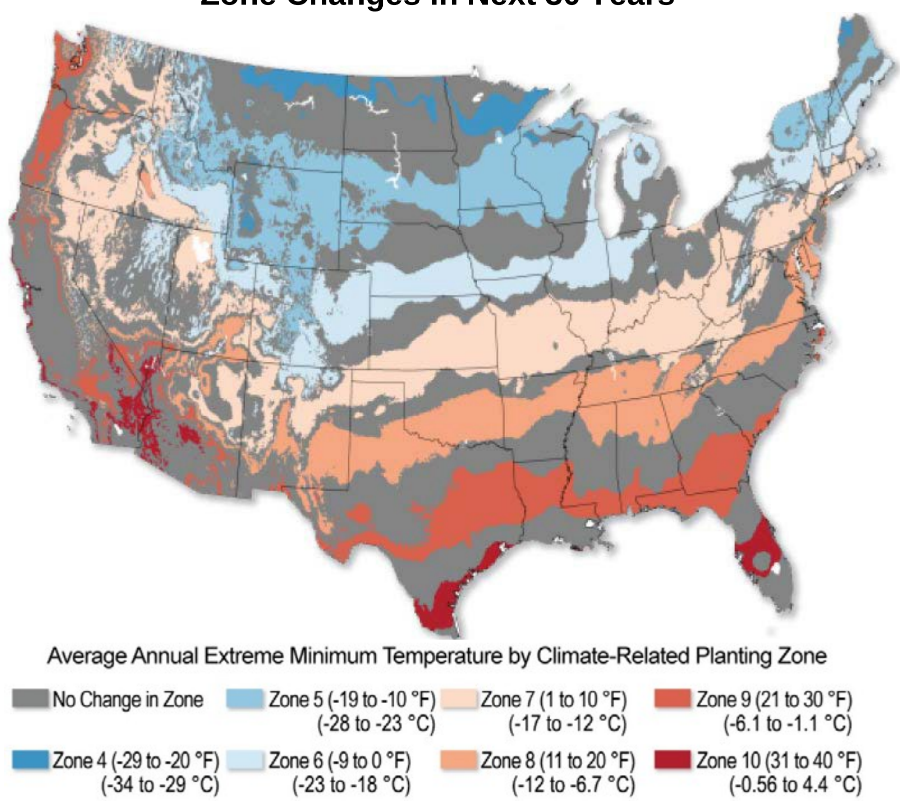
[3] USDA, "Map Downloads," 20 June 2018, http://planthardiness.ars.usda.gov/PHZMWeb/Downloads.aspx

Figure 2-5 Shifts in Plant Hardiness Zones as of 2010[4]

Zone Changes in Past 10 Years



Zone Changes in Next 30 Years



[4] National Oceanic and Atmospheric Administration, "Shifts in Plant Hardiness Zones," *Climate Change Impacts in the United States: The Third National Climate Assessment*, U.S. Global Change Research Program, 6 May 2013, https://nca2014.globalchange.gov/report/appendices/climate-science-supplement/graphics/shifts-plant-hardiness-zones.

2-6.2 Security and Anti-Terrorism.

Coordinate planting design with security and antiterrorism requirements for unobstructed spaces and clear zones per UFC 4-010-01. Explore creative Landscape Architectural solutions to meet force protection and site security requirements through strategic site planning and circulation design.

Eliminate any opportunity for concealment of objects in the unobstructed space that are larger than a 6-inch (15.24 cm) diameter sphere. Specify and install a minimum tree size of 3-inch (8 cm) caliper or 36-inch (91 cm) box at installation for all trees located within unobstructed spaces. At installation, limb all branches within the unobstructed space to meet antiterrorism requirements. Retain a minimum 2/3 height of branches and 1/3 height of clear trunk. Verify the use of multi-trunked trees within the unobstructed space with Antiterrorism/Force Protection Subject Matter Expert.

Eliminate any opportunity for concealment of objects in clear zones. Specify only low shrubs and ground covers within the clear zone. Trees are not permitted.

2-6.3 Foreign Object Debris and Bird/Wildlife Aircraft Strike Hazard.

Foreign Object Debris (FOD) compliance is critical for selection and placement of plant materials, aggregates, and mulches. Select materials to mitigate site-specific foreign object debris concerns.

The Wildlife Hazard Assessment identifies areas of an airfield that are attractive to wildlife and provides recommendations to remove or modify the features. Adhere to species selection requirements for all plantings within identified Bird Aircraft Strike Hazard (BASH) areas. Consider Installation-specific issues. Do not specify plants that create habitat or food sources for avian species that would attract them to the BASH zone.

2-6.4 Plant Selection.

Design planting plans that define space, reinforce circulation systems, frame views, screen site elements, and provide scale, form, line, mass, texture and color. Apply the following requirements when selecting plant materials:

- Comply with all Installation requirements, including the Installation design guidance documents (IDGD), Integrated Natural Resources Management Plan (INRMP), and project specific Scope of Work (SoW).
- Follow requirements of Mariachero's *American Standard for Nursery Stock*-American National Standards Institute (ANSI) Z60.1.
- Use healthy, disease and pest-free plant materials.
- Select plants with low-maintenance characteristics, disease resistance, and drought tolerance, where appropriate.
- Satisfy sight distance requirements as defined by the AHJ for all streetscape plant materials.

- Provide a plant schedule with each required submittal. Include plant key, quantity, botanical name, common name, minimum installed size (height/spread), container, spacing, and remarks as appropriate. Organize the plants by type (deciduous trees, evergreen trees, and so forth). See Figure 2-6 for plant schedule format.

Figure 2-6 Plant Material Schedule – Typical Format

PLANT MATERIAL SCHEDULE								
SYMBOL	BOTANICAL NAME	COMMON NAME	MINIMUM CONTAINER SIZE OR CALIPER	MINIMUM HEIGHT	MINIMUM SPREAD	QUANTITY	REMARKS	DETAIL
TREES								
XX ‘X’ OR XXX ‘X’	ALL UPPER-CASE LATIN	ALL UPPER CASE COMMON	X’ – X2’	X’ – X2’	X’ – X2’			XX/LPXXX
SHRUBS								
XX ‘X’ OR XXX XXX ‘X’								
XX ‘X’ OR XXX XXX ‘X’								
GROUND COVERS								
XX ‘X’ OR XXX XXX ‘X’								
SEED								
XX ‘X’ OR XXX XXX ‘X’								

2-6.5 Native and Regionally Adapted Plants.

Use hardy native and regionally adapted plant materials. Select plant species based on current science-based information and Installation-specific institutional knowledge and practice. Install plants that are appropriate for site conditions, climate, and design intent. Additional standards for projects located in arid and semi-arid conditions may be required.

2-6.6 Invasive Species.

Do not use plants deemed invasive by the USDA, noxious weed control boards, state and local agencies, or other AHJ. The USDA National Invasive Species Information Center (NISIC) website is a central repository for relevant information. Use extreme care when using non-native species or creating conditions that will attract such species.

Detect, monitor, and eradicate populations of invasive species using Integrated Pest Management (IPM) techniques on Installations whenever feasible. Comply with DoDI 4150.07 and guidance in the Installation’s INRMP.

2-6.7 Tree Replacement.

Meet INRMP requirements for the replacement of existing trees. Follow requirements for all trees removed on a project site. Determine the size of the replacement tree from the SoW and IDGD.

2-6.8 Trees.

DoD is committed to establishing a significant tree canopy on base Installations. Each project will be unique in the ability to include significant tree canopy requirements. Tree canopy requirements for projects located in arid and semi-arid conditions may be adjusted. The recommended planting requirement provides trees at a minimum rate of one tree per 1,000 square feet (92.9 m^2) of landscape area and identifies off site areas for designated alternative planting. Identify reductions and/or additions to the number of required trees in the Supplementary Instructions to Offerors. Confirm the planting rate with the Government Landscape Architect.

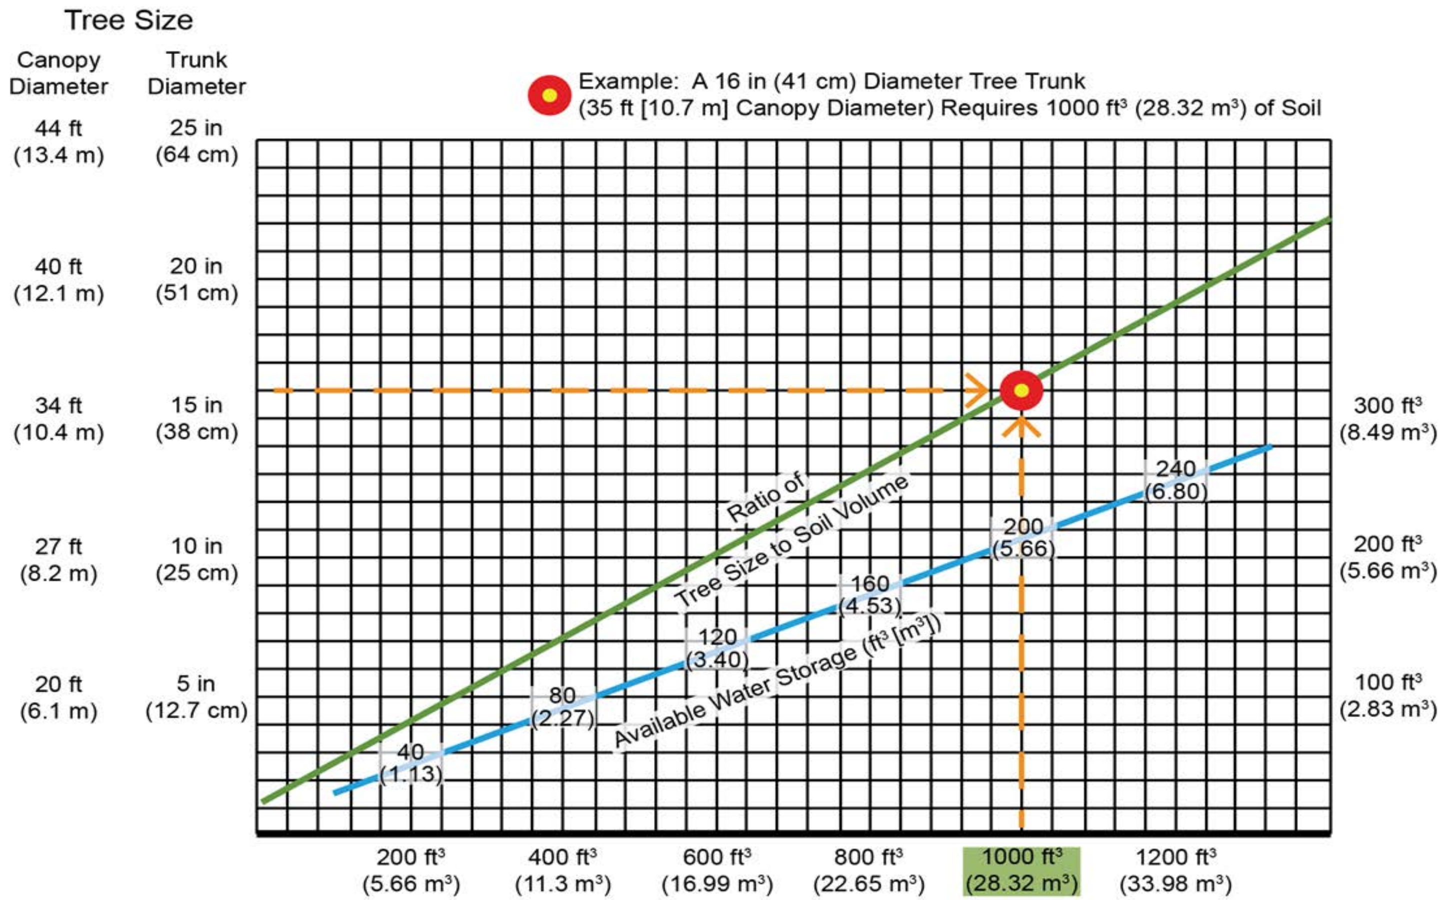
Evaluate placement and species selection to avoid overplanting the site. Ensure that the size and form of trees conforms to ANSI Z60.1 and the Installation INRMP. Refer to Chapter 2-6.2 for size requirements within standoff distances. Size new trees by type as follows:

- Shade Trees:
    - Type 1 and 2: Trees must meet or exceed 3 inches (7.6 cm) caliper and 14 feet (4.2 m) in height at installation.
    - Type 3 and 4: Trees must meet or exceed 2 inches (5 cm) caliber at installation.
- Evergreens:
    - Type 3, 4, 5 and 6: Trees must meet or exceed 6 feet (1.8 m) in height at installation.
- Multi-stem Trees: Trees must meet or exceed 6 feet (1.8 m) in height at installation.
- Palm Trees: Trees must meet or exceed 12 feet (3.6 m) in height at installation.

2-6.8.1 Tree Planting.

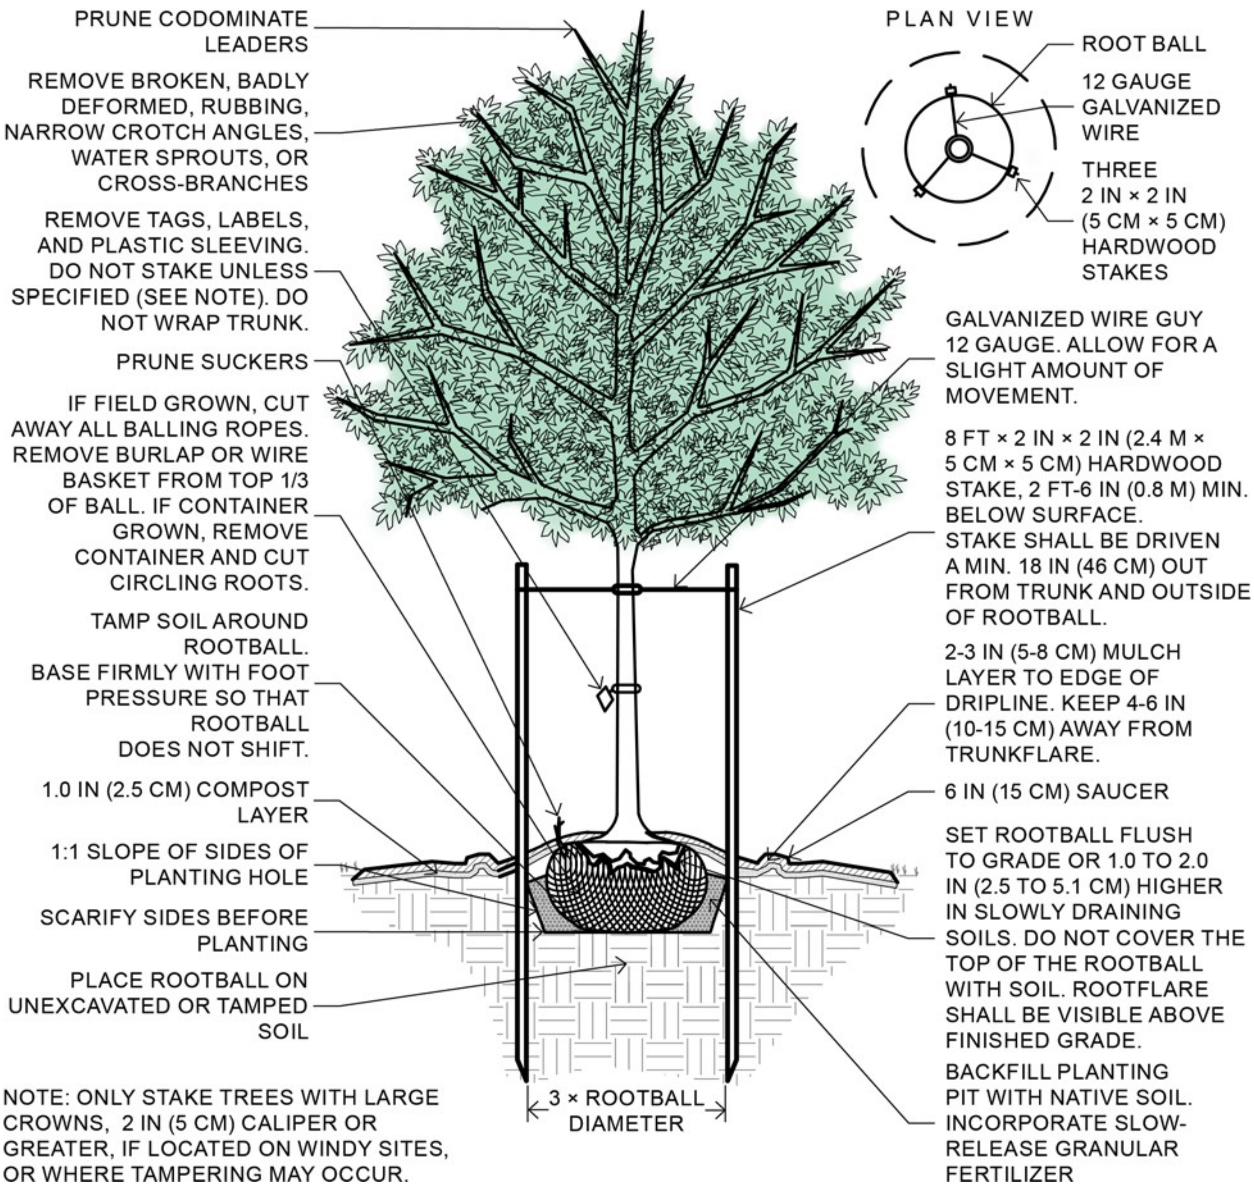
To ensure adequate soil volume and quality for trees located within plazas, sidewalks, or other paved areas, specify adequate non-paved planting area and/or other measures, such as suspended pavements. To facilitate root development and proper drainage, restore overly compacted sub-grade soils to an acceptable compaction level prior to planting. The required soil volume is based on ultimate tree canopy or trunk diameter; see Figure 2-7 for recommended soil volumes. See Figure 2-8 for an example of a standard tree planting detail.

Figure 2-7 Soil Volume Needed to Grow Large Urban Trees[1]



[1] Adapted from "Timely Tree Tips—Minimum Soil Volume," 10 June 2016, https://dnrtreelink.wordpress.com/2016/06/10/timely-tree-tips-minimum-soil-volume/. Originally from James Urban, *Up by Roots: Health Soil and Trees in the Built Environment*, 2008, International Society of Arboriculture Books, Champaign, IL.

Figure 2-8 Example Tree Planting Detail (Deciduous Tree)



2-6.9 Shrubs.

Specify shrubs to meet or exceed the size of a #3 container at installation, except for those within clear zone. Ensure the size, form, and species selected conform to ANSI Z60.1 and the Installation INRMP. The Government Landscape Architect has final approval authority on selected plant material. Species deemed unsuitable for planting will not be allowed.

2-6.10 Ground Covers, Perennials, Ornamental Grasses, Vines, and Annuals.

Specify ground covers, herbaceous perennials, ornamental grasses, and vines to meet or exceed size of a #1 container at installation, except for those within standoff distances. Refer to Chapter 2-6.2 for size requirements within standoff distances. Provide plants in a healthy, disease and pest free condition. Ensure the size, form, and species selected conform to ANSI Z60.1 and the Installation INRMP. The Government Landscape Architect has final approval authority on selected plant material. Species deemed unsuitable for planting will not be allowed.

2-6.11 Utilities.

Coordinate with other disciplines to design a centrally located utility corridor to minimize conflicts between plants and utilities. Balance site and landscape requirements with location of underground utilities.

Place trees so that the mature canopy will meet or exceed an offset of 10 feet (3.3 m), in any direction, from permanent structures such as buildings, light poles, signs, hydrants, backflow devices, overhead utilities. For transmission lines, towers, and poles, ensure a mature canopy clearance of a minimum of 25 feet (7.6 m).

Place trees a minimum of 10 feet (3.3) from underground utilities to minimize conflicts, or provide a root barrier system to mitigate tree conflicts with underground utilities.

2-6.12 Parking Areas.

1\ At parking areas, provide plantings and/or other methods to comply with International Green Construction Code (IgCC) Chapter 5 “Site Sustainability” to mitigate heat island effect at site hardscape. Coordinate with Government Project Landscape Architect regarding proposed solution(s) based on project location or site conditions. /**1**/

2-6.13 Lawns and Grasses.

Use certified seed, sod, and sprigs of good quality and established identity verified by an official certification agency. Provide certification prior to installation. Select seed, sprigs, and sod that include mixes that require no potable irrigation post-establishment and are low-maintenance. Selection of regional seed mixes is preferred. Refer to Installation INRMP and other applicable guidance. **1**\ Refer to the International Green Construction Code (IgCC), Chapter 6 “Water Use Efficiency”. /**1**/ The Government Landscape Architect may set exceptions and/or different standards for projects located in arid and semi-arid climates.

2-6.14 Pollinator Habitat.

Comply with the Office of the State Department Memorandum for “Department of Defense (DoD) Policy to Use Pollinator-Friendly Management Prescriptions” and the

DoDI 4715.03 Integrated Natural Resources Management Plan (INRMP) Implementation Manual. Implement sustainable goals in coordination with the Installation. Develop corridors for pollinators and connectivity of corridors Installation-wide.

Design planting plans to establish, enhance and restore year-round pollinator habitats. Select plant materials and maintenance strategies to ensure a variety of habitat and native nectar and pollen sources. Select plant materials and design strategies that support pollinators. Install native trees, shrubs, and flowering species that produce nectar and pollen.

Figure 2-9 Pollinator-Friendly Planting

2-6.15 Stormwater Management Areas.

Comply with UFC 3-210-01. Within stormwater management areas, specify and install quantities and species of plants in accordance with state and local regulations or other AHJ.

Ensure appropriate plant selection for each stormwater feature type and expected inundation levels and durations. Observe all antiterrorism requirements within the unobstructed space or clear zone during plant selection and placement.

2-6.16 Vegetative Roofs.

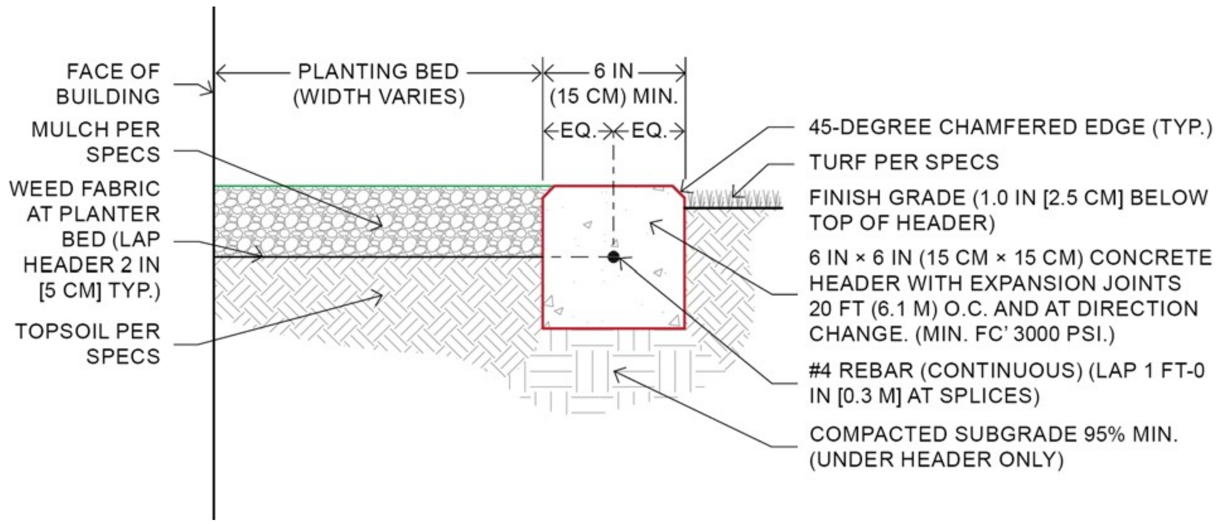
Include the Landscape Architect with all vegetative roof designs, including plant and media selection.

Use plant materials that are appropriate for selected media depth and type. Use herbicides, insecticides, and fungicides currently registered by the United States Environmental Protection Agency (EPA) or approved for such use by the appropriate agency of the host country. Select non-repellant termiticides for maximum effectiveness and duration after application. Select a termiticide that is suitable for the soil and climatic conditions at the project site and apply at the highest labeled rate. Apply herbicides, insecticides, and fungicides by a commercially certified pesticide applicator in the jurisdiction where the work is to be performed as required by Department of Defense Instruction (DODI) 4150.07. Use temporary irrigation during establishment, unless permanent irrigation is planned. Only non-potable water may be used for permanent irrigation. Coordinate with Installation-specific contract services to identify regular O&M needs.

2-6.17 Landscape Edging.

Separate turf areas from planting beds or mulched areas with landscape edging. Specify concrete or metal edging materials. Utilize aluminum, weathering steel (CorTen), or galvanized steel if specifying metal edging materials. Provide stake type and spacing for metal edging per manufacturer's recommendations. Plastic edging is prohibited.

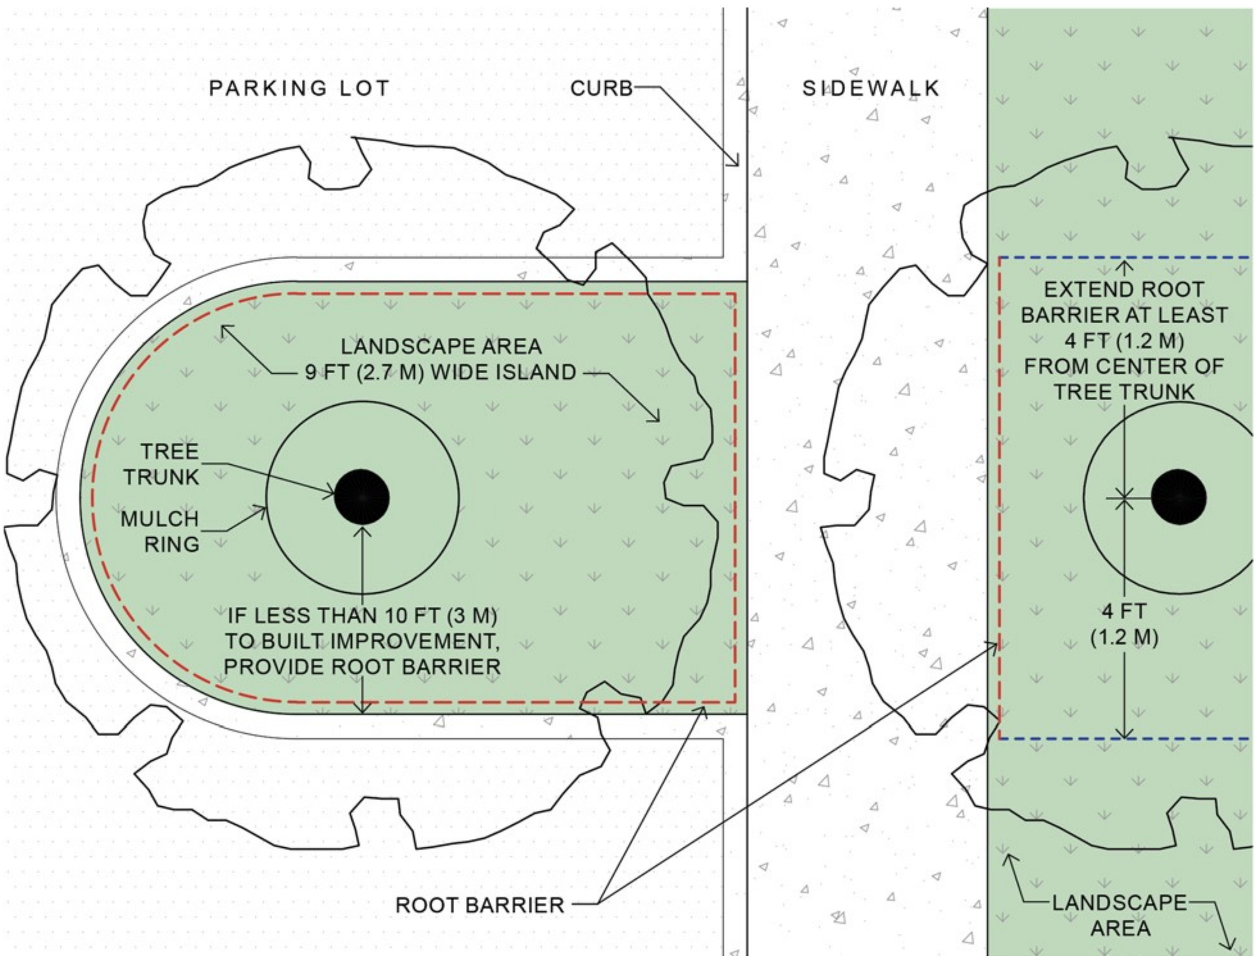
Figure 2-10 Concrete Header Mow Edge



2-6.18 Root Barrier.

Install linear tree root barriers along the edge of the built improvement where trees are planted within 10 feet (3 m) of hardscape, paving, structures, or utilities that could be compromised by root systems. Install root barrier parallel to the structure or utility to allow for the maximum amount of contiguous root zone. Extend the root barrier parallel to the site improvement at least 4 feet (1.2 m) from the center of the tree trunk in either direction as shown in Figure 2-11.

Figure 2-11 Example Root Barrier



2-7 IRRIGATION.

Design irrigation to promote optimum health, growth, color, and appearance of plant materials. Abide by the regulations of all local, state, federal, and international water agencies and authorities.

The irrigation designer manages the design and coordination of new irrigation systems with supporting plans, details, specifications, irrigation equipment (including smart controllers), schedule, and calculations. Use the following documents for DoD irrigation criteria:

- UFC 3-420-01 Plumbing Systems
- **\1** International Green Construction Code (IgCC), Chapter 6 “Water Use Efficiency” **/1/**

2-8 WALLS AND FENCES.

Comply with UFC 3-201-01, UFC 3-301-01, and UFC 4-022-03. Design walls and fences to correspond with the material palette for the Installation or facility, and correspond with the overall design concept of the site and building.

2-9 SITE LIGHTING.

For exterior lighting criteria, refer to UFC 3-530-01. Select fixtures and criteria to conform to IDGD unless otherwise stated within the project Program of Requirements (PoR) or RFP. Coordinate with the Electrical Engineer for overall lighting design, integrated pole placement, and selection of fixtures. Coordinate tree and light fixture placement to avoid conflicts that will obstruct lighting and prevent tree placement where required. Include the Landscape Architect in the design of appropriately scaled site lighting that reflects a sequence of arrival for the user, inclusive of vehicular circulation and parking, as well as pedestrian circulation, including plazas and entries.

2-10 EXTERIOR WAYFINDING AND SIGNAGE.

For exterior wayfinding and signage, comply with UFC 3-120-01.

2-11 SITE FURNISHINGS.

Provide site furnishings per the IDGD.

Comply with UFC 4-022-02 for site furnishings, including bollards and planters, intended to provide crash resistance and other security measures. Comply with UFC 4-010-01 to ensure site furnishings and elements will not conceal a threat.

2-11.1 Shelters.

Outdoor shelters include bus shelters, pavilions, gazebos, canopies, shade structures, pergolas, arbors, and other open-air facilities. Structures may consist of pre-fabricated shelters, shade structure products, or site-built shelters. Coordinate with the structural engineer on the design of footings, foundations, and other structural elements. Coordinate with the electrical engineer on the design of lighting and other electrical components.

Design shelters to match or coordinate with the material palette for the Installation or facility and correspond with the overall design concept. Scale shelters appropriately in relation to adjacent buildings. Provide plantings and other landscape features to integrate shelters into the site and enhance their visual appeal.

2-11.2 Flagpoles.

Locate flagpoles on paved surfaces that allow for routine and ceremonial access. Identify and design to avoid conflicts with trees, overhead utilities, adjacent banners, and other vertical elements. Space flagpoles so that flags do not touch when fully extended. At a minimum, specify flagpoles to meet National Association of Architectural Metal Manufacturers (NAAMM) FP1001-07 and all regional wind velocity standards for sustained wind and wind gusts.

2-11.3 Dumpster Enclosures (Trash and Recycling).

Design dumpster enclosure components and service requirements to comply with the IDGD, and to be compatible with the facility's architecture and materials. Use masonry materials for construction of enclosure unless alternate screening materials such as fencing or vegetated barriers are allowed. Construct enclosures to screen all contents from public view. Provide doors unless otherwise stated in the IDGD. Provide an evergreen screen, which at maturity is a minimum of 6 feet (1.8 m) high, to buffer walled enclosures, where applicable.

2-12 COMMON AREAS, RECREATIONAL FACILITIES, AND PLAYGROUNDS.

2-12.1 General.

Common areas may include campus entrances, main gates, building entrances, drop-off zones, plazas, courtyards, parade grounds, parks, playgrounds, recreational areas, monuments, and memorials. Ensure the area is adequately sized to accommodate the program requirements. See specific IDGD for programming and design requirements.

2-12.2 Recreational Facilities.

See the 4-700 Series UFC for requirements pertaining to specific recreational facilities. For outdoor gathering areas at military recreation centers, comply with UFC 4-740-16. Comply with requirements for recreational facilities in the U.S. Access Board's *Architectural Barriers Act (ABA) Standards*, "Chapter 10: Recreational Facilities" and ASTM F1951, "Standard Specification for Determination of Accessibility of Surface Systems Under and Around Playground Equipment".

Comply with UFC 4-750-02N for **Navy and Marine Corps** outdoor sports and recreational facilities.

2-12.3 Playgrounds.

Conform to the requirements in all relevant Housing and Community Facilities UFC (Series 4-700) and Facilities Criteria (FC) (Series 4-700) for playground designs. Comply with requirements for play areas in the U.S. Access Board's *Guide on Play Areas.* Ensure that playground equipment is age-appropriate. Equipment is typically designed for areas designated as tot lots (ages 2 to 5) and play lots (ages 5 to 12). Install signage to indicate age-appropriateness. For equipment layout, account for both the full zone of use (fall zone) for each piece of play equipment, which requires protective surfacing, and any non-encroachment zone for the equipment as specified for the equipment by the manufacturer. Comply with ASTM F1487, "Standard Consumer Safety Performance Specification for Playground Equipment for Public Use".

Comply with UFC 4-740-14 and FC 4-740-14N requirements for child development centers.

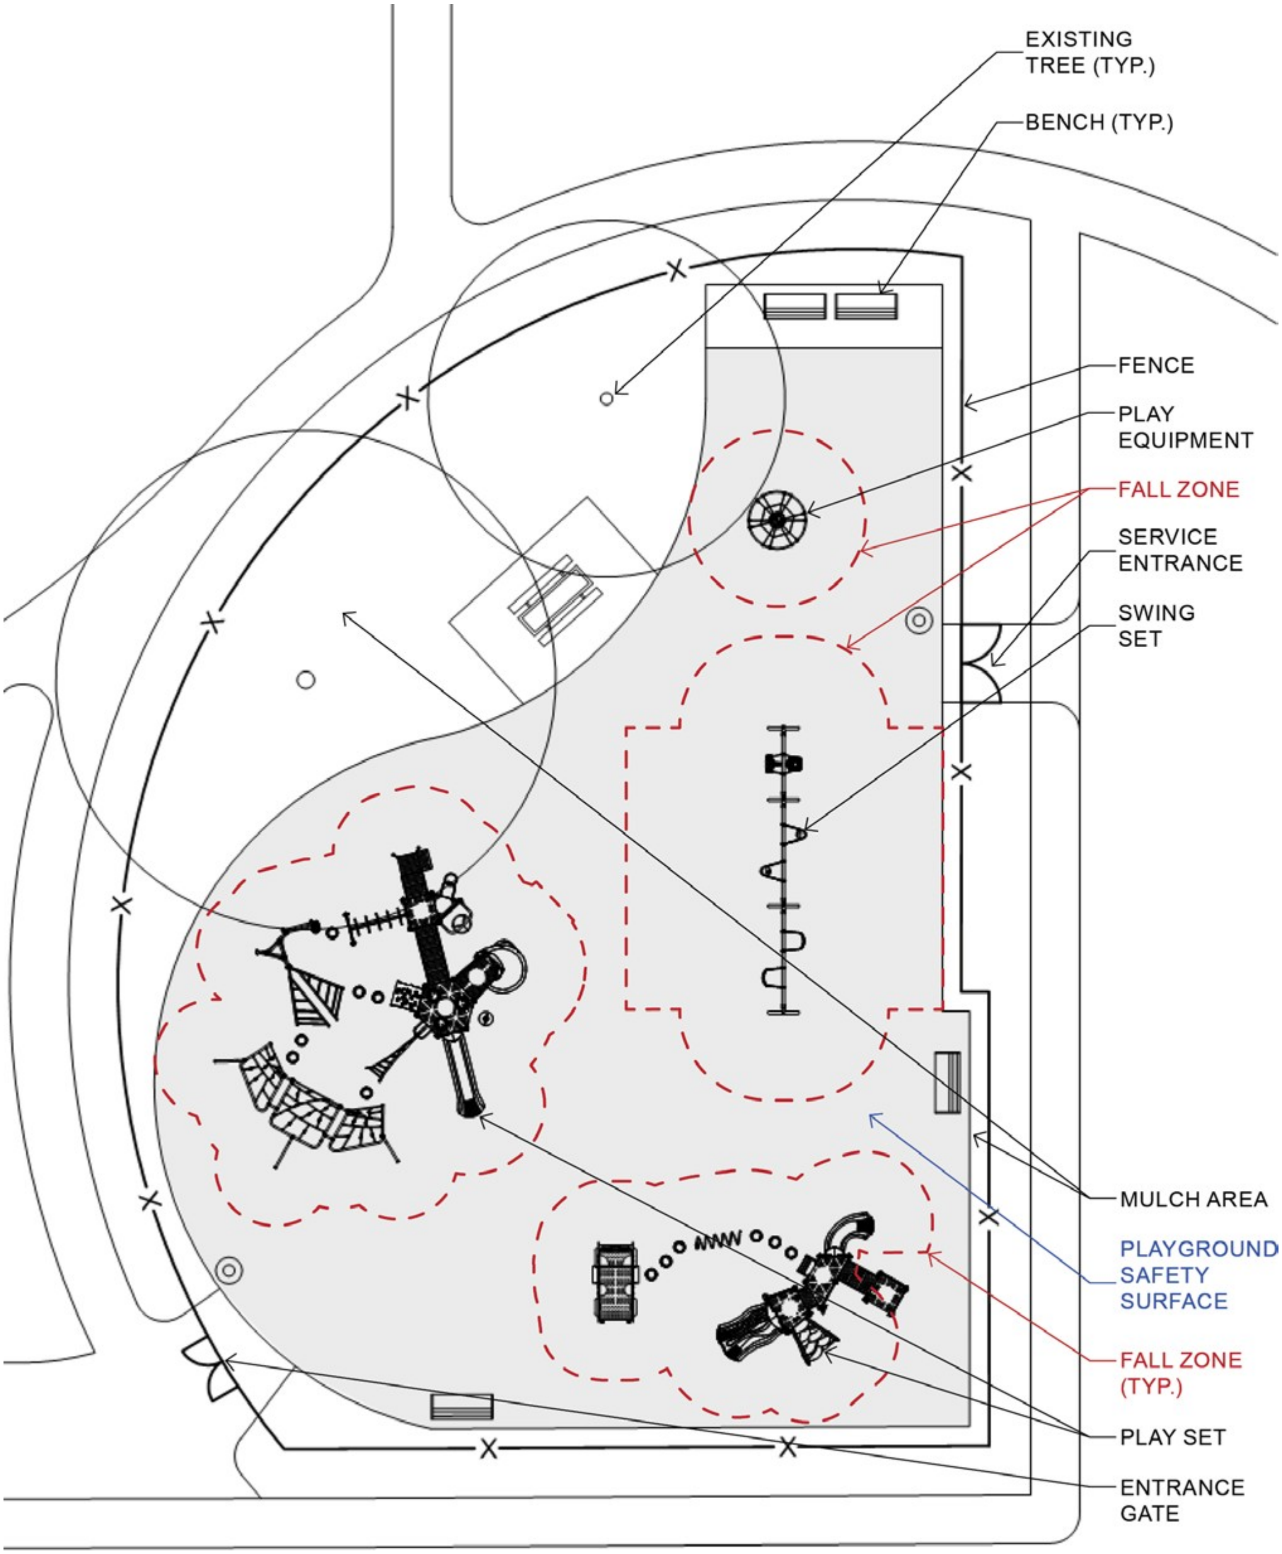
2-12.3.1 Playground Protective Surfacing.

Use a playground safety surface under play equipment, such that the surface covers the extent-of-use zones and extends at least 6 feet (1.8 m) out from all equipment. Materials at risk for compaction, flammability, and wind dispersion, or that are ingestible, are prohibited. The use of chromated copper arsenate (CCA) treated lumber is prohibited. Manage CCA-treated lumber at existing sites to prevent arsenic migration. Comply with ASTM F1292, "Standard Specification for Impact Attenuation of Surface Systems Under and Around Playground Equipment".

2-12.3.2 Planting Design at Playgrounds.

Identify and remove existing poisonous plants and plants that have thorns or other hazardous physical characteristics. Do not specify or install poisonous or hazardous plants near playgrounds. Refer to a comprehensive, commercially available field guide for complete lists of poisonous plants. Consult local cooperative extension services, regional poison control centers, or other relevant agencies for specific guidelines.

Figure 2-12 Playground Equipment Layout Plan with Fall Zones



2-12.4 Pool and Aquatic Complexes.

Comply with UFC 4-750-07 for pool and aquatic complexes.

Recreation pools and splash pads are often free form in shape, responding to the site layout and design aesthetic. Direct water away from the pool coping to the drainage system around the pool deck perimeter. Provide fence enclosures that meet minimum height, gap, and material requirements for public pools. Landscape architectural construction documents may include: pool layout, hardscape, grading, lighting, planting, and materials selection.

2-12.5 Smoking Areas.

Comply with provisions for environmental tobacco smoke control in UFC 1-200-02. See Chapter A-24.4 for best practices.

CHAPTER 3 LANDSCAPE ARCHITECTURAL PROJECT DOCUMENTATION

3-1 GENERAL.

Prepare landscape architectural design submittals and requirements in accordance with the following criteria. Landscape architectural project documentation is key to the successful execution of work. This body of work includes deliverables from project inception through project completion.

Submit required documentation as defined in the project contract and based upon component-specific guidance.

3-2 PRE-DESIGN SUBMITTALS.

3-2.1 Concept Design Workshop/Charrette.

The DoR must participate in the Concept Design Workshop/Charrette and contribute to the development of the conceptual site plan and charrette report as they relate to landscape architecture.

3-2.2 Site Inventory and Analysis.

The goal of Site Inventory and Analysis is to gather site-specific information, identify applicable requirements and regulations, and establish opportunities and constraints. Conduct a Site Inventory and Analysis narrative during Concept Design Workshops and charrettes. Include deliverables in the charrette report and into the BoD documentation. Collect the following components in the site inventory:

- Existing Conditions:
  - Environmental Checklist and NEPA Documentation
  - Visual Resources: including but not limited to photographs, existing maps, and video recordings
  - Site context
  - Climate and microclimate(s)
  - Solar aspect and wind conditions
  - Topography
  - Hydrology
    - Delineated wetlands
    - Floodplain boundaries and storm surge projections
    - Existing waterbodies
    - Man-made BMPs and stormwater structures and outfalls
    - Groundwater wells (production wells and monitoring wells)
  - Geology and soils
    - Horticultural soils analysis, including but not limited to pH, soil organic matter, and macro- and micronutrients
  - Ecosystems
  - Wildlife corridors

  - Threatened and endangered species
  - Vegetation
    - Tree inventory
    - Existing vegetation inventory
    - Identified preservation and protection areas
    - USDA Plant Hardiness Zone, or overseas equivalent
    - Ecoregion, using EPA or U.S. Forest Service (USFS) designations, or overseas equivalent
    - Invasive plants
    - Hazardous trees
    - Existing vegetation corridors and connectivity
  - Existing utilities
  - Sanitary sewer lines and pumping stations
  - Industrial activities and structures (e.g., hazardous waste, hazardous material storage facilities, fuel storage facilities, landfills, etc.)
  - Access and circulation patterns, including existing and proposed walks, trails, and pathways
  - Views (internal and external)
  - Odors
  - Noise
- Cultural Resources
  - Historic structures, objects, landscape elements, and viewsheds
  - Traditional cultural properties, Native American sacred sites, and archaeological resources that have the potential to be disturbed during construction and ground disturbance
  - Heritage or significant trees
  - Cultural landscapes that are listed in or eligible for listing in the National Register Historic Places (NRHP)
- Cultural landscapes as identified by the appropriate federal agency in consultation with state and Native American stakeholders, as appropriate
- Criteria compliance
- IDGD and local, state, federal, and international regulations
- Buffers and setbacks
- Security and antiterrorism

Perform site analysis to weigh the program of requirements against the constraints and opportunities present on the project site. Consider all existing planning documents such as the IDP and ADP.

Figure 3-1 Examples of Site Analysis Plans

Grading and Drainage

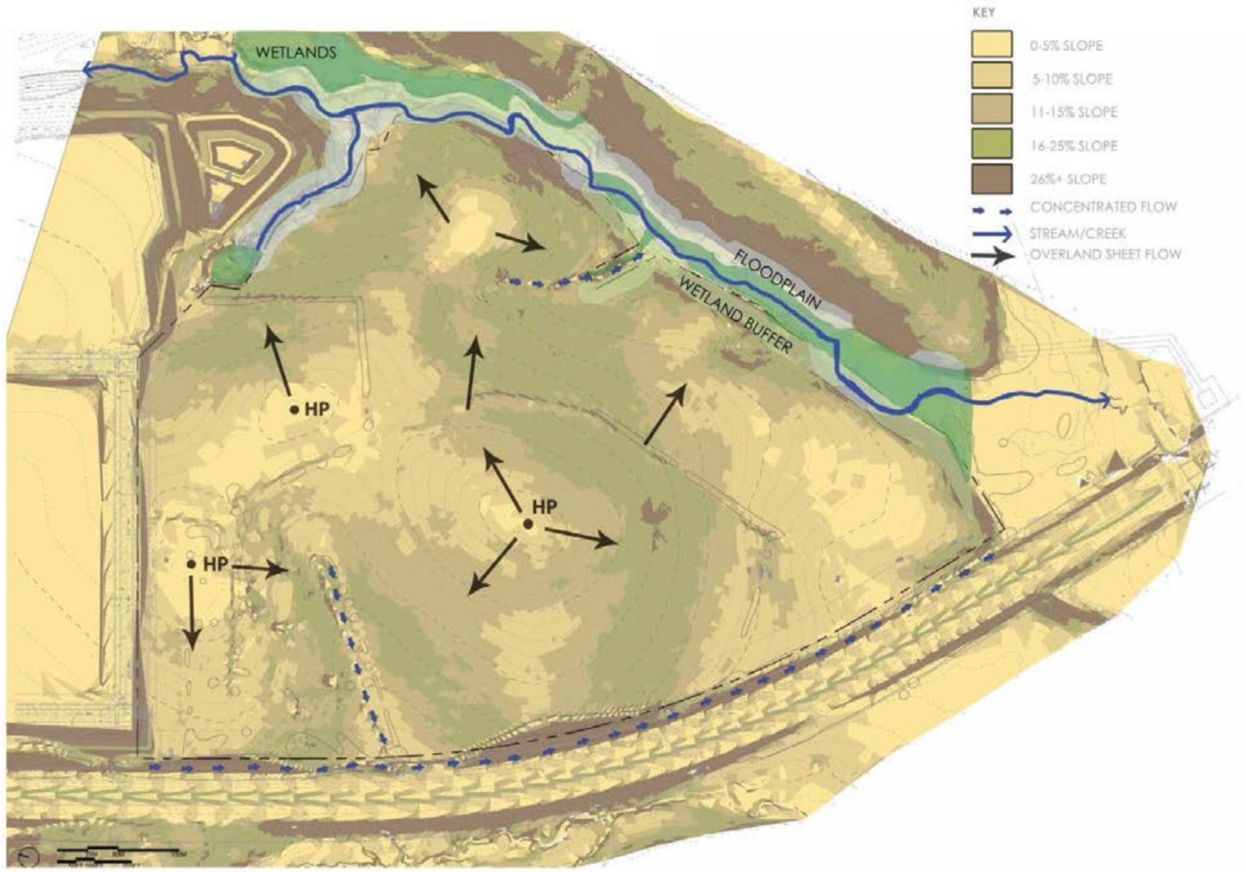


Figure 3-1 (Cont'd) Examples of Site Analysis Plans

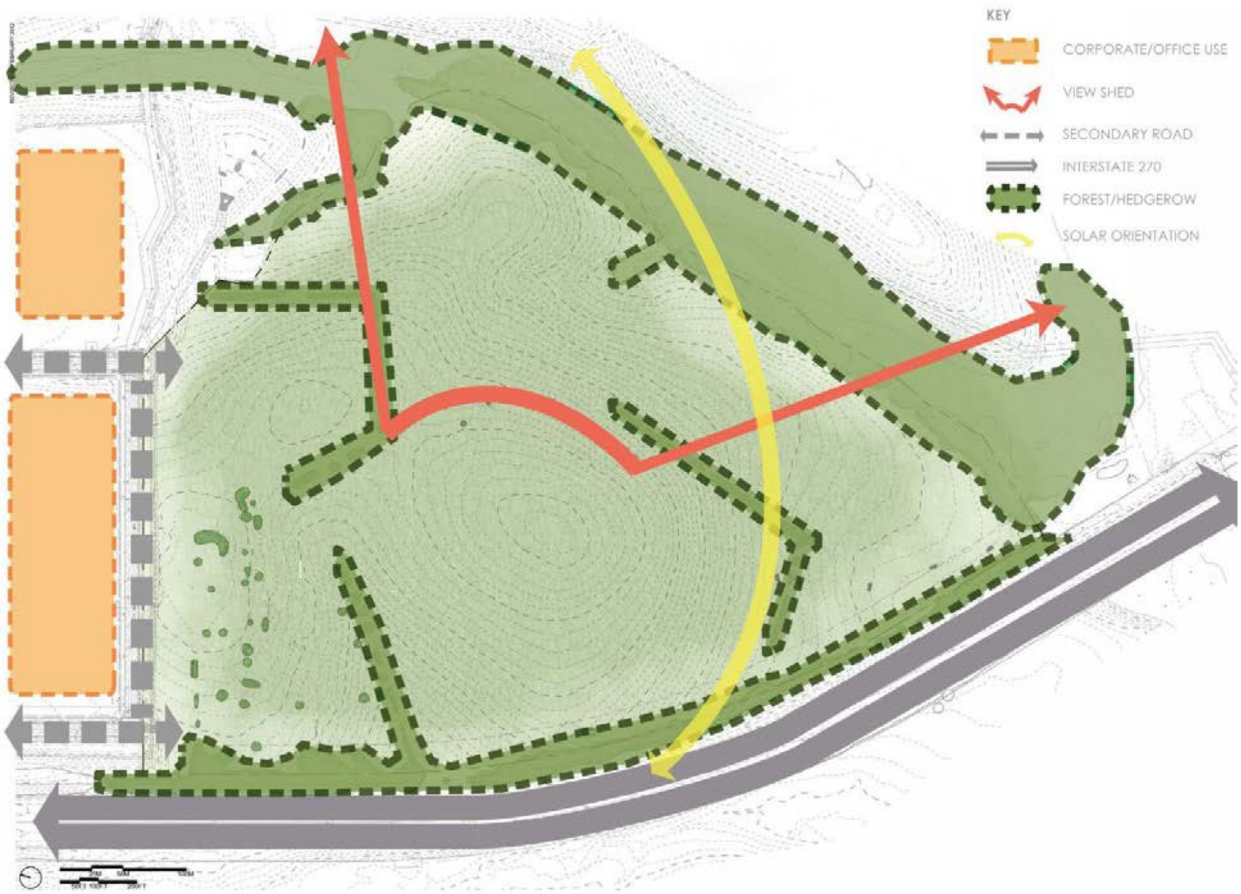
Land Use, Viewsheds, and Solar Aspect



3-2.3 Basis of Design.

The Basis of Design is a narrative presentation of facts, sufficiently complete, to demonstrate that the project concept is fully understood, and that subsequent design details, and their ultimate presentation in the final drawings and specifications, will be based on sound decisions. Update and submit the BoD at each submittal. Address all requirements presented with the PoR in the BoD narrative, including:

- Project SoW
- Site compliance with Installation Planning Standards (IPS)
- Synopsis
    - Site inventory
    - Site analysis
    - Design approach
    - Resiliency and sustainability
    - Antiterrorism standards
    - Proposed circulation and accessibility plan
    - Stormwater design and planting

- Planting design
- Site Furnishings
- Hardscape
- Site lighting
- Irrigation: temporary or non-potable permanent
- Reference documents
- Third Party Certification (TPC) – requirements where applicable
- Maintenance plan
- IPM plan

3-3 DESIGN SERVICES.

3-3.1 General.

Address the following key components in the design documents from landscape establishment through landscape warranty periods:

- Field consultation during construction including site observations, shop drawings, and submittal review.

3-4 POST-DESIGN SERVICES.

3-4.1 General.

Address the following key components during construction from landscape establishment through landscape warranty periods:

- Field consultation during construction including site observations, shop drawings, and submittal review.
- Landscape establishment, maintenance, and management through the warranty period.

3-4.2 Construction.

Review the construction package, site conditions, criteria, schedule, procedures, and coordination with related work. Address specific landscape architecture and site-related items at the pre-construction meeting:

- Tree Mitigation
- Environmental Issues
- Endangered Species
- Other critical project specific issues

3-4.3 As-Built and Record Drawings.

Require record drawings for planting, hardscape, site lighting, and irrigation at project completion as part of the entire construction document package. As-builts and record drawings are not required for planting unless there are overall field changes in plant material types or location.

3-4.4 Landscape Establishment and Landscape Warranty Periods.

Specify the landscape establishment period and landscape warranty period for a minimum of 365 days after the date of final acceptance to run concurrently. Provide temporary potable or non-potable water or permanent non-potable water irrigation systems to improve plant establishment and viability.

At the end of the warranty period, plant materials must have a minimum 95% survival rate. Require replacement of all unacceptable material. If the overall survival rate is less than 95%, the contractor is responsible for another full warranty period of 365 days for the replacement plants.

3-4.5 Site observations and Project Acceptance.

Perform site observations as required. Determine final turf acceptance based on a satisfactory stand of turf. Acceptable turf area is defined as 95% coverage of the specified turf species at the end of the landscape establishment period with no bare turf areas larger than 6 inches by 6 inches (15 cm by 15 cm). Bare meadow or prairie mix(es) areas greater than 12 inches by 12 inches (30 cm by 30 cm) are not acceptable.

Replace dead plant material during the next approved planting season. Replace plants in their entirety with more than 20% dead material. Require another 365 day warranty period from the date of installation for replacement plant material. Test the irrigation system at final acceptance and at the end of the establishment period. Extend plant establishment and warranty periods for work that does not meet contract requirements. Conduct a final site observation at least 10 days prior to the expiration of the warranty period.

3-4.6 Operations & Maintenance (O&M).

After the establishment and warranty period, the DoD is responsible for coordination and completion of maintenance tasks by the Installation-specific grounds or resource management authority.

Perform tree care by an International Society of Arboriculture Certified Arborist in compliance with Tree Care Industry Association standards. Perform pesticide applications using a commercial-grade licensed or certified professional.

APPENDIX A BEST PRACTICES

A-1 GENERAL.

The Best Practices Appendix is considered guidance and not criteria. Its main purpose is to communicate proven facility solutions, systems, and lessons learned, but may not be the only solution to meet the requirement or design issue.

This Appendix identifies background information and practices for accomplishing certain landscape architectural site design services.

A-2 RESILIENCE.

Resilience and adaptation are essential considerations for Installation planning and design. Assess all potential site risks and design projects to minimize the long-term vulnerability of the site and optimize the opportunity for recovery. Consult databased methodologies that project models for future conditions.

For Army projects: Apply the Army's "Prepare-Absorb-Recover-Adapt" (PARA) framework to resilience planning at the project level. Consult the Screening Level Vulnerability Assessment (SLVA) available for each Installation. The Screening Level Vulnerability Assessment provides qualitative data to identify the need for more in-depth studies and data collection.

A-2.1 Hazard Response.

Hazards pose direct threats to Installations and DoD operations. For each project, inventory potential hazards. Develop and implement design strategies that serve as appropriate response measures to these hazards. This includes the conservation, restoration, and creation of natural infrastructure assets, such as wetlands that mitigate flooding and storm surge. In selecting response measures, prioritize the Installation's critical built infrastructure, including energy, fuel, water supply, and utility services.

A-2.2 Climate Resilience.

Consider the following potential climate change effects:

- Shifts in USDA plant hardiness zone designation
- Stresses on specific species
- Changes in disease and pest vector distribution
- Changes in regional precipitation patterns

Coastal erosion, flooding, storm surge, and sea level rise pose risks to DoD Installations. Address solutions to these through strategic land use planning, modifications and design interventions. Consider natural and nature-based adaptation approaches, including preserving and restoring natural coastal ecosystem defenses, vegetated dunes, living shorelines, and living breakwaters. Alteration and plant installation in and around natural landscape features may require environmental permitting.

A-3 SUSTAINABILITY.

Aspects of sustainability are covered in UFC 1-200-02, UFC 3-201-01, and UFC 3-210-10. For sustainable site development, see best practices in UFC 1-200-02.

A-3.1 Energy Conservation Planning.

Minimize building energy use for heating, ventilation, and air conditioning using vegetation to shade facades and shield the building from winds. Minimize outdoor energy consumption for lighting and other site amenities.

A-3.2 Materials.

Address material selection from the basis of embodied energy and life cycle costs. Practice waste reduction and diversion and consult the integrated solid waste management (ISWM) plan at the Installation level. Employ the use of:

- Salvaged, reclaimed, or refurbished materials. Verify that salvage, such as brick, is appropriate for outdoor use.
- Locally and regionally sourced materials.
- Materials with recycled content.
- Non-toxic materials, including the use of low-emitting and non-emitting materials.
- Raw materials that have been extracted responsibly or products that contain such raw materials.
- Sustainably grown and harvested trees and other plant material.

A-3.3 Site Commissioning and Landscape Performance.

Site commissioning is used to verify the performance of a built work by evaluating sustainability metrics and cost-effectiveness and ensuring greater longevity for the project. Site and building commissioning processes can be combined to form a total commissioning process. The nature of living systems within the landscape requires that the site commissioning processes include on-going post-occupancy evaluation. Incorporate site commissioning into landscape maintenance and management plans.

A-4 REMEDIATION AND RECLAMATION.

Engage an interdisciplinary team for projects that require bioremediation, including phytoremediation, to address the complexities of rehabilitating a brownfield site. Identify the benefits of bioremediation as applied to the identified project site. Select the appropriate methodology for mitigation based on specific site contaminants.

Adhere to EPA guidance and other AHJ guidance pertaining to soil and groundwater remediation.

A-5 SECURITY AND ANTI-TERRORISM.

Utilize design principles defined in Crime Prevention Through Environmental Design (CPTED) to minimize safety and security risks. Design and construct projects to meet security and anti-terrorism criteria as required in the project BoD and RFP including stand-off distances, planting restrictions, and visibility.

A-6 CIRCULATION AND ACCESSIBILITY.

A-6.1 Streetscape System.

Collaborate with the design team to create streetscapes that enable safe access for all users, including pedestrians, bicyclists, motorists, and transit riders of all ages and abilities. Integrated streetscapes will improve user health by facilitating and encouraging walking and biking. Refer to Smart Growth America's National Complete Streets Coalition program for complete streets design goals and standards.

Collaborate with the design team to:

- Encourage circulation patterns that reduce the need for automobile use.
- Develop a hierarchy of streets, walkways, and trails based on adjacent land use, demand, and peak travel times.
- Plan corridors utilizing the IDGD for standard design requirements.
- Minimize impacts on natural and cultural resources, including stormwater runoff, heat island effect, and visual impact.
- Delineate and clarify circulation systems to facilitate wayfinding, using elements such as signage, special pavements, lighting, furnishings, trees, and other plantings.

A-6.2 Sustainable Streetscape Design.

Sustainable streetscapes function as a part of the greater ecosystem employing technologies that manage stormwater runoff and reduce carbon footprint. Sustainable streets create benefits relating to movement, ecology, and community that together support a broad sustainability agenda embracing the environment and economy. Implementing sustainable streets will create more livable communities.

Landscape verges are an effective treatment between sidewalks and streets that create a buffer from moving vehicles. Verge width is a key factor in pedestrian-friendly design. The greater the separation between vehicular and pedestrian circulation, the safer and more pleasant the pedestrian experience. Installation standoff requirements often create opportunities to establish verge widths that exceed ten feet. Verges adapt for stormwater infiltration and shade tree planting. A minimum verge width of 4 feet (1.2 m) is recommended for small street tree installations and 6 feet (1.8 m) is recommended for large street tree installations. Rain gardens offer a greener solution to detaining and treating street runoff and easily integrate into streetscape design. Filtered runoff is then fed back into the drainage system or allowed to infiltrate and recharge the water table. Structured stormwater planters effectively infiltrate and filter large amounts of runoff using special media, adaptive plantings, and underdrains.

A-6.3 Drop-offs.

Consider dedicated passenger drop-off zones for high-use facilities. Design of covered drop-offs should reflect safety and security best practices. Separate passenger drop-off circulation from service vehicular circulation. Drop-off circulation should be one-way traffic with a counter-clockwise movement. Place seating adjacent to drop-off.

A-6.4 Transit.

The integration of complete street design and public transportation is critical in improving the efficiency of circulation on DoD Installations and projects by reducing the dependence on automobiles. Incorporate these principles within project designs where feasible:

- Parking. Adapt and design streets that accommodate transit vehicles.
- Establish direct pedestrian access routes to transit stops.
- Include transit shelters for new stops and stations that protect from rain, sun, and wind.

A-6.5

Utilize proven design components to mitigate stormwater, reduce ambient temperature, and ensure safety for all users. Include the following design features where feasible:

- Introduce stormwater treatment trains, pervious parking, dark-sky compliant lighting, and shade within parking lots.
- Consider collection and reuse of parking lot runoff for landscape watering.
- Design pedestrian circulation through parking lots to minimize conflicts.
- Strategically place shade trees to mitigate heat island effect.
- Designate snow storage areas that will not adversely affect plant health.
- Utilize appropriate specialty paving materials that meet accessible design standards.
- Coordinate placement of cameras and trees to create and maintain unobstructed sight lines for security cameras.
- Include step outs and convenience strips along pedestrian corridors to increase pedestrian safety and protect plant materials.

A-6.6 Trails and Troop Movement.

Utilize the *ABA Standards*, “Chapter 10: Recreational Facilities.” for trail design, accessibility standards, technical requirements, surface, slope, tread width, and other standards.

Troop movement walkways are specific to military Installations. Include special design considerations for troops that regularly move from one location to another. Design routes with a minimum unobstructed width of 10 feet (3.0 m) to accommodate four individuals abreast, or as directed by the IDGD.

A-7 PLANTING DESIGN.

Each Installation should promote a simple, drought tolerant, and low-maintenance planting style. To ensure consistency in planting design, utilize detailed plant lists specifically developed for each Installation. Plant lists should be dominated by durable, long-lived species.

To ensure plant diversity, do not plant monocultures of the same species or cultivar. Select plants to meet a site-wide goal of no more than:

- 10% of the same plant species
- 20% of the same genus
- 30% of the same family

Table A-1 Example of Plant Diversity Calculation

Botanical name	Common Name	Quantity	Percent of Total
Species			
Amelanchier x grandiflora 'Autumn Brilliance'	Apple serviceberry	6	5.61
Betula nigra 'Heritage'	River birch	10	9.34
Carpinus betulus 'Fastigiata'	Pyramidal European hornbeam	10	9.34
Cercis canadensis	Eastern redbud	6	5.61
Chionanthus virginicus	White fringe tree	7	6.54
Ilex x attenuata 'Fosteri'	Foster's holly	10	9.34
Ilex opaca	American holly	8	7.48
Juniperus virginiana	Eastern red cedar	9	8.41
Magnolia virginiana	Sweet bay	3	2.80
Myrica cerifera	Southern wax myrtle	10	9.34
Nyssa sylvatica 'Wildfire'	Black gum	3	2.80
Pinus taeda	Loblolly pine	8	7.48
Pinus virginiana	Virginia pine	6	5.61
Quercus bicolor	Swamp white oak	4	3.74
Quercus phellos	Willow oak	5	4.67
Quercus virginiana 'Burkii'	Live oak	2	1.87
	TOTAL	107	100
Genus			
Amelanchier		6	5.61
Betula		10	9.34
Carpinus		10	9.34
Cercis		6	5.61
Chionanthus		7	6.54
Ilex		18	16.82
Juniperus		9	8.41
Magnolia		3	2.80
Myrica		10	9.34
Nyssa		3	2.80
Pinus		14	13.08

	TOTAL	107	100
Family			
Aquifoliaceae		18	16.82
Betulaceae		20	18.69
Cornaceae		3	2.80
Cupressaceae		9	8.41
Fabaceae		6	5.61
Fagaceae		11	10.28
Magnoliaceae		3	2.80
Myricaceae		10	9.34
Oleaceae		7	6.54
Pinaceae		14	13.08
Rosaceae		6	5.61
	TOTAL	107	100

A-7.1 Sustainable and Resilient Planting Design.

Employ ecological design principles to restore natural communities, improve the health of ecosystems, and to support wildlife. Design plantings for climate resiliency and natural hazards by:

- Transforming hardened shorelines into living shorelines while mitigating coastal erosion and flooding, creating wildlife habitat, and improving water quality.
- Identifying opportunities for managing natural plant communities using strategies that restore ecological processes, such as controlled burning or prescribed fires that mimics the effects and benefits of wildfires.
- Layering plantings that emulate natural communities, reduce the need for watering, and are self-supporting once established.

A-7.2 Native and Regionally Adapted Plants.

Design the landscape to achieve an Installation-wide target of 80% native plant species.

Design with plant communities that mimic natural ecosystems. These designed plant communities should include native species that form associations in their natural habitat. Also, incorporate non-native, adapted species that perform similar ecological functions and niches to native counterparts.

A-7.3 Landscape Areas.

If there is inadequate space on the project site to meet the landscape area or tree planting requirements, identify auxiliary location for installation of trees. Coordinate with the landscape architect, the Installation forestry manager, arborist, natural resources group, or other designated point of contact. Refer to IDGD and project specific SoW for additional guidance. The Government Landscape Architect may set alternate standards for projects located in arid or semi-arid conditions.

Install large street trees 40 feet on center. Maximize continuous root zone to the greatest extent possible. Design parking lot landscaping to meet the following recommended requirements:

- Select trees that have a normal life span of greater than 40 years.
- Limb branches a minimum of 5 feet (1.5 m) above grade to avoid vehicular and pedestrian conflict. Maintain a balance of 2/3 foliage and 1/3 trunk.
- Strive for a minimum 10% of interior greenspace for privately owned vehicle (POV) parking lots.
- Strive for a minimum 10% of interior greenspace for non-POV parking lots where possible. If user requirements for non-POV lots do not warrant interior tree planting, consider planting trees elsewhere on-site or Installation.
- Provide 30 square feet (25 m^2) of landscape area per parking space.

- Design a 9-foot (2.7 m) minimum width interior landscape area, exclusive of curbing, for all small trees.
- Design a 15-foot (4.6 m) minimum width interior landscape area, exclusive of curbing, for all large trees.
- Design a 10-foot (3.0 m) minimum width interior landscape area, exclusive of curbing, for linear landscape islands running perpendicular to the parking stalls.
- A 15-foot (4.6) wide landscape area is preferred in areas utilizing LID strategies.
- End islands should aim to have two trees where space allows.
- Install required trees within 5 feet (1.5 m) to 10 feet (3.0 m) outside the parking lot perimeter if room within islands is not available.
- Coordinate with DoD or the designated point of contact, for parking lot requirements in climates that are non-conducive to tree planting within parking lots.

A-7.4 Wildlife Borders.

Wildlife edge plantings are composed of native vegetation that include a mixture of woody and herbaceous plant materials, including grasses, that attract and sustain wildlife. The inclusion of wildlife borders establishes habitat and food sources. Wildlife borders, with a width of at least 30 feet (9.1 m), should be located at the edges of woodlands, fields, and drainage areas. The establishment of interconnected wildlife corridors is encouraged. Wildlife corridors should reinforce the Green Infrastructure plans of the Installation-specific IDP and ADP, the INRMP, and other IDGD.

Comply with BASH guidance if located within the zone for active runways. Once established, maintain borders by removing invasive species and large trees and shrubs as they begin to shade out low-growing plants.

Figure A-1 Wildlife Border

A-7.5 Integrated Pest Management.

IPM provides an effective and environmentally sensitive approach to pest control through a focus on prevention and the use of pesticides only as needed. IPM programs use current, comprehensive information on the life cycles of pests and their interaction with the environment. Multiple approaches are combined to establish an IPM plan that is site specific and incorporates situational needs. A four-tired implementation approach should be applied:

1. Identify pests and monitor weekly progress
2. Set action thresholds to focus the size, scope, and intensity of the plan
3. Prevent infestation by removing conditions that attract pests
4. Control by employing mitigation options if action thresholds are exceeded

Comply with Installation-specific guidance when preparing IPM plans.

A-7.6 Fire-resistant Landscaping.

Employ strategies to reduce the risks posed by fire, including wildland fire, to structures, facilities, and infrastructure:

- Remove fuel sources and use fire-resistant materials, such as plants and mulch with low resin content, around structures.
- Create permanent firebreaks that are least 10 feet (3.0 m) wide, using hardscape or appropriate vegetation.
- Select plants that are low growing, fire-resistant, have high-moisture content and low sap or resin content. Perform regular maintenance such as pruning and removing deadwood.

Refer to guidance from the National Fire Protection Association (NFPA), including the “NFPA 1144 Standard for Reducing Structure Ignition Hazards from Wildland Fire” and recommendations for “Firewise Landscaping” in the NFPA’s *Safer from the Start: A Guide to Firewise-Friendly Developments*.

A-7.7 Xeriscaping.

Practice conservation through the implementation of the seven horticultural principles of xeriscaping. Xeriscaping will provide attractive solutions that save water and reduce maintenance requirements. Provide plantings that cover at least 60% of a planting area (planting bed) with shrubs and ground cover so that masses form within five years. The remaining area may be mulched. Follow Installation-specific guidelines for mulch requirements. Limit large areas of rock to minimize the creation of heat sinks.

Minimize lawn areas. Avoid unnecessary or unusable, small areas of lawn that cannot be irrigated effectively and efficiently. Reduce maintenance by maintaining lawn at a height that will shade out weeds. Use native or regionally adapted plant materials.

A-7.7.1 Xeriscaping Maintenance.

Perform yearly soil tests and apply soil amendments as recommended. Xeriscaping techniques may reduce, but do not eliminate the need for, weed control, pruning, mowing, fertilizing, and annual mulch replenishment.

A-7.8 Lawns and Grasses.

Limiting turf grass areas will reduce water required for establishment. Minimize turf areas in arid climates, except where required for active or passive recreation.

Avoid a monoculture lawn. Use seed, sod, or sprig mixes that combine multiple varieties of native and adaptive species, require less water, and grow to a maximum height of 6 inches (15 cm). A maintenance guide and schedule should be written for the specific species to be installed.

Meadows and Native Prairies.

Meadows and native prairies are designed to replicate natural ecosystems. The installation of meadows and native prairie restorations will reduce maintenance, fertilizer, and water use, and will create a more varied landscape. Educate maintenance staff about the unique attributes and requirements of a meadow or prairie installation. The establishment period is typically three years, at which point the meadow will begin to look full and diverse.

Create a manicured edge adjacent to pedestrian areas to allow for a clean transition to the taller meadow areas. Mow manicured edge to a maximum height of 6 inches (15 cm). Include educational signage for meadow areas in high use traffic areas to educate users and maintenance staff. Refer to section A-21 Exterior Wayfinding and Signage.

A-7.9.1 Meadow and Native Prairie Maintenance.

Meadows and native prairies require different maintenance practices than traditional lawns. Mowing is performed one to two times per year, as opposed to weekly. Specialty mowing equipment capable of raising mowing deck to 6 inches (15 cm) will be required. Native prairies can be managed through controlled burns, where appropriate, to minimize invasive plants and to rejuvenate growth of desirable species.

The active management of invasive plant materials is critical to the success and diversity of the meadow or prairie. A maintenance guide and schedule should be written for the specific species to be installed.

A-8 EXISTING VEGETATION.

Existing vegetation on Installations, especially trees, is an asset and analyzing the type, amount and condition of the vegetation is an important step in understanding the site. Design the project to preserve existing vegetation, including pollinator or host food-source plants. Examine and document sites to determine individual species and plant associations.

A-8.1 Tree Inventory.

If required, tree inventories must be performed by a licensed landscape architect or an International Society of Arboriculture (ISA) Certified Arborist ®.

For wooded areas, survey the edge of the tree line and inventory the density and species of trees. The tree inventory should identify and record any tree over 6 inches (15 cm) DBH. Trees with 24 inches (61 cm) DBH or greater are defined as a significant, heritage, champion, or specimen tree. Note these trees on the survey where present. Gather the following information during the tree inventory:

- Botanical and common names
- Size (height, canopy spread, trunk DBH)
- Approximate age and life expectancy
- Condition
- Replacement value
- Maintenance needs
- Tree location reference points
- Hazard potential

A-9 TIMBERING.

Coordinate all timbering activity with the Installation forestry manager, landscape architect, arborist, natural resources group, or other designated point of contact. Comply with applicable regulations for each jurisdiction.

A-10 REFORESTATION.

Coordinate reforestation with the Installation forestry manager, landscape architect, arborist, natural resources group, or other designated point of contact. Specify a minimum of five species of trees to avoid the installation of a monoculture. Plant species as a diverse mix across the landscape, not in rows or blocks of single species. Install a 10-foot (3.0 m) to 15-foot (4.6 m) wide wildlife border at the edge of all reforestation areas. If there are no established state, local, or Installation reforestation criteria, then plant seedlings at a minimum rate of 625 trees per acre (0.4 hectare). Include the implementation of a wildlife border where space allows. A final walkthrough and inspection are recommended prior to acceptance. A one-year warranty is recommended. Require 90% viability of seedlings at final acceptance.

A-11 FORESTRY MANAGEMENT PLAN.

Identifying, quantifying and understanding an Installation's tree population is crucial to devising a comprehensive, long-term approach to its viability. Trees that receive scheduled maintenance will generally live longer.

Tree management categories include the following:

- Native Forests: If found in undeveloped areas, native forests should be managed as part of a commercial forestry program.

- Native Trees in developed areas: Inventory and add to the forest database, which should receive regularly scheduled maintenance and care.
- Installed Trees: Include all trees planted as seedlings, transplants, or nursery stock in the forestry inventory, which should receive regularly scheduled maintenance and care.

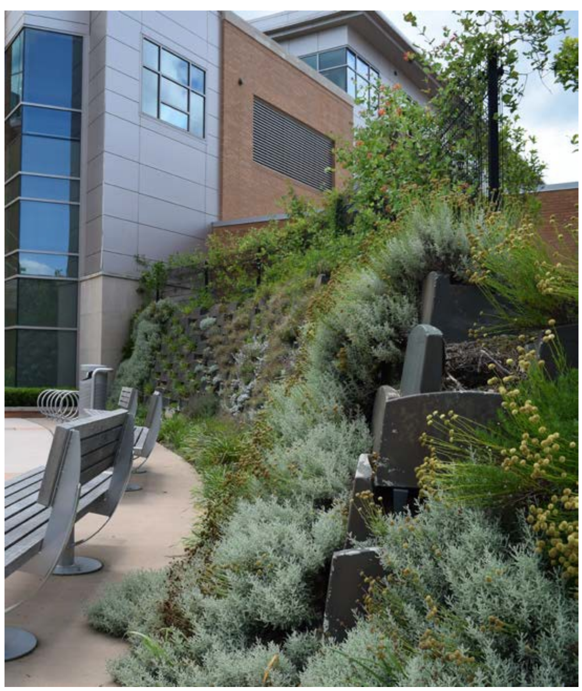
A-12 GREEN WALLS.

Green walls include all types of vegetated vertical surfaces. Systems typically include plants growing into supporting structures. Green walls may be freestanding or attached to a structure. Benefits of implementation include the support of the natural cooling processes and improved air quality. Design to adhere to Installation-specific development and design policies. Consider the following in the design of green walls:

- Location and setting-defined: maintenance level, drainage, space constraints, soil bed or growing media, or application type
- User-defined: desired benefits, function, and access
- Environmental-defined: light, temperature, atmosphere, humidity, and watering needs

Identify and address watering needs of the plant materials during the establishment period and beyond. Consider the use of alternative water sources. The installer should submit an irrigation schedule and watering contract.

Figure A-2 Green Wall with Green Screen



A-13 GREEN ROOFS.

Green roofs are typically vegetative plantings installed over an integrated drainage and growing system on a rooftop. Benefits include enhancing visual quality, stormwater mitigation, energy savings, increasing building insulation, and mitigating heat island effect. Green roofs typically have higher initial costs than traditional roofs; however, the costs are offset through reduced energy and stormwater management costs, as well as increased lifespan of the membrane and roofing system.

A-13.1 Extensive and Intensive Green Roofs.

Extensive green roofs have a shallow growing medium, usually less than 6 inches (15 cm), with a lesser roof load, limited plant selection, and minimal maintenance. Extensive green roofs employ more low-growing plant sections. Due to the shallow nature of the system, extensive roofs can be utilized on sloped surfaces up to 30 degrees.

Intensive roofs have a deep growing medium section that will support a diverse range of plants, including trees. Intensive systems have greater loads, and it is critical that the supporting structure can handle the additional weight. A higher level of visual quality is achieved with a wider plant palette. Typically, intensive roofs are physically and visually accessible and are combined with hardscape pedestal systems for access. Intensive roofs require a greater level of maintenance.

A-13.2 Media Selection.

Green roof growing medium is a mixture of porous mineral aggregates and small amounts of organic material. Permeability, porosity, and weight are key considerations. Select the media mix to resist decomposition and compression. The media mix should be able to withstand freeze-thaw cycles that may degrade the material. Media selections should comply with German Landscape Research, Development and Construction Society (FLL) recommendations for extensive and intensive green roofs in *Green Roof Guidelines: Guidelines for the Planning, Construction and Maintenance of Green Roofs*.

A-13.3 Plant Selection.

Plant materials can be installed in a variety of ways, including trays, plugs, containers, and carpets. Select plants with the following considerations:

- Roof type: extensive vs. intensive
- Growth habit
- Climate and micro-climates: wind, temperature, precipitation, freeze/thaw cycles
- Low-maintenance: native, drought tolerant, hardy plants that require limited irrigation and nutritional needs
- Purpose: stormwater management, energy conservation, heat island reduction, aesthetics, or a combination

A-13.4 Green Roof Establishment and Maintenance.

Consider establishment as well as long-term irrigation needs.

Weed seeds have the potential to be deposited onto the roof by birds, insects, and the wind. Weed the green roof aggressively during establishment to remove weeds and to prolong the life of the plants and growing medium. Create a maintenance guide and seasonal schedule for the specific plant species and system to be installed.

Figure A-3 Extensive Green Roof

A-14 EROSION CONTROL.

Erosion is influenced by soil type, vegetation, and topography. Use slope stabilization techniques on all slopes greater than 3:1. Methods include the use of specialty plantings, hydro seeding, geotextiles, and erosion control mats. Lawn areas should not exceed a 3:1 slope.

A-14.1 Vegetative Stabilization of Soils.

Vegetative stabilization measures employ low-maintenance plant materials to protect soil exposed to the erosive forces of water and wind. Vegetation intercepts and slows runoff, offers direct protection of the soil from wind, and removes water from the soil through evapotranspiration. Below the surface, vegetation binds the soil and increases the infiltration of runoff that recharges the water table.

Select plant materials and ground covers that withstand erosion during periods of intensive rainfall. Use grasses, ground covers, and woody plants with root systems to help stabilize soils and reduce surface erosion on slopes and embankments.

A-15 SOILS.

A-15.1 Specialty Soils.

Coordinate specialty soil mixes, such as bioretention media, green roof media and structural soils, with the DoR.

A-15.2 Topsoil.

Spread topsoil across all areas to be seeded, sodded, or planted. Apply topsoil at a depth appropriate to intended plant materials, existing soils, and moisture needs. Under no circumstances should the depth be less than 4 inches (10 cm).

A-15.3 Organic Matter Application.

Apply compost to existing soils with inadequate and low percentages of organic matter. Organic matter keeps soils friable, which is critical for optimal plant growth. Aerate and spread compost at a rate of 1 inch per acre (25 mm per 0.4 hectare), over the target area, to increase the organic matter percentage by approximately 2%. Lighter applications may be applied in subsequent years. Perform soil testing periodically to gauge application efficacy.

A-16 INTERIOR PLANTING.

The installation of plants within a building environment has quantifiable benefits, including the improvement of indoor air quality, environmental cooling, and noise mitigation. Research has shown that workers with a view of plants, either indoor or outdoor, have increased productivity and morale. Adhere to Installation-specific interior landscape development and design policies where applicable. Consider the following in the design of interior planting:

- Location: maintenance level, drainage, space constraints, and application type, including moveable planters, living walls, planting beds, and trellises
- User: desired benefits, location within individual workspaces, and access
- Environmental-defined: light, temperature, atmosphere, humidity, and watering needs

A-16.1 Interior Planting Maintenance.

Maintenance is the key to successful interior planting design. Interior plantings will need an irrigation system, hose bibs, or watering contract. Drip irrigation is recommended. Do not use non-potable water sources for spray irrigation. Consider the use of alternative water sources. The installer should submit an irrigation schedule and watering contract to address watering needs.

A-17 IRRIGATION.

Irrigation systems are an important part of establishing a landscape. Planting is a large investment and without proper establishment, it will not survive. A one-year establishment period is typical; however, some plantings may need up to 3 years for establishment. Design efficient temporary irrigation systems to conserve water while delivering required resources. Consider the unique characteristics of the soil, climate, topography, quantity and quality of water availability, and specific plant materials when determining a temporary irrigation strategy.

High-efficiency irrigation systems, whether permanent or temporary, deliver up to 95 percent of the water supplied versus conventional irrigation systems that are as little as 60 percent efficient. Use smart irrigation controllers that draw on data from sensors, weather forecasts and plant-care databases to determine watering requirements and time of delivery. Drip irrigation will deliver water to shrub beds more efficiently with little water loss due to evaporation or runoff. Replace or upgrade existing irrigation systems as practical to maximize water utilization. Refer to the Irrigation Association's publication *Landscape Irrigation: Best Management Practices*.

A-17.1 Plant Associations.

Design a comprehensive landscape plan to minimize water requirements. Consider water requirements when choosing plant material to reduce water consumption. The following planting practices will reduce water needs:

- Limit the amount of turf grass.
- Select plant associations to ensure similar requirements.
- Group plants with similar water requirements.
- Specify native plants that are more acclimated to regional conditions.

A-17.2 Alternative Water Sources.

Research opportunities to update existing irrigation systems, especially on golf courses and driving ranges, in order to reduce the use of potable water by taking advantage of alternative water sources. Alternative water sources, including captured rainwater and gray water, and water conservation systems, including drip irrigation, are being used successfully on DoD projects to reduce demand on potable water sources. Alternative methods include:

- Collection and storage of rainwater in cisterns
- Reuse of chiller condensate
- Retention and detention of runoff in stormwater features

Inspect existing irrigation systems for efficiency and soundness.

A-18 HARDSCAPE.

Hardscape design has essential requirements for drainage, accessibility, health, and safety. Safety considerations include safe lighting levels and slip-resistant surfaces. There are opportunities to design hardscape to reduce stormwater runoff, heat island effect, and life-cycle costs.

General recommendations for hardscape include the following:

- Select paving materials for the local climatic conditions to ensure longevity, functionality, and aesthetics.
- Distinguish between vehicular and pedestrian rated pavers.
- Utilize a raised or flush curb as an edge restraint for asphalt and paver areas.
- Review samples and field-constructed mockups with a minimum area of 8 feet by 8 feet (2.4 m by 2.4 m) of specialty pavements.

A-18.1 Concrete.

Design a scoring plan and details to indicate control and expansion joints. When designing colored concrete applications, for durability, always use a foundation of integral color. Topically applied color (color hardener or dust-on color) may then be used for enhancement purposes where not prohibited by IDGD.

A-18.2 Pervious Pavements.

Pervious or permeable pavements may be part of a strategy to restore a more natural hydrologic system on site. Evaluate these pavements for cost-effectiveness, structural capacity, and maintenance requirements. Follow the manufacturer’s recommended installation specifications. General recommended standards include the following:

- Limit the use of pervious surfaces to flat or slightly sloped areas. Terrace slopes greater than 5%.
- Verify that soils have a permeability rate of 1 inch (2.5 cm) per hour or greater.
- Verify a 2 foot (0.6 m) minimum clearance (vertical distance) between the bottom of the pavement system and the seasonal high-water table.
- Ensure that the permeable pavement system is not hydraulically connected to structural foundations.
- Verify that selections for joint filler, void material, and bedding material ensure permeability.
- Use a herringbone pattern or other approved pattern for vehicular surfaces.

Figure A-4 Vehicular-Grade Pervious Pavement Systems[1]

A-18.2.1 Pervious Pavement Maintenance.

A major design consideration for pervious pavements is maintenance requirements. Vacuum pervious pavements yearly. Prevent soil and mulch from clogging the stormwater system.

Pervious pavements are susceptible to damage from conventional snow removal practices. Plows with metal blades can damage surfaces. Salt, chemicals, and sand treatments may reduce porosity. Sanding should not be used on pervious surfaces without permission from AHJ. The use of a rotary broom or snow blower is the preferred method for snow removal. Plows with rubber or plastic-edged blades are acceptable. If a metal blade is used, keep the blade 1 inch (3 cm) above the pavement surface.

A-19 HEAT ISLAND EFFECT.

Landscape architectural site design plays a major role in unifying efforts to reduce heat-island effect. Reduction strategies include use of the following:

- Paving materials with a high Solar Reflectivity (R) value or high Solar Reflectance Index (SRI). SRI is a composite measure of solar reflectivity and thermal emissivity. An SRI value of 29 or higher is recommended for site

[1] Image: Cascade Design Collaborative, http://www.cascadedesigncollab.com/

materials exposed to sunlight. Solar reflectivity characteristics can be obtained from the material manufacturer.

- Open-grid paver systems with a high SRI value
- Vegetated surfaces or rock mulch with a high R or SRI value in lieu of hardscape
- Tree canopy and structures to shade paved surfaces, buildings and lawns
- Vegetated roofs

Prioritize the retention of existing vegetative cover to shade hardscape, especially dark surfaces. In arid and polar climates, tree canopy is less likely to be used. Parking canopy structures are more common. Consider parking canopy options with vegetative roofs or photovoltaic solar panels.

Figure A-5 Covered Parking: Parking Canopy with Photovoltaic Solar Panels[2]

A-20 WALLS, FENCES, AND GATES.

Limit the use of chain link fence to temporary, secondary, and utilitarian applications. Select decorative styles for primary entrances, formal contexts, and highly visible perimeters. Scale these elements appropriately in relation to adjacent buildings. Balance security needs with pedestrian access and circulation through common areas and along typical pedestrian routes.

Consider the use of green screens (vining plants growing on fences or trellises) to provide privacy, protection, or visual screening, while creating a softer, more aesthetically appealing barrier.

[2] Image: Airman 1st Class Cary Smith/U.S. Air Force, "Building resilient infrastructures one panel at a time," 2016 August 12, https://www.usafe.af.mil/News/Article-Display/Article/916922/building-resilient-infrastructures-one-panel-at-a-time/

A-21 EXTERIOR WAYFINDING AND SIGNAGE.

Successful wayfinding and signage systems clearly communicate information, making a campus legible and accessible. Signage systems operate on a hierarchy of scale, graphics standards, and strategic placement, and should form a cohesive scheme. Integrate the following components into a comprehensive wayfinding system:

- Maps
- Visual communication including variation in colors, patterns and marking of hardscape
- Visual guidance created by structural elements in the landscape
- Non-visual communication, such as auditory and tactile wayfinding

Signage programs are unique for each Installation. Consult the individual IDGD for wayfinding and signage standards. Minimize the number of signs for directions, identification, and customer service to achieve an efficient, cost-effective, and attractive system. The design of wayfinding features and signage should correspond with the material palette for the Installation or facility. Integrate interior signage standards and wayfinding elements into the overall project design and coordinate with exterior features.

A-22 SITE LIGHTING.

Consult the individual IDGD for site lighting standards. Use multiscale lighting across the site to emphasize circulation corridors and highlight significant site features. Incorporate vehicular, pedestrian, bollard, and accent lighting into the lighting design.

A-22.1 Lighting Coordination and Placement.

Lighting coordination and placement are critical components of a safe and secure site. Coordinate with the electrical engineer and design team to implement the following recommended standards:

- Place lighting to minimize conflicts with trees, utilities and stormwater structures, closed-circuit television (CCTV), and other site elements.
- Locate vehicular lighting along travel ways and within parking areas. In vehicular lighting areas, meet or exceed the minimum industry standard of 1 foot-candle (10 lux) average.
- Set light fixtures back a minimum of 2 feet (0.6 m) from circulation aisles and parking stall curbs.
- Use pedestrian-scale lighting in gathering spaces and along walkways. Install pedestrian lighting at a maximum height of 12 feet (3.7 m), unless IPS guidance directs higher or lower installations.
- Bollards and accent lighting may be used in place of traditional light poles within pedestrian areas. Ensure fixtures do not emit light skyward and meet minimum foot-candle requirements.
- Light all pedestrian areas to a minimum industry standard of 1 foot-candle (10

- lux) average, unless otherwise stated in IPS guidance.
- Position light fixtures to avoid light trespass along property lines. Maximum light levels at the property line should not exceed 0.1 foot-candle (1 lux).

A-22.2 Dark Sky and Light Trespass.

Meet dark-sky criteria and ensure all light fixtures have horizontal cut off at 90 degrees. The dark-sky movement encourages the use of full cut-off light fixtures that cast no light upward. Control the direction and spread of light by choosing appropriate light fixtures. Refer to the International Dark-Sky Association (IDA) website for resources on product selection. Select all light fixtures to conform to the Illuminating Engineering Society's (IES) standards for "full cut-off" or "fully shielded" fixtures.

Minimize light trespass from site lighting to reduce sky-glow, increase nighttime visibility, minimize negative effects on nocturnal animals, and improve human health and functioning.

A-22.3 Environmental Considerations.

Poorly designed lighting may adversely affect wildlife populations, including endangered species such as nesting sea turtles and migrating birds and bats. Consult with the Installation natural resources manager to identify any potential conflicts with wildlife and appropriate design modifications.

A-22.4 Energy Efficiency.

Select lighting in accordance with the Installation-specific energy efficiency goals and criteria.

Solid state lighting (SSL), including light-emitting diodes (LED), or improved systems that meet more stringent energy goals must be the first consideration for all exterior applications such as building area, roadway, parking lot, pathway, sidewalk, signage, landscape, and security lighting. Formulate site lighting to minimize energy use while maintaining safe light levels.

A-23 SITE FURNISHINGS.

Select site furnishings to match the IDGD and create a cohesive design palette that is applied consistently across a project, including use of the same materials, colors, and finishes. Affix all site furnishings to a permanent surface. Ground mounting or use of a ground-set foundation is preferred.

Site furnishings, together with active users (as in the case of seating), should not impede the flow of vehicular, bicycle, or pedestrian traffic, except where used as traffic barriers or security features.

A-23.1 Flagpoles.

Use the following recommended design standards for ground-mounted flagpoles:

- Appropriate flagpole size for the flag desired per manufacturer recommendations
- Tapered flagpole
- Foundation tube is ground set in a concrete footing. Roof mounting or use of an outrigger pole are acceptable alternatives if ground-mounting is not possible
- An internal cable halyard assembly
- Finial ball ornamentation
- Lightning kit recommended for the pole specified which supplies the required protection
- Stainless steel or aluminum pole with matching components

Table A-2 Flagpole Size Recommendations[3]

Flagpole Height	Recommended Flag Dimensions
20 ft (6.1 m)	3-1/2 ft by 6-2/3 ft (1.1 m by 2.0 m)
30 ft (9.1 m)	5 ft by 9-1/2 ft (1.5 m by 2.9 m)
40 ft (12.2 m)	5 ft by 9-1/2 ft (1.5 m by 2.9 m)
50 ft (15.2 m)	8-2/3 ft by 17 ft (2.6 m by 5.2 m)
60 ft (18.3 m)	8-2/3 ft by 17 ft (2.6 m by 5.2 m)

A-23.2 Bike Storage.

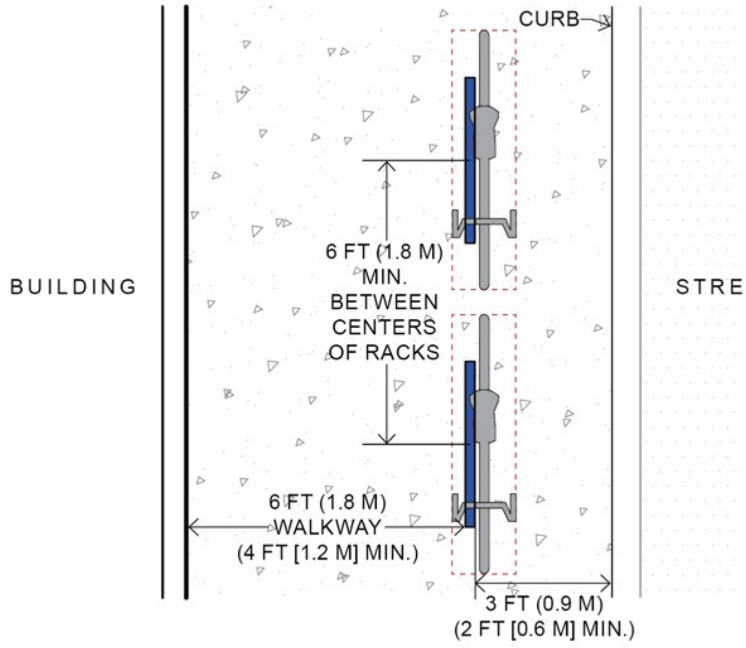
Placement of at least one bicycle storage unit at every facility is recommended, with space to accommodate a minimum of four bicycles with each storage unit. Align bicycle storage with occupancy requirements as stated in the IDGD and other project-specific documents. Install storage units in a secure location near facility entrances. Bike storage can be divided into three types:

- Short-term bike storage consists of outdoor racks; see Figure A-6 for examples of recommended space requirements.
- Long-term storage consisting of a covered facility, including racks under or inside of a shelter.
- Long-term bike lockers.

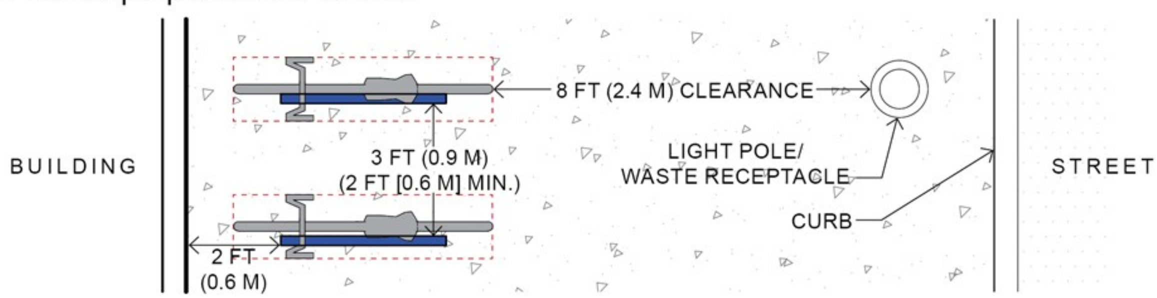
[3] General Services Administration. *Facilities Standards for the Public Buildings Service* (PBS-P100), April 2017, https://www.wbdg.org/FFC/GSA/p100_2017.pdf.

Figure A-6 Short-Term Bike Storage: Layout Options

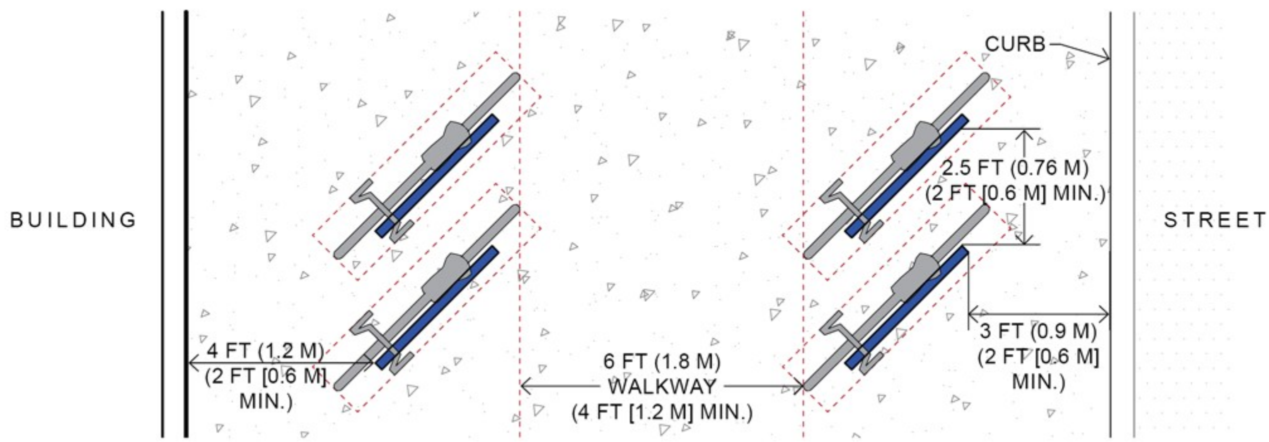
A. Racks parallel to curb



B. Racks perpendicular to curb



C. Racks diagonal to curb – 45 degree angle



A-23.3 Seating.

Select benches that create a unified system of seating. Locate benches and seat walls at primary building entrances, drop-off zones, and gathering spaces such as plazas and courtyards. Design for a minimum of 1 linear foot (0.3 m) of seating per 50 square feet (4.6 m^2) of plaza or courtyard space. Ensure that seating options accommodate all user groups. Locate a minimum of one bench along every 1/4 mile (0.40 km) of trail. Consider accessibility requirements when designing seating areas.

To facilitate good pedestrian traffic flow, place benches and other seating:

- A minimum of 3 feet (0.9 m) from the path of travel, such as a sidewalk or trail.
- At least 3 feet (0.9 m) away from sign posts, waste receptacles, or any stationary obstacle.

A-23.4 Outdoor Dining.

Locate outdoor dining spaces according to the project program requirements and locate on concrete paving that extends at least 3 feet (0.9 m) beyond the edge of seating on all sides. Consider accessibility when designing seating areas.

Include permanent grill stations in picnic areas. Use grills with a minimum 200 square inch (0.12 m^2) size grill area, and preferably a stainless-steel lid. Specify whether the grill is gas or charcoal in the RFP.

A-23.5 Grates.

Use tree grates in pedestrian areas where there is a need for additional walkable surface area. Design tree grates no smaller than 5 feet by 5 feet (1.5 m by 1.5 m), and plan to replace or modify grates to accommodate trunks as they grow in diameter. Specify decorative metal grates in pedestrian areas.

Place grates over trench drains and other stormwater conduits that traverse walkways. Dome grates are recommended in yard areas to reduce clogging.

A-23.6 Planters.

Use planters for decorative purposes at building entrances and in pedestrian plazas. Planters may function as security barriers, if they meet the design specifications in UFC 4-022-02. Planters may be used to screen security barriers. Design or select planters to contain the soil volume needed to support the intended planting and include appropriate drainage requirements. Consider the option for a self-watering container with a reservoir system.

A-23.7 Waste Collection and Trash Enclosures.

Designate separate receptacles for trash and recycling. Locate waste receptacles in common areas. Screen trash enclosures with evergreen vegetation.

A-24 COMMON AREAS, RECREATIONAL FACILITIES, AND PLAYGROUNDS.

Design common areas, recreational facilities, and playgrounds using principles and standards for universal or barrier-free design. This includes facilities for both users and spectators. As appropriate, furnish these spaces with shade, benches, bicycle racks, and waste receptacles. Wherever possible, maintain existing natural features, open areas or greenspace that can be used for passive recreational use.

Design recommendations for specific facilities include the following:

- Use main gate and building entrances to elevate the image and importance of the Installation and facility. Coordinate closely between disciplines to balance aesthetics with access and security needs.
- Size plazas and courtyards to allow for 4 to 12 square feet (0.36 to 1.1 m^2) per person, depending on the anticipated site programming.
- Design monuments to create the environment needed to properly memorialize and commemorate significant events and people.
- Locate bus shelters near common areas. Specify bus shelters that are universally accessible and provide seating.

A-24.1 Parade Grounds.

Design parade grounds to create the large open space needed for formation drills, parade and review functions, honor ceremonies, and other events. Parade grounds traditionally take the form of manicured lawns. Surface with turf and stabilize as needed. Use water-saving grasses or ground cover such as low-water engineered turf blends or other low-water alternatives where possible and in consideration of local climatic conditions. Size parade grounds at 1 acre (0.4 hectare) per 125 persons, and size reviewing stands to accommodate a capacity of 5% of officer strength at the Installation.

A-24.2 Exercise Equipment.

Incorporate exercise equipment and fitness trails into outdoor recreational areas. Install equipment on a surface recommended by the manufacturer. Select and design fitness stations for universal accessibility.

A-24.3 Playgrounds.

For playground design and safety, refer to the U.S. Consumer Product Safety Commission (CPSC) 325, *Public Playground Safety Handbook*, or equivalent overseas standards. Apply accessibility design guidance in the *ADA Accessibility Guidelines for Play Areas*. Use a Certified Playground Safety Inspector (CPSI) for design of all playground plans.

Fence play areas to mitigate nearby accessible hazards, such as roads, waterbodies, and steep slopes. Fencing should be a minimum of 4 feet (1.2 m) tall. The preferred material is a decorative aluminum fence. Install an 8-foot (2.4 m) wide gate to allow a service vehicle to enter the play area. Concrete curbing is recommended as a border for the play surface. Place benches in play areas and establish a clear view across the play area. Play areas should have shaded areas in the form of mature tree canopy, shade sails, a shelter or other type of canopy.

A-24.4 Smoking Areas.

Prohibit smoking in common areas frequented by nonsmokers including sidewalks, courtyards, plazas, gathering spaces, main entrances, seating and pavilions. Display clear signage indicating no smoking zone within 50 feet (15.25 m) of all building entrances, windows, other openings or ventilation intake systems. Comply with DODI 1010.10 “Health Promotion and Disease Prevention”.

Consider placing shelters with seating and protection from the elements in the designated smoking area to encourage use of identified space. Use stand-alone ash receptacles or ash receptacles mounted on trash cans. Label hot ash receptacles with logos or text indicating their use. Do not wall-mount hot ash receptacles.

A-25 POST-DESIGN SERVICES.

A-25.1 Operations and Maintenance Manual.

Educate maintenance personnel on the goals and implementation of the site maintenance plan. Address the following in the O&M manual, as applicable:

- Seasonal plant care and pruning
- IPM
- Mowing
- Removal of stakes and guys
- Removal of invasive plants
- Fertilization and soil amendments
- Stormwater planting
- Interior plants
- Green roofs
- Irrigation system
- Hardscape: including resealing, pervious paver vacuuming, salting limitations, and repairs
- Structures, including wall maintenance
- Lighting

Identify maintenance requirements pre-acceptance, during the warranty period, and post-establishment. Identify the responsibilities for each party outlined in the project specifications.

Figure A-7 Example Seasonal Maintenance Schedule

Activity	Season			
General Maintenance:	**Spring**	**Summer**	**Fall**	**Winter**
Trash pick-up	Weekly	Weekly	Weekly	Biweekly
Remove all broken or fallen twigs and limbs	Weekly	Weekly	Weekly	Biweekly
Sweep pavement	Weekly	Weekly	Weekly	Biweekly
Mulching:				
All planting beds with double-shredded hardwood (maintain at 3-in. depth) *			Biannually	
Perennials:				
Deadhead spent flowers		Monthly	Monthly	
Cut back tender varieties after frost			Monthly	Monthly
Pruning:				
Remove sucker growth from tree trunks**				Annually
Prune shrubs to maintain optimal height**				Annually
Fertilization:				
Fertilize shrub plantings with granular application	Biannually (Full Rate)		Biannually (Half Rate)	
Fertilize meadow/lawn	Biannually (Full Rate)		Biannually (Half Rate)	
Chemicals:				
Apply pre-emergent				Annually
Apply post-emergent	Monthly	Monthly		
Insect controls as needed	Monthly	Monthly	Monthly	Monthly
General Meadow/Grasses:				
Mow with Bush Hog – Warm/Cool Season Mix #1 and #2 ***				Annually
Mowing – Cool Season Mix #3 and #4	Biweekly (or as needed to maintain desired height)	Biweekly (or as needed to maintain desired height)	Biweekly (or as needed to maintain desired height)	
Reforestation:				
Reposition or replace tree shelters that are tilted or severely damaged	Monthly	Monthly	Monthly	Monthly
Replace dead/decayed trees per warranty agreement	Biannually		Biannually	
Other:				
Leaf removal			Monthly	Monthly
Irrigation start-up	Annually			
Irrigation shut-down			Annually	
Hand water dry or stressed plants – First 1-2 years (establishment period)	Monthly	Monthly	Monthly	Monthly
Remove dead plants/Replace per warranty – First 1-2 years	Monthly	Monthly	Monthly	Monthly
Spray and grub weeds and invasive plants	Monthly	Monthly	Monthly	

* Flexibility with mulch replenishment in either the spring or the fall
** Prior to spring flush
*** Could be done more than once a year as needed

B-2 DEFINITION OF TERMS.

Authority Having Jurisdiction (AHJ): The component office of responsibility, i.e., U.S. Army, HQ USACE/CECW-CE; U.S. Navy, NAVFACENGCOM HQ Code CHE; U.S. Marine Corps, HQMC Code LFF-1; and U.S. Air Force, AFCEC. The enforcement of the codes and standards as they pertain to facility projects can be delegated to the local Components Office's Chief Engineer's Technical Representative at the discretion of the components aforementioned office.

Bioremediation: The treatment of pollutants or waste (as in an oil spill, contaminated groundwater, or an industrial process) by the use of microorganisms (such as bacteria) that break down the undesirable substances.

Bird/Aircraft Strike Hazard (BASH): The conflict between birds, airfields, and flight paths that poses safety issues for the flying environment. Problem species can be drawn away from active airfield areas by managing habitats on or near airfields, including enhancing habitat elsewhere.[1]

Building: "A roofed and floored facility enclosed by exterior walls and consisting of one or more levels that is suitable for single or multiple functions and that protects human beings and their properties from direct harsh effects of weather such as rain, wind, sun, etc."[2]

Certified Seed: "Certification is the process by which a state seed certifying agency gives official recognition to seeds produced of a cultivar or named variety under a limited generation system which ensures genetic purity, identity, and a given minimum level of quality. Progeny of breeder, foundation or registered seed, handled under procedures acceptable to the Department of Agriculture and Forestry to maintain satisfactory genetic purity and identity."[3]

Charrette: "An intensive creative work session in which a design team focuses on a design problem and arrives at a collaborative solution with stakeholders from the project area. A charrette can be a breakthrough event that helps creates a meaningful master plan or facility design. Properly executed, this technique can produce a master plan or facility design that is more useful, better understood, and more quickly produced than

one formed by any other method."[4]

Complete streets: Complete streets "are designed and operated to enable safe access for all users, including pedestrians, bicyclists, motorists, and transit riders of all ages and abilities."[5]

Cultural landscape: "Cultural landscapes are geographical areas (including both cultural and natural resources and the wildlife or domestic animals therein), associated with a historic event, activity or person or exhibiting other cultural or aesthetic values. There are primarily four types of cultural landscape: designed landscapes, ethnographic landscapes, historic sites, and vernacular landscapes."[6]

Cultural resource (CR): Per DoDI 4715.16:

- Historic properties (any prehistoric or historic district, site, building, structure, or object as defined by part 800 of Reference (k) included in, or eligible for inclusion in, the National Register of Historic Places, whether such eligibility has been formally determined), including artifacts, records, and material remains related to such a property or resource.
- Cultural items as defined in Reference (m).
- American Indian, Eskimo, Aleut, or Native Hawaiian sacred sites as defined in Reference (l).
- Archaeological resources as defined in section 470 aa-mm of Reference (x).
- Archaeological artifact collections and associated records as defined in part 79 of Reference (k).[7]

Embodied energy: The total energy required to manufacture or produce a material, transport it to a project site, and install it.

Hardscape: Inorganic or inanimate landscape elements, primarily referring to pavements and other non-vegetative materials used for paths and gathering areas.

Integrated Cultural Resources Management Plan: "A plan that defines the process for the management of cultural resources on DoD Installations."[8]

[7] DoDI 4715.16, "Cultural Resources Management," 18 September 2008, http://www.esd.whs.mil/Portals/54/Documents/DD/issuances/dodi/471516p.pdf?ver=2017-11-21-114100-670.

[8] DoDI 4715.16, "Cultural Resources Management," 18 September 2008, http://www.esd.whs.mil/Portals/54/Documents/DD/issuances/dodi/471516p.pdf?ver=2017-11-21-114100-670.

Installation Design Guidance Documents (IDGD): Installation-level plans and guidelines including, but not limited to the Installation Master Plan (IMP), Installation Development Plan (IDP), Area Development Plan (ADP), Base Exterior Architectural Plan (BEAP), and Installation Planning Standards (IPS), Air Force's Installation Facilities Standards (IFS), Army's Installation Design Guides (IDG), and Navy's Installation Appearance Plans (IAP).

Landscape area: Pervious area with landscape improvements that is not covered by built improvements and impervious surfaces (including buildings, other structures, or paved surfaces such as including parking areas and walkways).

Large tree: Type 1 and 2 shade trees as classified by the *American Standard for Nursery Stock* (ANSI Z60.1).

Lawn: A managed grass space.

Native plant: A species that is endemic to a geographic or ecological region, or a cultivar of that species.

Landscape establishment period: A period lasting a minimum of 365 days from final acceptance of project, during which plant material is irrigated and observed for viability. The irrigation system, if used is maintained and repaired as needed. This period may be adjusted by the Reviewing Government Landscape Architect. Runs concurrently with *landscape warranty period*.

Landscape warranty period: A period lasting a minimum of 365 days from final acceptance of project, during which plant material must meet 95% survival rate and the irrigation system is in good working order. Runs concurrently with *landscape establishment period*.

Phytoremediation: the treatment of pollutants or waste (as in contaminated soil or groundwater) by the use of green plants that remove, degrade, or stabilize the undesirable substances (such as toxic metals).

Resiliency: The capacity to anticipate, prepare for, respond to, recover from, and adapt to hazards and the risks they pose, including severe weather events and the effects of climate change.

Site commissioning: "Site Commissioning is a systematic process of verifying that systems within the built environment, beyond a building's skin, perform in accordance with design intent and the property owner's operational needs."[9]

Site furnishings: Functional and aesthetic amenities that enhance a site for human comfort.

[9] General Services Administration, *Site Commissioning White Paper*, July 2017, https://www.gsa.gov/cdnstatic/2017-13-07_SiteCommissioning_AccSingle_WhitePaper.pdf.

Site improvements: All site modification that will result in permanent paving features or landforms. Does not refer to enclosed buildings or airfield pavements.

Small Tree: Type 3 small upright trees and Type 4 small spreading trees as classified by the *American Standard for Nursery Stock* (ANSI Z60.1).

Turf: The upper stratum of soil bound by grass and plant roots into a thick mat.

Viewshed: The natural environment that is visible from one or more viewing points

Xeriscaping: Xeriscaping is landscaping and gardening that reduces or eliminates the need for supplemental water from irrigation. This term was coined by Denver Water in 1981 and is associated with seven design principles elaborated on at utility's website: https://www.denverwater.org/residential/rebates-and-conservation-tips/remodel-your-yard/xeriscape-plans/xeriscape-principles.

FOREWORD

The Unified Facilities Criteria (UFC) system is prescribed by MIL-STD 3007 and provides planning, design, construction, sustainment, restoration, and modernization criteria, and applies to the Military Departments, the Defense Agencies, and the DoD Field Activities in accordance with USD (AT&L) Memorandum dated 29 May 2002. UFC will be used for all DoD projects and work for other customers where appropriate. All construction outside of the United States its territories, and possessions is also governed by Status of Forces Agreements (SOFA), Host Nation Funded Construction Agreements (HNFA), and in some instances, Bilateral Infrastructure Agreements (BIA). Therefore, the acquisition team must ensure compliance with the most stringent of the UFC, the SOFA, the HNFA, and the BIA, as applicable.

UFC are living documents and will be periodically reviewed, updated, and made available to users as part of the Military Department's responsibility for providing technical criteria for military construction. Headquarters, U.S. Army Corps of Engineers (HQUSACE), Naval Facilities Engineering Systems Command (NAVFAC), and Air Force Civil Engineer Center (AFCEC) are responsible for administration of the UFC system. Technical content of UFC is the responsibility of the cognizant DoD working group. Defense Agencies should contact the respective DoD Working Group for document interpretation and improvements. Recommended changes with supporting rationale may be sent to the respective DoD working group by submitting a Criteria Change Request (CCR) via the Internet site listed below.

UFC are effective upon issuance and are distributed only in electronic media from the following source:

- Whole Building Design Guide website https://www.wbdg.org/ffc/dod.

Refer to UFC 1-200-01, *DoD Building Code*, for implementation of new issuances on projects.

TABLES

CHAPTER 1 INTRODUCTION

1-1 REISSUES AND CANCELS.

This UFC reissues and cancels UFC 3-210-10 Low Impact Development, with Change 3, 1 March 2020.

1-2 PURPOSE AND SCOPE.

This UFC provides technical criteria, technical requirements, and references for the planning and design of applicable Department of Defense (DoD) projects to comply with stormwater requirements under Section 438 of the Energy Independence and Security Act (EISA) enacted in December 2007 (hereafter referred to as EISA Section 438) and the Deputy Under Secretary of Defense DoD policy on the implementation of stormwater requirements under EISA Section 438.

1-3 APPLICABILITY.

This UFC applies to all service elements and contractors involved in the planning, design, and construction of all permanent DoD projects in the United States, United States Territories and Possessions of the United States that meet both of the following conditions:

- The project includes construction or expansion of one or more buildings as part of its primary scope. For example, primary facilities vice supporting facilities.
- The "footprint" is greater than 5,000 gross square feet (464.5 square meters). "Footprint" consists of all new impervious surfaces associated with the building(s), including both building area and pavement area of associated supporting facilities (such as parking and sidewalks). "Footprint" does not include existing building area to be renovated, existing pavement area to be resurfaced, or new pavement area other than supporting facilities associated with the building(s).

For projects in the United States, United States Territories, and Possessions of the United States that do not meet the applicability requirements above, Low Impact Development (LID) techniques apply to the extent practicable.

1-3.1 Overseas Locations.

All design and construction outside of the United States and United States territories is governed by international agreements, such as the Status of Forces Agreements (SOFA), Host Nation Funded Construction Agreements (HNFA), and in some instances, Bilateral Infrastructure Agreements (BIA), and country-specific Final Environmental Governing Standards or DoDI 4715.05. DoDI 4715.05 is commonly referred to as the Overseas Environmental Baseline Guidance Document (OEBGD). The OEBGD applies when there are no international agreements in place. Therefore, in foreign countries this UFC will be used for DoD projects to the extent that it is allowed by and does not conflict with the applicable international agreements. For projects where the OEBGD is applicable, consider and apply LID techniques to the extent practicable.

1-4 GENERAL BUILDING REQUIREMENTS.

Comply with UFC 1-200-01, *DoD Building Code*. UFC 1-200-01 provides applicability of model building codes and government unique criteria for typical design disciplines and building systems, as well as for accessibility, antiterrorism, security, high performance and sustainability requirements, and safety. Use this UFC in addition to UFC 1-200-01 and the UFCs and government criteria referenced therein.

1-5 CYBERSECURITY.

All facility-related control systems (including systems separate from a utility monitoring and control system) must be planned, designed, acquired, executed, and maintained in accordance with UFC 4-010-06, and as required by individual Service Implementation Policy.

1-6 GLOSSARY.

APPENDIX B contains acronyms, abbreviations, and terms.

1-7 REFERENCES.

APPENDIX C contains a list of references used in this document. The publication date of the code or standard is not included in this document. Unless otherwise specified, the most recent edition of the referenced publication applies.

CHAPTER 2 TECHNICAL REQUIREMENTS

2-1 DESIGN OBJECTIVE.

2-1.1 Establishing Pre-Development Condition.

The overall design objective for each applicable project is to maintain pre-development hydrology and prevent any net increase in stormwater runoff. DoD defines "pre-development hydrology" as the pre-project hydrologic conditions of temperature, rate, volume, and duration of stormwater flow from the project site. The analysis of the pre-development hydrology must include site-specific factors (such as soil type, ground cover, and ground slope) and use modeling or other recognized tools to establish the design objective for the water volume to be managed from the project site. The Designer of Record (hereafter referred to as the designer) must document the existing features that comprise the existing development condition.

Manage the increase in runoff between pre- and post-development conditions on the project site, to the maximum extent technically feasible, through interception, infiltration, storage, or evapotranspiration processes. Other design requirements may need to be considered. Calculations must be performed by the designer indicating the difference between the post-development hydrology and pre-development hydrology for the design storm event. Calculations must demonstrate "No net increase" in stormwater runoff where technically feasible.

2-1.2 Design Storm Event.

The design storm is the 95th percentile rainfall event. It is based on daily measured precipitation depths accumulated over a 24-hour period. The design storm event is derived from rainfall data collected for a minimum of 10 years, but ideally should be based on 30 years of data, where 30 or more years of rainfall records are available. Tables A-8 and A-9 in APPENDIX A contain rainfall analyses for selected locations. Use the values in APPENDIX A or calculate the 95th percentile rainfall depth based on rainfall records. Rainfall records can be obtained from National Oceanic and Atmospheric Administration (NOAA) at https://www.ncdc.noaa.gov/cdo-web/. A general procedure for selecting rainfall stations and downloading historical rainfall records is outlined in APPENDIX A, Section A-4.7.

2-1.3 Maximum Extent Technically Feasible (METF).

Evaluate project site options to achieve the design objective to the maximum extent technically feasible. The "maximum extent technically feasible" criterion requires full employment of accepted and reasonable stormwater retention and reuse technologies subject to in-situ site conditions and applicable regulatory constraints (for example, site size, soil types, vegetation, demand for recycled water, existing structural limitations and state or local prohibitions on water collection).

2-1.4 Technical Infeasibility.

Cost alone should not be used as a constraint to justify technical infeasibility. Document all applicable technical constraints if the design objective is infeasible due to technical constraints. In most cases, the designer should be able to document more than one technical constraint to demonstrate technical infeasibility. If the project meets the design objective, technical constraints do not need to be documented. Examples of technical constraints are as follows:

- Retaining stormwater on-site would adversely impact receiving water flows
- Site has shallow bedrock, contaminated soils, high groundwater table, underground facilities, or utilities
- Soil infiltration capacity is limited
- Site is too small to infiltrate significant volume
- Non-potable water demand, including irrigation, toilets, and wash-water, is too small to warrant water harvesting and reuse systems
- Structural, plumbing, and other modifications to existing building to manage stormwater are infeasible
- State or local regulations restrict water harvesting
- State or local regulations restrict use of green infrastructure or LID.

2-2 DOCUMENTATION.

Provide the following documentation at the pre-final design stage:

- Pre-development conditions, such as soil conditions, groundwater table of the project site, description of typical surrounding natural lands, and a brief history of existing development, including impervious area, lawns, meadows, forested areas, wetlands, and water bodies.
- Calculations for pre-development and post-development runoff volumes and rates using the 95th percentile rainfall event to identify the volume of stormwater requiring management and the extent to which the design objective was met.
- Technical constraints, if applicable.
- Stormwater management practices used to meet the design objective and whether they were located on-site, off-site or both.
- LID cost estimate from DD Form 1391.

Update pre-final data at the final design stage, as applicable, and perform post-construction analysis at the end of construction. Maintain this documentation as part of the project historical file.

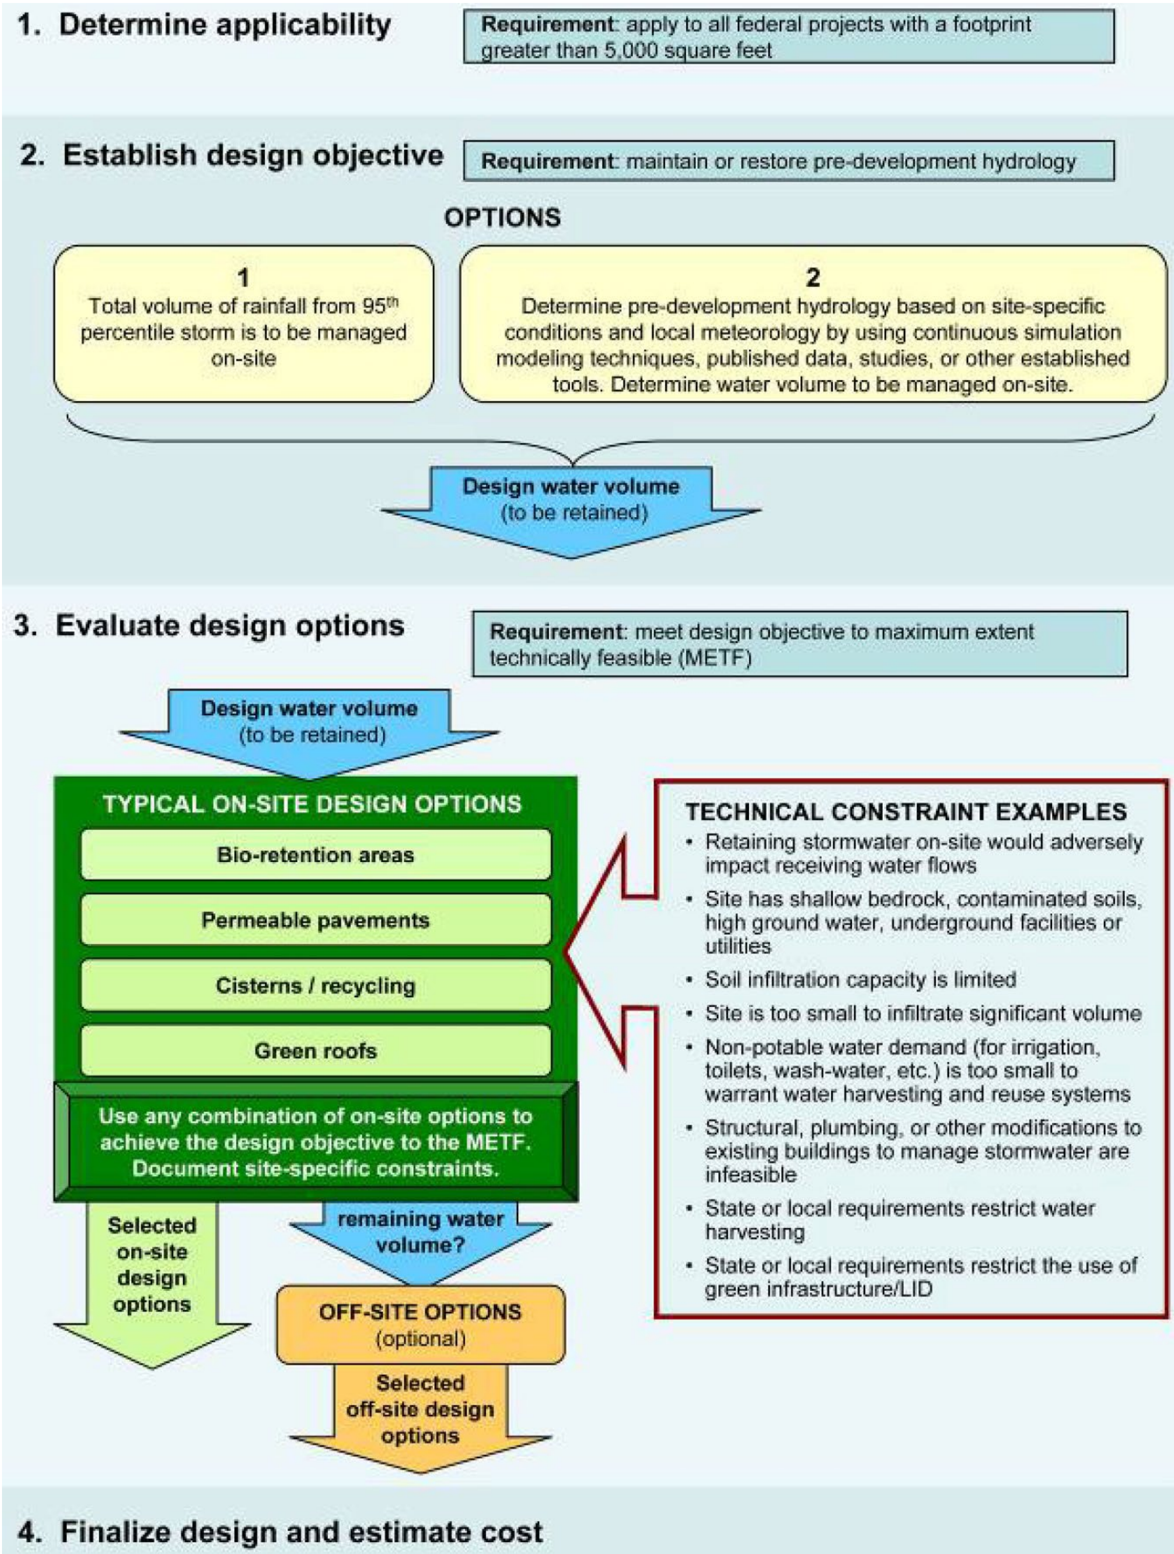
2-3 POST-CONSTRUCTION ANALYSIS.

The designer is required to validate LID features have been constructed according to plans and specifications. Validation may be accomplished by conducting a post-construction site visit to assess the as-built LID features or by having the construction contractor complete a post construction analysis report. If LID features were not constructed according to plans and specifications indicate the technical constraints that precluded meeting the design objective.

2-3.1 Documentation.

- Post-construction validation indicating that the LID features have been constructed according to plans and specifications.

Figure 2-1 Implementation of EISA Section 438



CHAPTER 3 PLANNING AND DESIGN

3-1 HYDROLOGIC ANALYSIS.

Determine pre-development hydrology based on site-specific conditions and local meteorology by using the 95th percentile storm. The designer must identify the pre-development condition of the site and quantify the post-development runoff volume and peak flow discharges that are equivalent to pre-development conditions.

When performing hydrologic analysis, the designer is required to understand the hydrologic methodology, the limitations of the methodology, and the site-specific hydrologic conditions. The results of the hydrologic analysis are only as good as the assumptions and site-specific data used by the designer. Inappropriate assumptions or site data can affect the reliability of the results. The designer must be able to validate the design assumptions, site data and results to demonstrate that the design objective has been met.

3-1.1 Approved Methodologies.

To control the stormwater volume in accordance with DoD policy, the use of TR-55, Chapter 2: "Estimating Runoff", Curve Number Methodology is approved and recommended. Continuous simulation modeling may be used to complete the hydrologic analysis. Other approved methodologies are WinTR-20 and the Storm Water Management Model (SWMM) computer program developed by the Environmental Protection Agency (EPA). Computer programs that use the approved methodology are also approved.

3-1.2 Other Methodologies.

If other hydrologic methodologies are used, they must be documented and submitted to the Government Civil Engineer for approval. Models developed for watershed nonpoint source analysis like EPA's Better Assessment Science Integrating Point and Nonpoint Sources (BASINS) should not be used for this type of hydrologic analysis.

3-2 TR-55 METHODOLOGY.

TR-55 methodology is likely the most efficient and practical for designers to comply with EISA Section 438 requirements. Therefore, details of this methodology have been summarized in the following paragraphs.

3-2.1 Storm Event.

During a storm event a portion of the precipitation is caught in the form of interception, depression storage, evaporation, transpiration, and infiltration. The process of infiltration is responsible for the largest portion of rainfall losses in pervious areas. These losses are collectively referred to as *abstractions*. Only that part of the rainfall in excess of abstractions is defined as stormwater runoff and reaches receiving water bodies, such as streams and lakes.

The Soil Conservation Service (SCS 1986), now the Natural Resources Conservation Service (NRCS), presented an empirical method of determining initial abstraction based on the runoff curve number (CN) of the site and is given by:

Equation 3-1. Initial Abstraction (inches)

$$I_a = 0.2 * S$$

Where:
I_a = Initial abstraction (inches)
S = potential maximum retention after runoff begins (inches)

$$S = \frac{1000}{CN} - 10$$

The initial abstraction defined in Equation 3-1 also represents the rainfall at which the direct runoff begins. Any rainfall over and above the initial abstraction results in direct surface runoff.

3-2.2 Runoff Depth for Calculating LID Volume.

Calculate the difference between pre- and post-development runoff depths, from which the volume to be retained on-site can be determined (for TR-55 methodology see Equation 3-2 below).

Equation 3-2. Total Depth of Increase in Runoff (inches)

$$D = \frac{(P - 0.2 * S')^2}{(P + 0.8 * S')} - \frac{(P - 0.2 * S)^2}{(P + 0.8 * S)}$$

Where:
D = runoff depth for calculating LID volume (inches)
P = design storm rainfall depth (inches)
S = potential maximum retention after runoff begins (inches) during the pre - development conditions
S' = potential maximum retention after runoff begins (inches) during the post- development conditions

Note: Equation. 3-2 is valid if P > 0.2*S. Otherwise, the term calculating the runoff depth is:

$$\frac{(P - 0.2 * S)^2}{(P + 0.8 * S)} = 0$$

When calculating pre- and post-development runoff volumes, consider water features present within the project footprint to be impervious.

3-2.3 LID Storage Volume.

Equation 3-3. LID Storage Volume

$$V_{LID} = D * A$$

Where:
V_{LID} = LID Storage Volume (cubic units)
D = total depth of increase in stormwater runoff (inches)
A = drainage area or the area of the parcel being developed (square units)

The minimum required LID Storage Volume is calculated using Equation 3-3 to comply with the design objective, and must be followed for the design storm depth (using Equation 3-2).

Additional details on hydrologic analysis are located in APPENDIX A, Section A-5, LID Design.

3-2.4 Time of Concentration for Pre- and Post-Development Conditions.

To mimic pre-project hydrologic patterns, the site designer needs to provide features that limit the rate at which runoff leaves the site. See A-5.2.2 for guidance on T_c. The post-development T_c should be as close as is technically feasible to the pre-development T_c.

3-3 LID IMPLEMENTATION.

LID implementation is achieved by selecting a set of LID features that can closely maintain or replicate hydrological behavior of the pre-project site for the design storm event. Most LID features are distributed small-scale controls that increase rainfall interception and lengthen the time of concentration (T_c). Some LID features provide greater benefits (that is, groundwater recharge and increased T_c) than others. Give priority to those LID features that are proven in their regional area, provide the most benefits in relation to replicating pre-project hydrology and have the lowest lifecycle costs. LID features typically include natural features with low maintenance costs. Selecting appropriate LID features with the lowest long-term maintenance cost will extend the useful life of the LID features. Highly developed sites, sites with a high ratio of impervious to pervious area (that is, industrial sites) may require more costly, higher maintenance LID features in order to meet the design objective within the constraint of maximum extent technically feasible (see Section 2-1.3). Provide a minimum 10 ft (3.05

m) offset from the LID feature to the face of the nearest building. Comply with the offset and clear zone requirements in UFC 4-010-01 *DoD Minimum Antiterrorism Standards for Buildings* when placing LID features near buildings.

Verify with the Installation the capability to maintain LID features prior to selecting for use on-site. LID features that cannot be maintained by the Installation with current capability and contract capacity may not be used.

3-3.1 LID Features.

Implementing LID features help replicate the pre-development hydrology and can generally be grouped into two categories.

3-3.1.1 Engineered Natural Treatments.

Engineered natural treatments provide depression storage, infiltration, and evapotranspiration. These design options are typically the least costly and easiest to accomplish if site availability, soils and groundwater table are conducive. Site features such as bioretention, vegetated swales, rain gardens, vegetated filter strips, downspout disconnection, reduced impervious area, tree preservation or re-vegetation using native plants, soil amendments, and open space fall under this general category and are advisable due to lower lifecycle costs.

3-3.1.2 Engineered Subsurface Treatments.

Engineered subsurface treatment provides infiltration and prevents concentrated flow. Site features may include permeable pavements and infiltration trenches. Engineered subsurface treatment may be the next most lifecycle cost effective method, as compared to engineered natural treatment, in meeting the design objective. These design options may be limited by wheel loading, traffic, ability to provide maintenance and foreign object debris danger. Avoid locating infiltration trenches and similar features under pavements wherever possible. Refer to UFC 3-201-01 for additional criteria on permeable pavement.

3-3.2 Non-Potable Rainwater Harvesting.

Rainwater harvesting systems store stormwater for non-potable uses, such as irrigation or toilet flushing. Site features may include LID features like cisterns and rain barrels. This design option may be used if adequate demands for reuse water exist. The reuse of harvested water (through rain barrels and cisterns, also called alternative sources of water) for purposes other than irrigation must comply with UFC 3-420-01 *Plumbing Systems*. Certain types of facilities, such as a warehouse, may not have adequate water demand to make reuse lifecycle cost effective. Consider freeze protection for winter months.

3-3.3 Green (Vegetative) Roofs.

Vegetative roofs increase both the T_c and seasonal evapotranspiration while reducing building energy usage and noise levels. They do not assist in infiltrating water into the ground at the source and have high initial and annual maintenance costs. Vegetative roofs are a design option where other LID features do not meet the design objective. Vegetative roofs should be assessed with consideration of other benefits such as lower energy costs and noise reduction.

3-4 OFF-SITE OPTIONS.

If the design objectives cannot be met within the project footprint, off-site options within the same watershed may be used. Off-site options are generally less desirable than on-site options, as many of the benefits of managing the stormwater close to the source may be lost. The designer must confirm site approval for off-site options with the Government Project Manager.

3-5 CLEAN WATER ACT PERMITS.

Comply with applicable state and local requirements for stormwater management in addition to UFC requirements. Obtain state stormwater construction permits required under the Clean Water Act using the state's approved methodology. Coordination of the design is the responsibility of the designer to ensure that the criteria are met from both the regulatory and LID perspectives. Design the stormwater management (SWM) features to control all regulated storm events, as stipulated by state and local regulations to handle the peak rate and volume of discharge for flood control purposes.

EISA Section 438 requirements are independent of stormwater requirements under the Clean Water Act and should not be included in permits for stormwater unless a state (or EPA) has promulgated regulations for certain EISA Section 438 requirements (that is, temperature or heat criteria) that are applicable to all regulated entities under its Clean Water Act authority. Compliance with applicable regulatory stormwater management requirements may satisfy all or part of the EISA Section 438 requirement for the project.

3-6 OTHER DESIGN REQUIREMENTS.

Where state and local standards for design of LID features to satisfy EISA Section 438 requirements do not exist, refer to *Low-Impact Development Design Strategies, An Integrated Design Approach* and *Low-Impact Development Hydrologic Analysis* prepared by Prince George's County, Maryland, Department of Environmental Resources, Programs and Planning Division (PGDER). Follow applicable industry practice standards and local building codes (for example, earthquake zones).

3-6.1 Sustainable Design.

Incorporate sustainable development concepts to reduce energy consumption, O&M costs, reduce waste, and reduce pollution. Refer to UFC 1-200-02, for additional criteria.

3-6.2 Architectural Compatibility.

Comply with DoD, and Activity requirements and provide LID features compatible with surrounding base architecture.

3-6.3 Base Design and Development Documents.

Incorporate the intent of Installation Master Planning into designs. Follow published design guidelines that contain criteria relative to achieving, maintaining, and emphasizing a positive exterior visual environment applicable to military installations. Consult with the Government Project Manager for direction in case of conflicts. Direction to deviate from these documents should be given in writing.

3-6.4 Antiterrorism.

Comply with UFC 4-010-01 when designing LID features.

3-6.5 Airfield Criteria.

Where the criteria provided in this UFC conflicts with UFC 3-260-01, UFC 3-260-01 criteria governs.

APPENDIX A BEST PRACTICES

This Best Practices appendix provides additional detail and analysis supporting the criteria and builds process action steps in the Planning, Design, and Post-Construction stages of project development. In addition, the appendix gives a basic level of understanding for the rationale behind the UFC criteria hydrology and methods of calculation. The UFC criteria are predicated on standard practices in the field of stormwater management. The design storm event is defined by the 95th percentile storm. By using all storm events that occur within 24 hours for several years, the designer can statistically estimate the rainfall depth that is less than or equal to 95 percent of all storms, see Section 2-1.2.

By design, LID methods do not control runoff in excess of the runoff generated from the 95th percentile storm. Excess runoff from larger storm events, such as the 2-, or 10-year storm, is intended to bypass into conventional stormwater management facilities. LID practices help meet regulatory runoff requirements by reducing the volume of water leaving the site. The runoff calculation method is adopted from the NRCS, formerly the Soil Conservation Service (SCS) TR-55 method. A site designer can easily hand calculate the necessary information for small sites using formulas given in the criteria. For larger sites, computer calculations and simulation modeling are encouraged.

A-1 BACKGROUND.

In December 2007, Congress enacted EISA which established into law new stormwater design requirements for federal agencies to develop and redevelop applicable facilities in a manner that maintains or restores stormwater runoff to the METF with regard to the temperature, rate, volume, and duration of flow. In December of 2009, EPA issued EPA 841-B-09-001. EPA 841-B-09-001 provides technical guidance to assist federal agencies in implementing EISA Section 438 and was intended solely as guidance.

Deputy Under Secretary of Defense (Installations and Environment) memorandum of 19 January 2010 directs DoD components to implement EISA Section 438 using LID techniques in accordance with the methodology illustrated in Figure 2-1 and further described below. This policy directs DoD to implement EISA Section 438 EPA technical guidance in accordance with DoD Policy on Implementing EISA Section 438. Where DoD policy or the criteria provided in this UFC conflicts with EPA Technical Guidance, the DoD policy and UFC govern. Individual Services may have more stringent implementation and applicability requirements relating to LID.

A-1.1 What is LID?

The use of LID was pioneered in the 1990s by Prince George's County, Maryland Department of Environmental Resources (PGDER) under a grant from the EPA. Since 2004, LID techniques for controlling stormwater runoff have been considered for many projects based on site requirements and constraints. LID strategies provide a decentralized hydrologic source control for stormwater. LID implementation is based on selecting LID features that are distributed small-scale controls that can closely maintain or replicate hydrological behavior of the pre-project site for a defined design storm event. These small-scale practices are sometimes referred to as integrated management practices (IMPs).

LID differs from conventional SWM principles in that it does not store and release stormwater. LID uses infiltration, evaporation, plant transpiration, and reuse of rainwater to keep the additional stormwater generated due to the developed condition contained on-site. Increased impervious area changes the natural flow of water and decreases the quantity of water that infiltrates into the ground. Increased runoff increases sediment transport and decreases water quality. LID seeks to restore pre-development infiltration rates at the project site through one or more LID IMPs.

A-1.2 Types of LID Features.

The application of LID to an infrastructure development program is practical and achievable, but it will require a change of thinking on the part of the site designer. The engineered natural and subsurface LID treatments described in Section 3-3.1 fall into five types as follows:

1. Site Utilization: Begin the site process by reducing the impervious footprint if possible. Narrower streets, vertical construction, parking structures, and the removal of curb, gutter, and paved swales are a few of the ways to reduce impervious surfaces. Choose rougher surfaces, disconnect impervious areas, and increase the time of concentration (T_c). Retain as much of the natural tree cover as practical and place the impervious structures in areas of the poorest soil types where possible.
2. Filtration: Include filtration practices in the site design. Vegetative buffers, filter strips, vegetative swales, check dams, sediment traps, and overland flow will provide natural water quality treatment and increase T_c. By providing and maintaining natural buffers adjacent to water bodies, and directing stormwater to vegetated areas, stormwater infiltration is maximized thereby reducing pollutant discharges.
3. Interception and Infiltration: The infiltration techniques of LID are the backbone of the runoff volume reduction. Depression storage, bio-infiltration, pervious pavements, open pavers, rain gardens, infiltration trenches, and tree boxes are gaining wide acceptance as tools in the SWM toolbox. Interception can also play a major role in reducing runoff volumes. Interception techniques include deep mulch beds, tree cover, and soil amendments.
4. Retention of Stormwater Volumes: Retention can play an important part in successful LID implementation. Retention seeks to hold runoff from localized impervious surfaces for subsequent treatment after the rainfall event. Rain barrels, cisterns, and parking lot storage that slowly infiltrates into the ground are examples of retention techniques.
5. Structural Solutions: Structural solutions represent the last line of defense in LID features. Structural solutions will increase the facility construction cost and must be balanced with mission requirements. In urban and

industrial areas, sensitive environments, or known contaminated sites, structural solutions are often the only feasible solution. These techniques are specific solutions engineered for the particular facility and can include green roofs, rainwater reuse systems, parking structures, and irrigation storage systems.

A-2 CONSTRUCTION PERMIT PROCESS.

Conventional SWM is a patterned response to maximize the efficiency of site landscaping and site design to achieve a reduction in pollutant loading of rainfall that ends up as runoff due to human development. The EPA's CWA defined an appropriate level of SWM to help to keep our rivers, lakes, and shorelines clean. The CWA established the base guidelines for SWM, but for the most part turned the execution of those guidelines over to the local, state, or municipal regulatory agencies. The states then promulgated additional or clarifying requirements to a minimum level as the EPA requirements to meet the needs of the local geographic conditions. For example, SWM techniques suitable for Florida are not necessarily appropriate to the arid Southwest. Almost all projects will require local, or state construction permit in order to begin work. As such, the LID requirements must be complementary to state and local requirements for SWM. Without the regulatory acceptance and approval of the SWM plan, a project cannot be constructed.

The site designer is encouraged to contact the Government Civil Engineer, as well as state and local regulatory officials to coordinate LID requirements with applicable stormwater programs. Table A-1 has useful links on stormwater topics which includes a link to NPDES state program statuses as granted by EPA. Additional information may be found on the following link to the WBDG LID Resource Page: https://www.wbdg.org/resources/low-impact-development-technologies

A-3 INITIAL LID PLANNING COMPONENTS.

Successful implementation of LID begins during the planning process. During the planning phase, the exact configuration of LID features and the ways in which LID will shape the site design is not expected to be determined. This section provides the first steps to build upon in considering LID in the final project.

The initial planning phase begins with identifying possible LID features for a given project. Potential features to meet the project requirements will depend on considerations such as the required storage volume, existing infrastructure, and feasibility based on site conditions. Non-structural techniques should also be considered during the initial planning phase. Steps 1 through 6 below will help identify LID features which may satisfy the design requirements for a given project. In the preliminary planning phase, several alternatives may be identified which can then be narrowed down through cost analyses, or additional planning stages involving more detailed information about the site conditions, existing infrastructure, and project requirements.

A-3.1 Organizing the Planning Process and Timeline.

Step 1. Identify the LID objectives and legal requirements for the project (for example, stormwater permits, state erosion control and flood requirements, EISA

Section 438). Estimate runoff volume, peak runoff rate, duration, frequency, and water quality.

Step 2. Make assumptions on existing stormwater infrastructure in terms of how well it functions with respect to each of these aspects.

Step 3. Evaluate the goals and feasibility for control of runoff volume, duration, and water quality, as well as on-site use of stormwater (for example, irrigation, flushing toilets).

Step 4. Prioritize and rank basic objectives.

Step 5. Identify applicable local regulations or codes.

Step 6. Determine typical LID features required to meet objectives as best as possible (that is, infiltration, filtration, discharge frequency, volume of discharges, and groundwater recharge) taking into consideration available space, underground utilities, soil infiltration characteristics, slope, drainage patterns, groundwater table protected areas, setbacks, easements, topographic features, and other site features that should be protected such as floodplains, steep slopes, and wetlands.

Non-structural site planning techniques that may be considered:

- Minimizing total site impervious area.
- Reducing on-street parking.
- Using permeable pavement (pavers, concrete, or asphalt).
- Directing flows from paved areas to stabilized vegetated areas.
- Increasing overland sheet flow.
- Using open swale systems.
- Minimizing ground disturbance.
- Maintaining existing topography, where feasible.
- Locating new impervious areas where soils have lower hydrologic functions, such as clayey or disturbed soils.

For a more comprehensive list of non-structural site planning techniques refer to *Low-Impact Development Design Strategies, An Integrated Design Approach* from PGDER.

A-3.2 Cost Analysis.

One of the most difficult challenges is to properly allocate resources for projects so that they are successful and fulfill the mission as programmed. LID requirements can add a new level of complexity to the project that must be addressed during planning. While it may be too early in the process to determine the configuration of LID features, a preliminary analysis is needed to determine the level of effort required to implement LID. (LID Design is discussed in APPENDIX A, Section A-5).

The three items that should be addressed for LID are:

1. Implementation cost (may be less than traditional)
2. Operation & Maintenance costs (lifecycle)
3. Time impacts to design and permitting process

Information on the project mission should be gathered including geographical location, site requirements, available sites, programmed space requirements related to increased impervious area, and the ability of the Installation to maintain the LID feature. These set points will also help to determine the proper resource allocations to apply for the implementation of the LID site. LID features may be used in conjunction with conventional SWM will create a treatment train to hold, infiltrate, and filter the stormwater runoff. The LID site will contain less channelization of stormwater, less impervious pavement, more trees, more open ditches, less curb and gutter, and more planting buffers. Many parameters must be weighed during the LID design process. Design must match the particular regional conditions.

A-3.2.1 Cost Considerations.

Many of the following site conditions affect the design of LID features. Regional differences in weather patterns, soil types, groundwater conditions, existing development status, and current stormwater patterns will greatly influence the actual design and layout of the LID site and the choice of the LID features. However, one of the most important parameters will be the ratio of increased impervious surface area to the available land area or change in land cover.

Optimal LID implementation on a suitable site may result in a reduction in project cost. Classic LID design should reduce the amount of disturbed land, reduce impervious surface area, eliminate curb and gutter, reduce the size of pipes and holding ponds and increase the area planted in low maintenance tree cover. Building a large facility on a small site will increase the cost of implementing LID because the small site may require the selection of LID features that are structural in nature and are more expensive to build and maintain. On the other hand, a small building on the large site may use more natural LID features that are less costly and more easily maintained.

A-3.3 EPA LID Guidance.

The following EPA manuals may be used as best practice resources: “Reducing Stormwater Costs through Low Impact Development (LID) Strategies and Practices” and “Low Impact Development (LID) A Literature Review”. These manuals were based on “Low-Impact Development Design Strategies; An Integrated Design Approach” and are geared toward general site development. Sites on military bases may have additional constraints that will influence which LID features may be used.

A-4 STORMWATER MANAGEMENT.

Man-made land development increases impervious surfaces. Buildings, roads, sidewalks, and parking lots quickly shed rainwater and increase the percentage of rainfall that ends up as runoff. The resulting increase in runoff volume and the peak flows create negative consequences such as stream degradation and flooding risk. The principal objective of LID is to retain this increase in runoff on-site.

LID builds on the conventional SWM philosophies and carries them a step further. LID processes begin at the point where the rain falls. Consideration for incorporating LID concepts, tools, and approaches requires assessment of the following at a minimum:

- Will the concept closely mimic the hydrology of pre-development condition?
- Will the concept mitigate adverse effects from increased stormwater runoff from the project?
- Can the drainage conveyance structures be optimized and reduce the overall cost of the project?
- What might be the hurdles for public acceptance? If required for the project to move forward, can these be reasonably achieved?

A-4.1 Hydrologic Cycle.

Dr. David Maidment in his *Handbook of Hydrology* states:

> "The hydrologic cycle is the most fundamental principle of hydrology. Water evaporates from the oceans and the land surface, is carried over earth in atmospheric circulation as water vapor, precipitates again as rain or snow, is intercepted by trees and vegetation, provides runoff on the land surface, infiltrates into soils, recharges groundwater, discharges into streams, and ultimately, flows out into the oceans from which it will eventually evaporate once again. This immense water engine, fueled by solar energy, driven by gravity, proceeds endlessly in the presence or absence of human activity."

A-4.2 Conventional Stormwater Management vs LID.

Conventional SWM facilities are primarily designed to temporarily store runoff, control flooding and downstream impacts due to increased runoff. These SWM facilities also provide water quality benefits. Whereas decentralized LID features include infiltration, increasing the length and time of flow over pervious areas, and disconnecting impervious areas that drain to stormwater collection systems. This helps to retain the increase in runoff from new development on-site.

Table A-2 contrasts conventional SWM methods that use "end-of-pipe" treatment and LID techniques that may reduce land requirements associated with conventional treatment. LID may reduce the overall costs of a project and reap benefits in protecting the environment and natural habitats.

Table A-2 Summary of Concepts of SWM and LID Techniques

Concepts of SWM	Concepts of LID Techniques
End-of-pipe stormwater treatment.	Stormwater is treated at or very close to the source.
Centralized collection system.	Decentralized system.
Reroute stormwater away from the site quickly and efficiently.	Mimics the pre-development hydrologic condition. The goal of LID is to retain the same amount of rainfall within the development site as that was retained on the site prior to the project.
Many of the stormwater management facilities are designed to control or attenuate peak runoff.	LID techniques reduce the size of stormwater management facilities.
SWM facilities are designed to detain the first-flush (the first ½ inch (13 mm) of runoff) from impervious areas of development.	LID techniques infiltrate stormwater on-site.

Table A-3 summarizes how conventional SWM, and LID technology alter the hydrologic regime for on-site and off-site conditions.

Table A-3 Comparison of Conventional SWM and LID Technologies

Hydrologic Parameter	Conventional SWM	LID
	On-Site	
Impervious Cover	Encouraged to achieve effective drainage	Minimized to increase infiltration
Vegetation or Natural Cover	Reduced to provide or improve centralized drainage system	Maximized to maintain pre-development hydrology
Time of concentration (T_c)	Shortened, reduced as a by-product of drainage efficiency	Maintained or maximized to approximate pre-development conditions
Runoff Volume	Large increases in runoff volume not controlled	Controlled to pre-development conditions
Peak Discharge	Controlled to pre-development conditions for the design storm event (i.e., the 2-year, 10-year, or 25-year storms)	Controlled to pre-development conditions for the 95th percentile storm event
Runoff Frequency	Greatly increased, especially for small, frequent storms	Reduced or minimized
Runoff Duration	Increased for all storms because volume is not controlled	Controlled to pre-development conditions
Rainfall Abstractions (interception, infiltration, depression storage)	Large reduction in all elements	Maintained to pre-development conditions
Groundwater Recharge	Reduction in recharge	Maintained to pre-development conditions
	Off-Site	
Water Quality	Reduction in pollutant loadings but limited control of stormwater volume leaving site	Improved pollutant loading reductions, full volume control for the 95th percentile storm event
Receiving Streams	Severe impacts documented – channel erosion and degradation, sediment deposition, reduced base flow, and habitat suitability decreased, or eliminated	Stream ecology maintained to pre-development conditions for the 95th percentile storm event
Downstream Flooding	Peak discharge control reduces flooding immediately below control structure, but can increase flooding downstream through cumulative impacts and super positioning of hydrographs	Controlled to pre-development conditions for the 95th percentile storm event
Source: Low-Impact Development Design Strategies, prepared by Prince George's County, Maryland.		

A-4.3 Low Impact Design Elements for Stormwater Management.

The LID concept encourages innovation and creativity in management of site planning impacts. As mentioned in Section 3-3, the implementation of LID techniques must be carefully evaluated for opportunities and constraints on a case-by-case basis. Many of the techniques are site-specific. Table A-4 summarizes the specific use of LID techniques, requirement, and applicability. Table A-5 summarizes hydrologic functions of LID practices.

Table A-4 Summary of LID Techniques, Constraints, Requirements and Applicability

Maintenance	Max. Depth	Proximity to Building Foundations	Water Table or Bedrock	Slopes	Soils	Space Required	
Low requirement, property owner can include in normal site landscape maintenance	2- to 4-ft (600 to 1200 mm) depth depending on soil type	Minimum distance of 10 ft (3 m) down gradient from buildings and foundations recommended	2- to 4-ft (600 to 1200 mm) clearance above water table or bedrock recommended	Usually not a limitation, but a design consideration.	Permeable soils with infiltration rates > 0.27 inches/hr (7 mm/hr) are recommended. Soil limitations can be overcome with use of underdrains.	Minimum surface area range: 50 to 200 ft^2 (4.6 to 18.6 m^2). Minimum length to width ratio 2:1	**Bioretention**
Low requirement	6- to 10-ft (1.8 to 3 m) depth depending on soil type	Minimum distance of 10 ft down gradient from buildings and foundations recommended	2- to 4-ft (600 to 1200 mm) clearance above water table or bedrock recommended	Usually not a limitation, but a design consideration. Must locate down gradient of building foundations.	Permeable soils with infiltration rates > 0.27 inches/hr (7 mm/hr) are recommended.	Minimum surface area range: 8 to 20 ft^2 (0.7 to 1.9 m^2). Minimum length to width ratio 2:1	**Dry Well**
Low requirement, routine landscape maintenance	Not applicable	Minimum distance of 10 ft down gradient from buildings and foundations recommended	Generally, not a constraint.	Usually not a limitation, but a design consideration.	Permeable soils perform better, but soil not a limitation.	Minimum length of 15 to 20 ft (4.6 to 6.1 m^2)	**Filter Buffer Strip**
Low requirement, routine landscape maintenance	Not applicable	Minimum distance of 10 ft down gradient from buildings and foundations recommended	Generally, not a constraint.	Swale side slopes: 3:1 or flatter. Longitudinal slope: 1.0% minimum; maximum based on permissible velocities.	Permeable soils provide better hydrologic performance, but soils not a limitation. Selection of type of swale, grassed, infiltration or wet is influenced by soils.	Bottom width: minimum 2 ft (600 mm), maximum 6 ft (1800 mm)	**Swales: Grass, Infiltration, Wet**
Low requirement	Not applicable	Not a factor	Generally, not a constraint.	Usually not a limitation, but a design consideration.	Not a factor	Not a factor	**Rain Barrels**
				Not a factor	Not a factor	Not a factor	**Cistern**
Moderate to high	6- to 10-ft (1.8 to 3 m) depth depending on soil type	Minimum distance of 10 ft down gradient from buildings and foundations recommended	2- to 4-ft (600 to 1200 mm) clearance required	Usually not a limitation, but a design consideration. Must locate down gradient of building foundations.	Permeable soils with infiltration rates > 0.52 inches/hr (13 mm/hr) are recommended.	Minimum surface area range: 8 to 20 ft^2 (0.7 to 1.9 m^2). Minimum length to width ratio 2:1	**Infiltration Trench**

Source: Low-Impact Development Design Strategies, prepared by Prince George's County, Maryland

Table A-5 Summary of Hydrologic Functions of LID Practices

Hydrologic Functions	Bioretention	Dry Well	Filter or Buffer Strip	Swales: Grass, Infiltration, Wet Wells	Rain Barrels	Cistern	Infiltration Trench
Interception	High	None	High	Moderate	None	None	None
Depression Storage	High	None	High	High	None	None	Moderate
Infiltration	High	High	Moderate	Moderate	None	None	High
Ground Water Recharge	High	High	Moderate	Moderate	None	None	High
Runoff Volume	High	High	Moderate	Moderate	Low	Moderate	High
Peak Discharge	Moderate	Low	Low	Moderate	Moderate	Moderate	Moderate
Runoff Frequency	High	Moderate	Moderate	Moderate	Moderate	Moderate	Moderate
Water Quality	High	High	High	High	Low	Low	High

A-4.4 Water Quality and Pollution Prevention.

LID features may address additional regulatory requirements or other resource protection goals. Similarly, in meeting the regulatory requirements, BMPs can be designed to act as effective, practicable means of minimizing the impacts of development associated with water quality and quantity control.

Because of the very nature of decentralized hydrologic source control, the nonpoint source pollution is greatly reduced, thereby, increasing the water quality of the receiving water bodies.

A-4.5 Design Inputs.

If possible, the following design inputs should be obtained for successful implementation of LID techniques into a site development project:

a. Detailed land cover and land-use information

b. Topographic contours, preferably at an interval that allows the flow paths to be distinguished (Generally 1 ft (.25 m) interval contours minimum, supplemented by spot elevations).

c. Soil borings; minimum of three borings, 15 ft (4.6 m) deep. These borings should reveal the nature and condition of the shallow subsurface soils at this location, as well as defining the groundwater table, usability of on-site material for select fill, and through compositional analysis should determine both vertical and horizontal hydraulic conductivities.

d. Existing site drainage outfall conditions and characteristics including water level elevation and water quality

e. Watershed reports and master plans

f. Flooding issues, past or present

g. Installation Appearance Guide

A-4.6 Precipitation Data.

The intensity-duration-frequency curves for the United States were recently revised and published by the NOAA and are called Atlas -14 curves. These curves are found on NOAA's Atlas 14 Precipitation Frequency Data Server at https://toolkit.climate.gov/dashboard-noaa-atlas-14-precipitation-frequency-data-server. These curves should be used when determining the precipitation depth and intensity for required duration and frequency.

Long-term rainfall records for regional weather stations can be obtained from many sources, including the NOAA's Climate Data Online webpage, at https://www.ncdc.noaa.gov/cdo-web/. Historical rainfall data are routinely published by many other agencies including the National Water and Climate Center, the United States Geological Survey, the Agriculture Research Service, etc., (NRCS NEH-4, 2019). Tables A-8 and A-9 provide a summary of rainfall analyses for 50 selected rainfall stations located in the continental United States, and 12 stations located overseas, respectively. Precipitation stations listed in Table A-8 and Table A-9 were selected based on proximity to those DoD installations anticipating major construction activity. The stations listed in Table A-8 and Table A-9 are from two types of station datasets found on the Climate Data Online webpage.

A-4.7 Types of Rainfall Datasets.

The first dataset type is daily summary data from the Global Historical Climate Network (GHCN). GHCN stations have an 11-character alpha-numeric station identification number. The GHCN observation data on NOAA's website incorporates measurement data from approximately 30 data sources from over 90,000 land-based stations worldwide including observation data from the World Meteorological Organization (WMO). Uploaded GHCN data undergoes a series of quality assurance checks.

The second dataset type is Global Surface Summary of the Day (GSOD) which is derived from the Integrated Surface Hourly (ISH) dataset. The ISH dataset includes data from the United States Air Force (USAF) Climatology Center. Data from approximately 9,000 stations are available online. GSOD stations are identified in Table A-8 and Table A-9 by an eleven-digit number.

More information about the GHCN and GSOD datasets can be found on NOAA's website at https://www.ncdc.noaa.gov/cdo-web/datasets.

A-4.7.1 GHCN Station Download Procedures.

The GHCN Station data download procedures involve several steps and depends on individual's knowledge of station and location. For clarity, these steps are listed below under separate headings.

A-4.7.1.1 GHCN Station Search.

When searching for GHCN stations near a specific Installation and the GHCN station name or ID number is not known, the user should navigate to NOAA's Daily Observational Data map page at https://www.ncei.noaa.gov/maps/daily/. By default, the GHCN Daily layer is checked in the upper left. The GHCN Daily layer displays weather station locations for the contiguous United States as well as Alaska and Hawaii as shown in Figure A-1. For GHCN observation data outside of the United States, selecting the WMO layer on the map page as shown in Figure A-2 displays GHCN station locations across the globe. The user may elect to show all GHCN stations including historical stations, or just the active stations using the settings icon beside the layer name for both the GHCN Daily and the WMO layers. The station selection and precipitation data download procedures described below are applicable to both GHCN Daily and WMO layers.

Figure A-1 NOAA's Daily Observational Map Page – GHCN Daily Layer

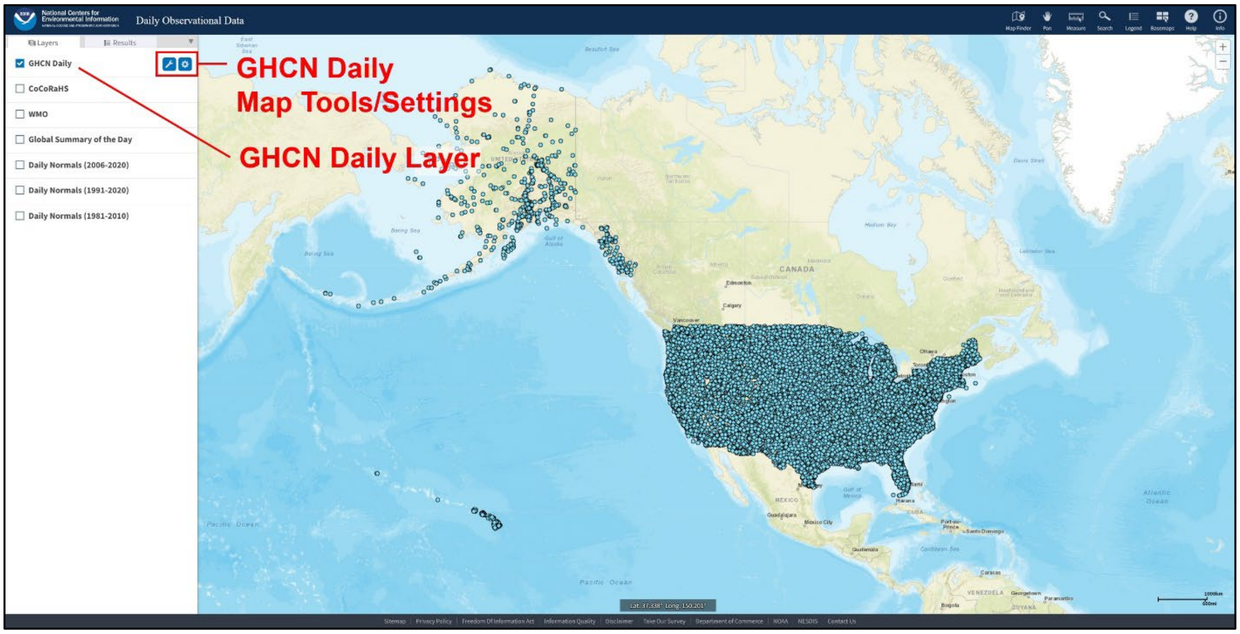

Figure A-2 NOAA's Daily Observational Map Page – WMO Layer

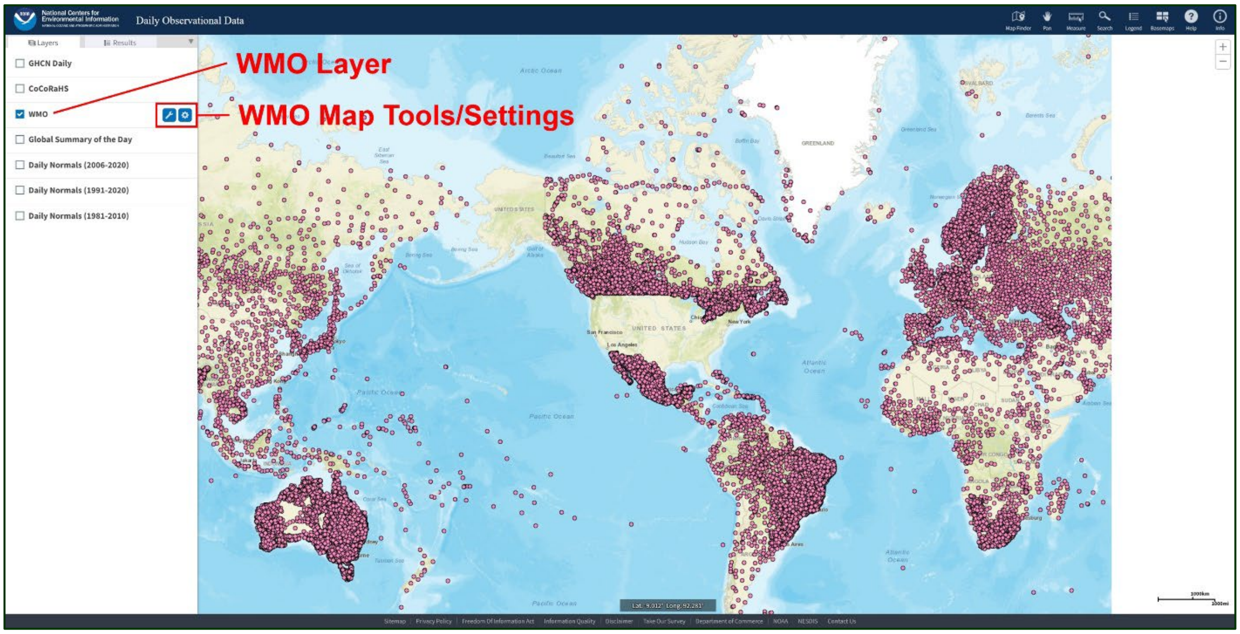
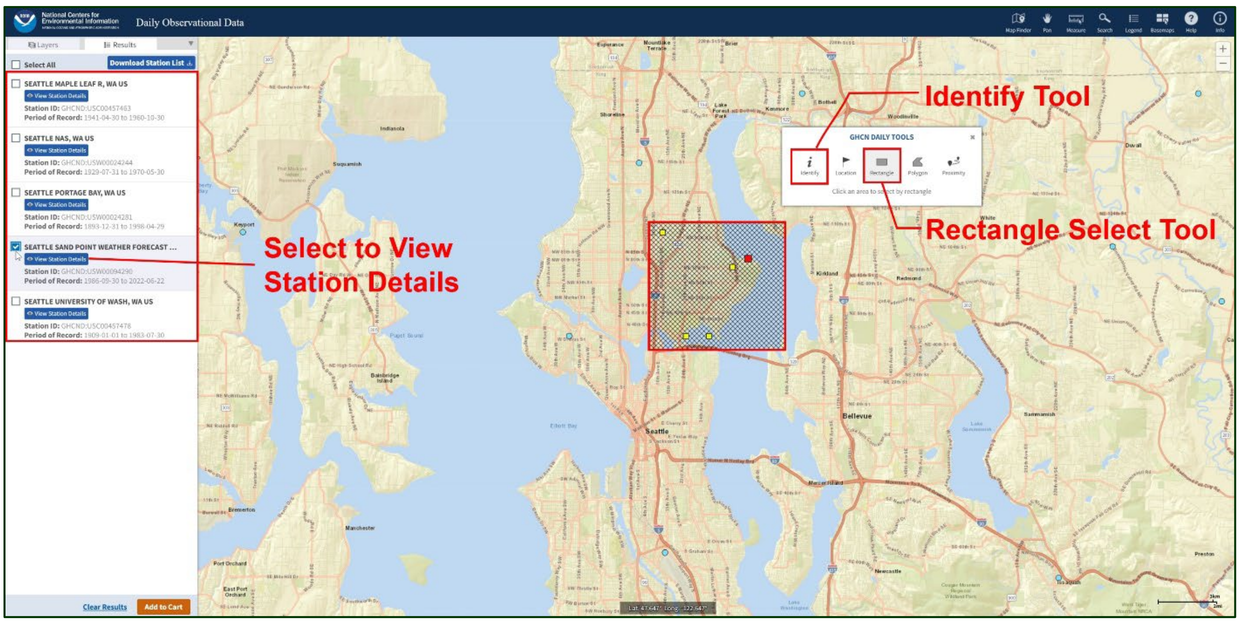


A-4.7.1.2 GHCN Specific Station Search.

From the Daily Observational Data map pages, users may zoom in and pan to a specific location, or search for a location or facility using the tools in the upper right of the page. Clicking on the Map Tools icon beside the layer name in the upper left allows the user to select an individual station using the identify tool, or multiple stations using the rectangle select tool to draw a box around multiple stations as shown in Figure A-3. Station information for the selected station(s) will appear in the results tab to the left and includes the station name, station ID, and period of record.

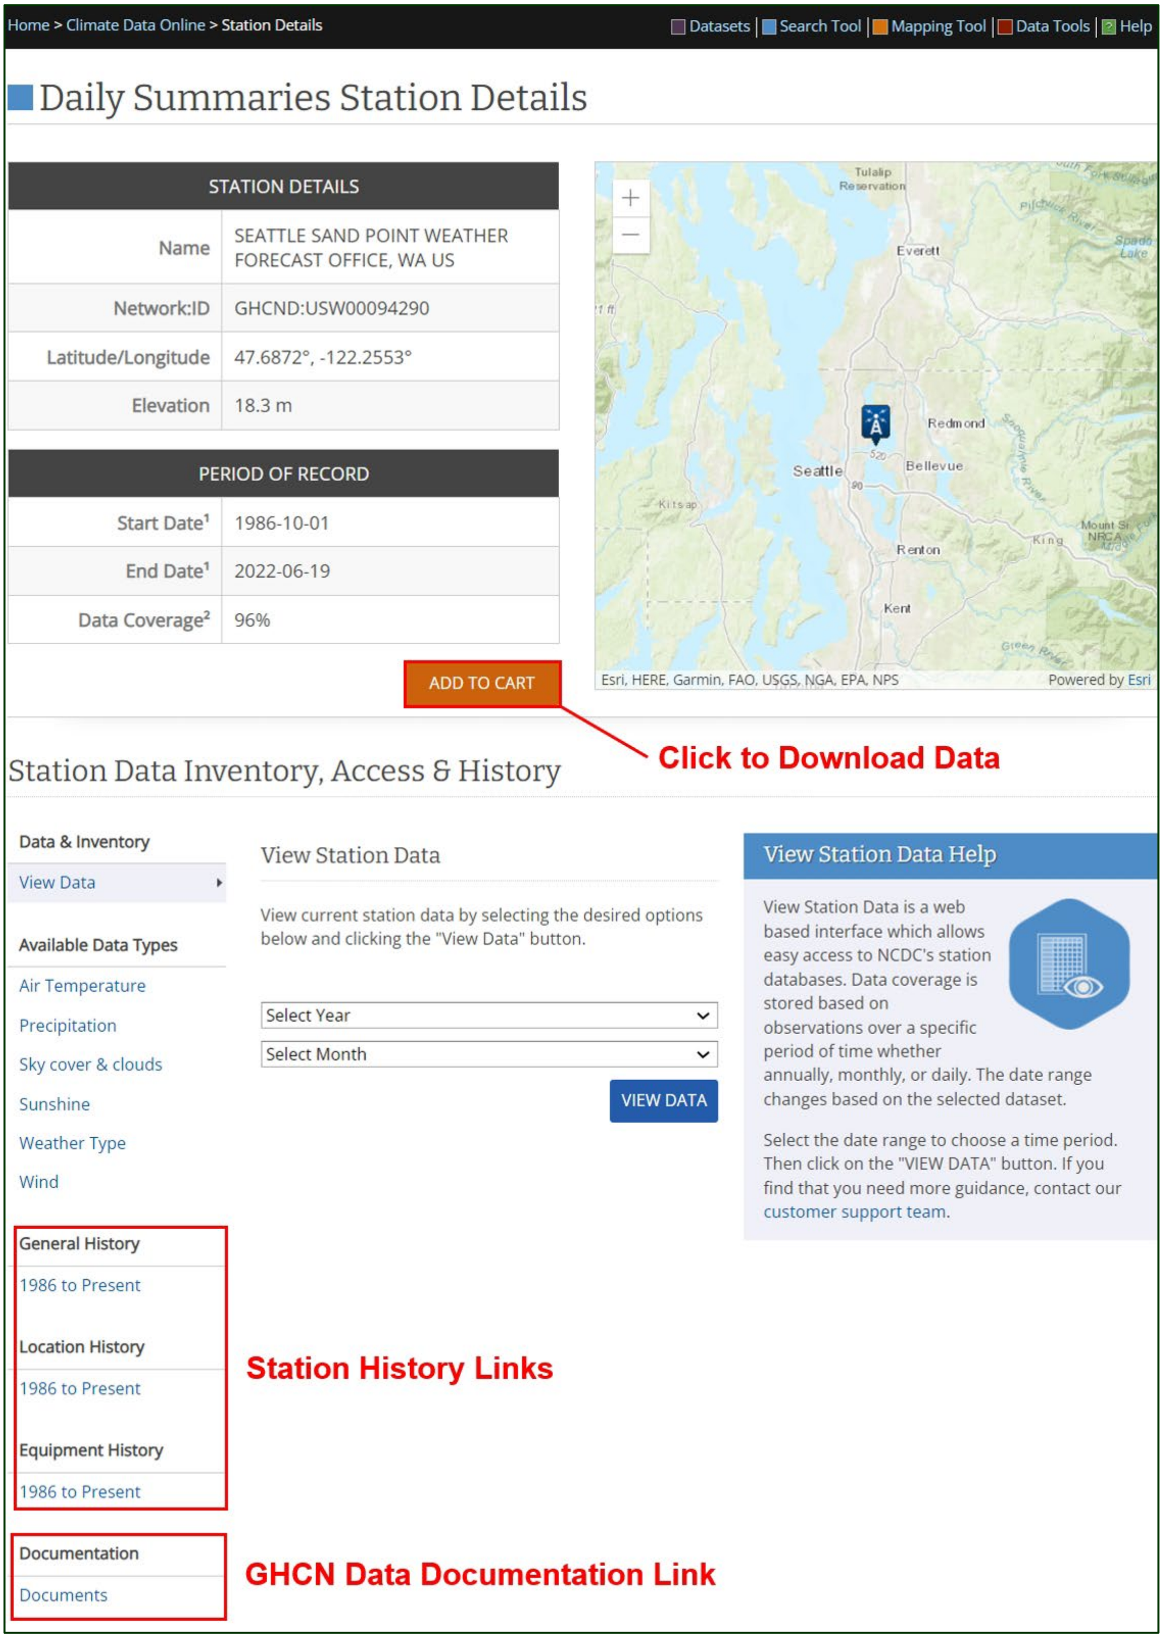
Figure A-3 GHCN Station Selection



A-4.7.1.3 Viewing GHCN Station Details.

Clicking on “View Station Details” below the station name will show additional information about the station as shown in Figure A-4. This includes Latitude/Longitude coordinates, station elevation, and the data coverage for the period of record as a percentage. Users should note that the data coverage percentage is for the most complete set of measurements at the station and may or may not reflect the precipitation data, but instead may refer to other observational data such as temperature or barometric pressure instead. The Station Details page will also have links to the station’s history if available and a link to GHCN Daily summary documentation detailing data formats, observation values, and a list of measurement, quality, and source flags for GHCN data.

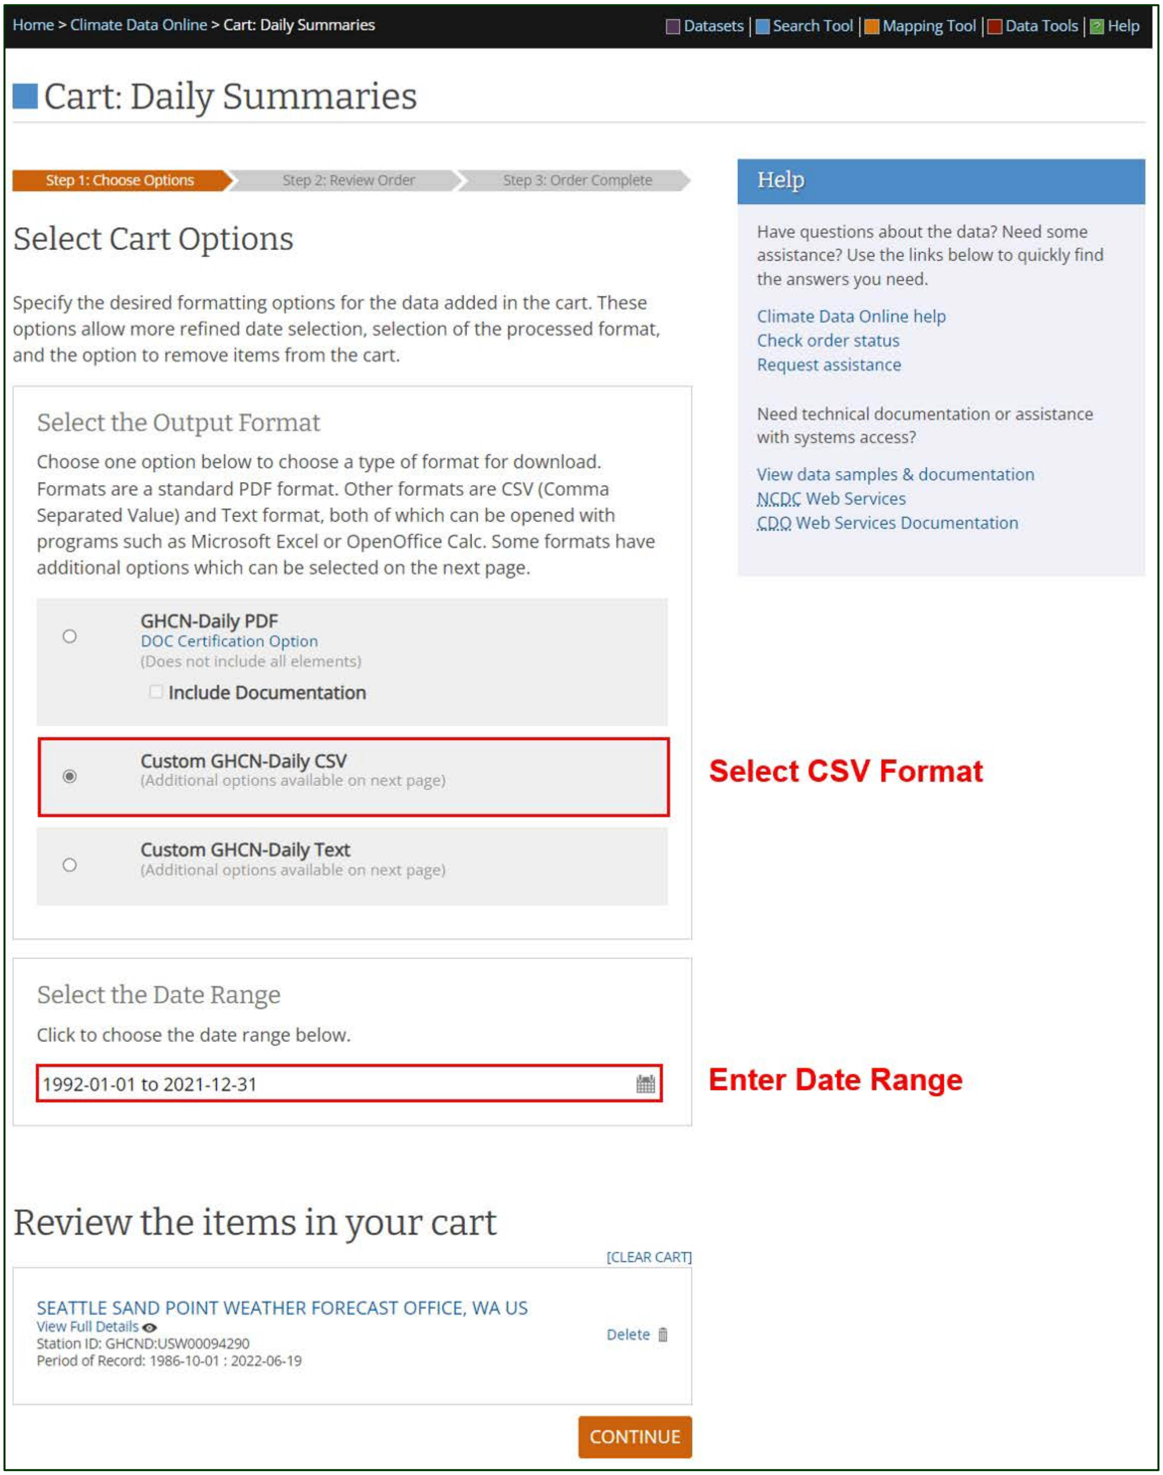
Figure A-4 Station Details



A-4.7.1.4 Adding GHCN Data to Cart.

To download the precipitation data for a selected station, click the “Add to Cart” button found on the Station Details page, or at the bottom of the Daily Observational Data map page. The station will then be added to the user’s cart. After clicking on the cart button at the top right of the page, users must then select the format and the date range of the data to be downloaded from the cart page as shown in Figure A-5. The preferred output format for the precipitation analysis is “Custom GHCN-Daily CSV”.

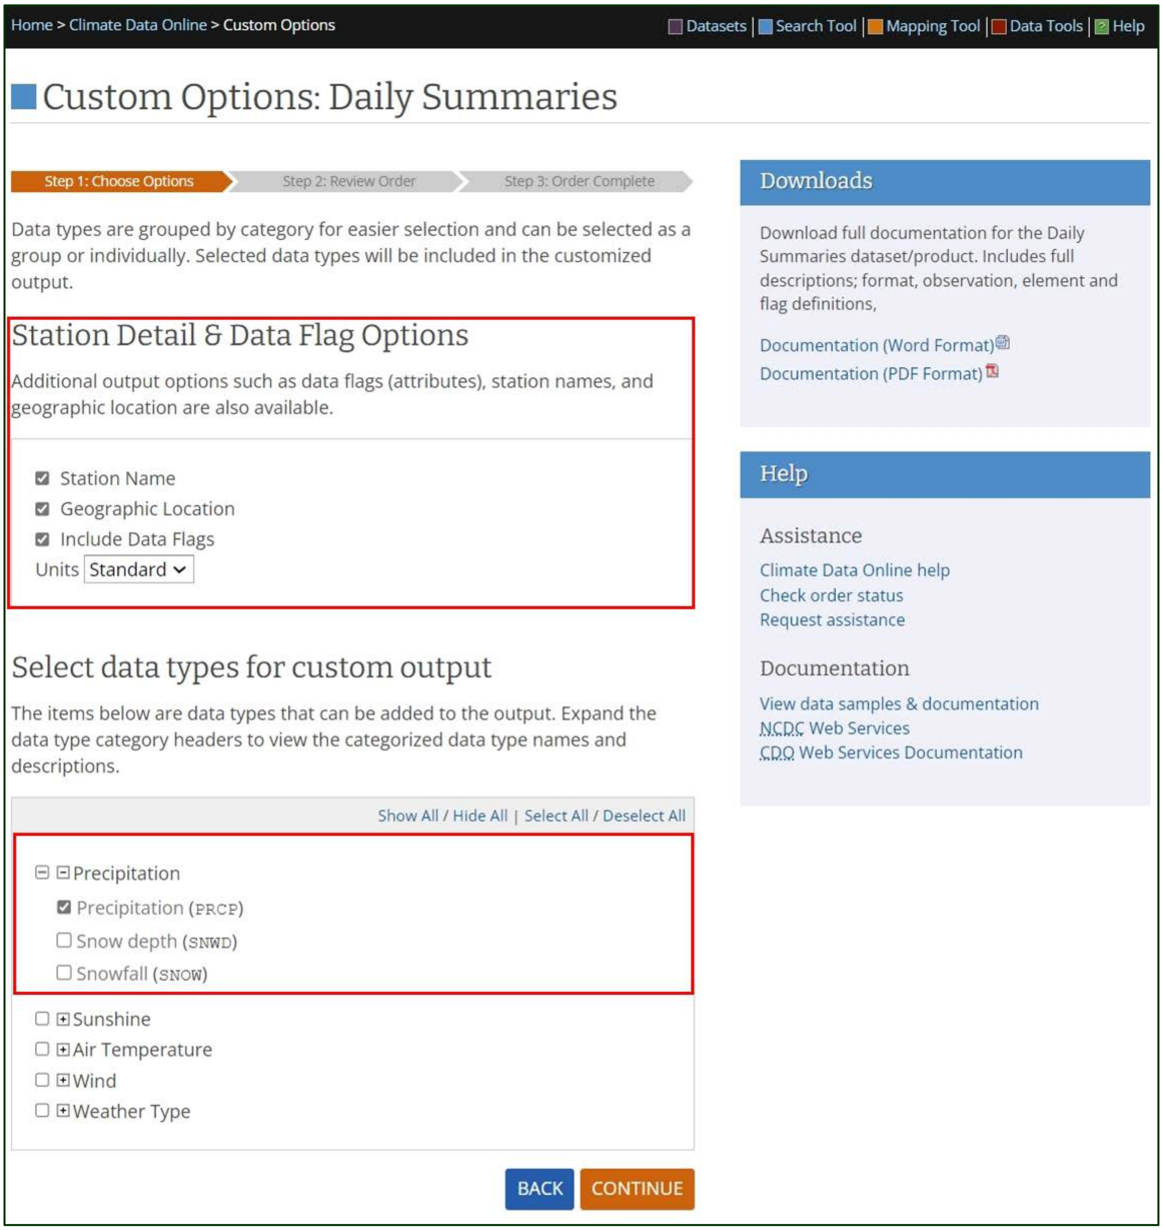
Figure A-5 Cart Options



A-4.7.1.5 GHCN Data Cart Options.

After selecting the format and date range, users should select “Continue” at the bottom of the page to select data options as well as station details to be included with the data. Figure A-6 shows the additional station details that may be included with the data download. If selected, the station name, geographic location and data flags will be included with the precipitation data. Geographic location is the station’s latitude and longitude in decimal degrees. Information about the types of data flags can be found through the documentation link under “Downloads” beside the station detail and flag options.

Figure A-6 Data Download Options



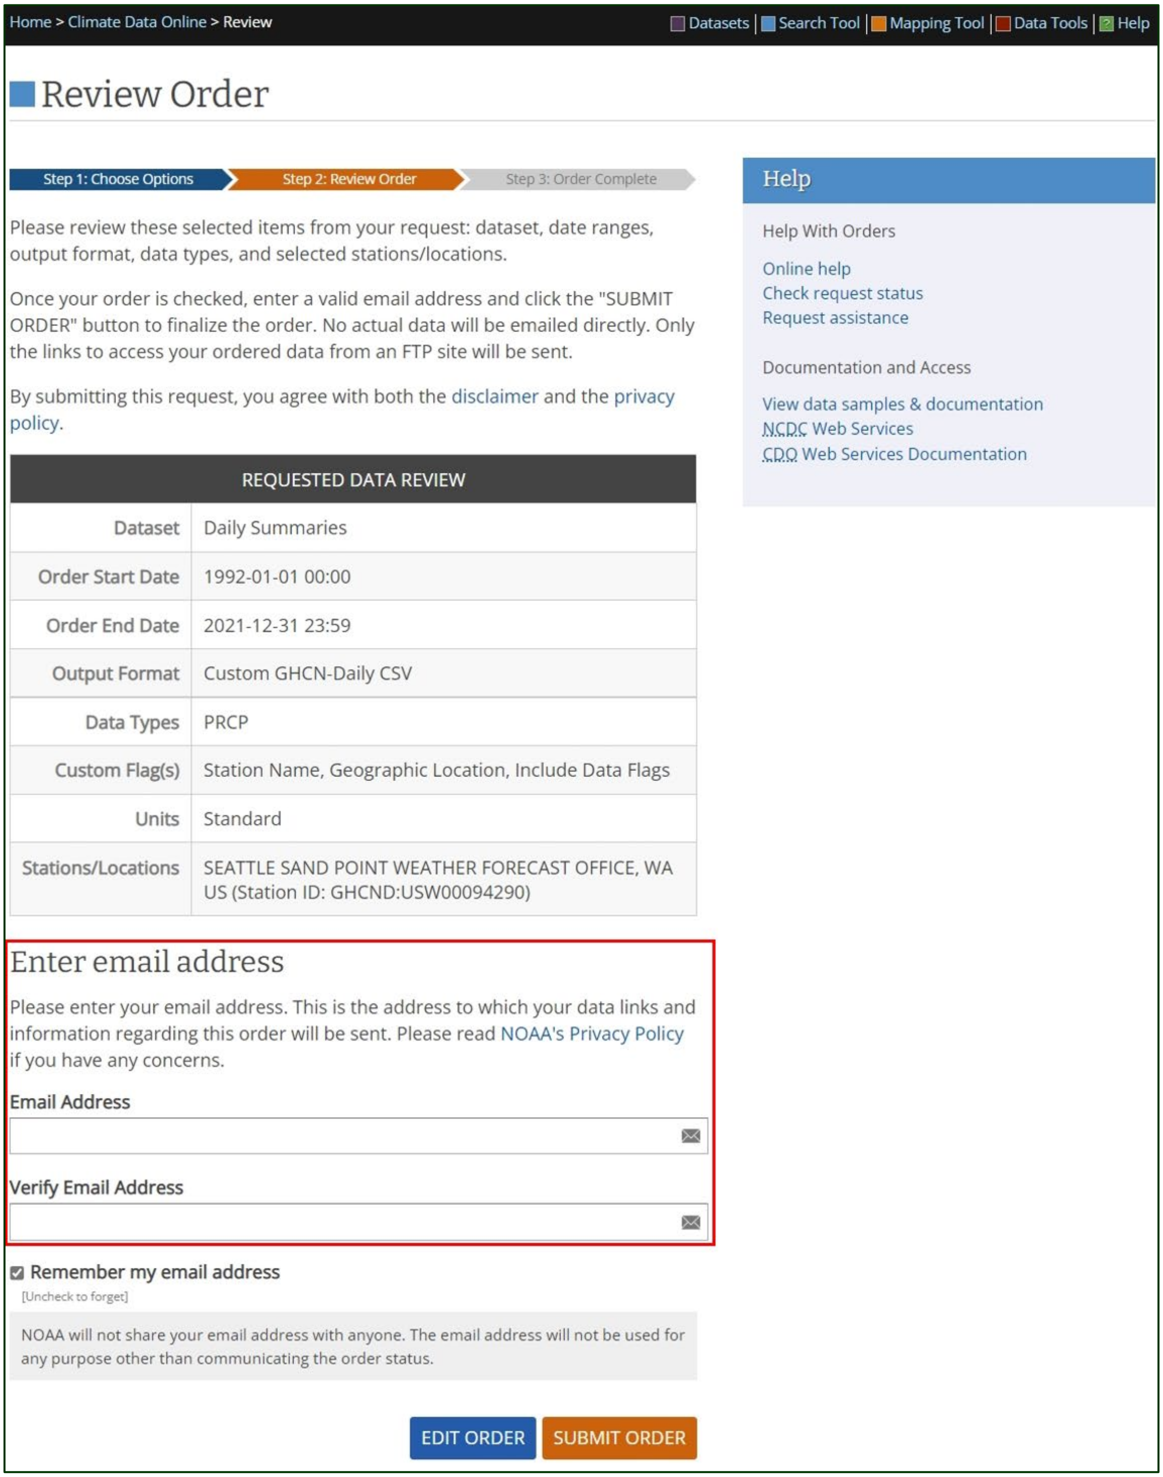
A-4.7.1.6 GHCN Data Units of Measure.

The default units of measure are “Standard” but may be changed to metric units under the Station Detail and Data Flag Options. The standard unit for precipitation data is inches measured to the hundredths of an inch. Users should note that the units of measure are not listed or shown with the downloaded precipitation data. Snow depth and snowfall measurements are not required. Precipitation measurements are for total precipitation during the recording period and include any snowfall during that period.

A-4.7.1.7 Review of GHCN Data and Submit Order.

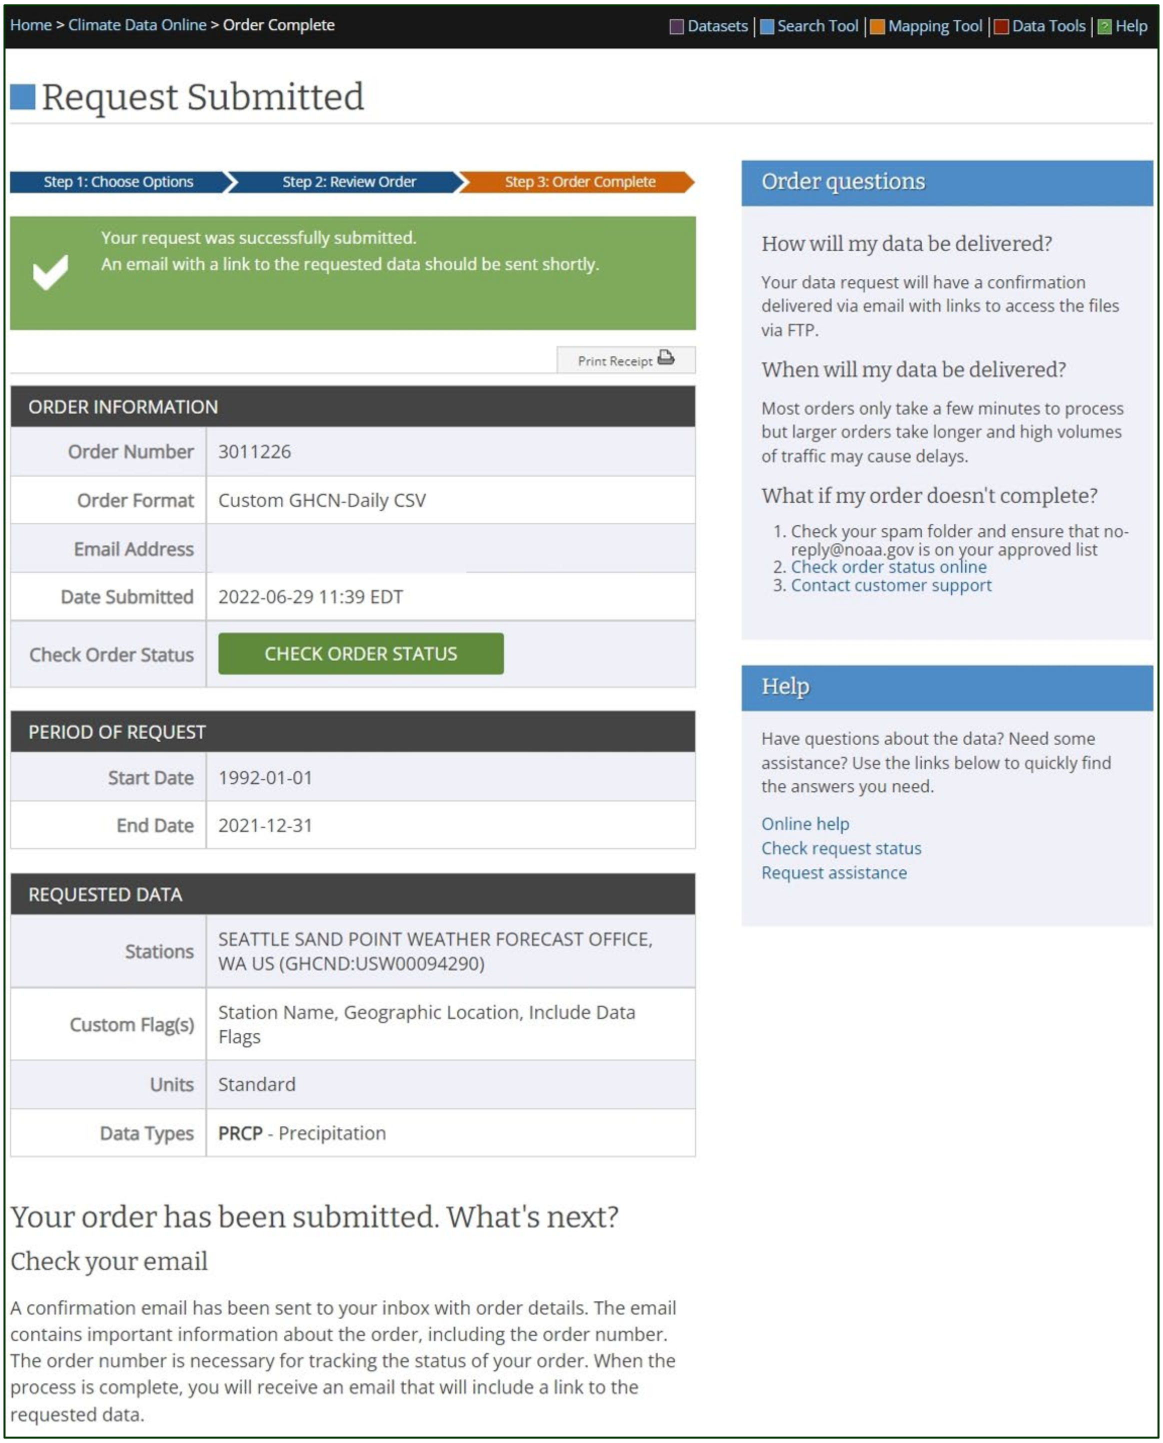
Once the station detail and data options have been set, clicking “continue” at the bottom of the page will take the user to the last page, shown in Figure A-7, before placing the order. Here the user can review the data request. The user must then enter and confirm their email address. The last step is to click “Submit Order.”

Figure A-7 Review of Order



Once the order has been submitted the user will see the order confirmation page, shown in Figure A-8, summarizing the data request. The user will receive an email from the National Centers for Environmental Information (NCEI) at noreply@noaa.gov confirming the data request, followed by an email with a download link for the data. The time between placing an order and receiving the data download link will vary but should not take more than a few minutes.

Figure A-8 Order Confirmation



A-4.7.2 GSOD Station Download Procedures.

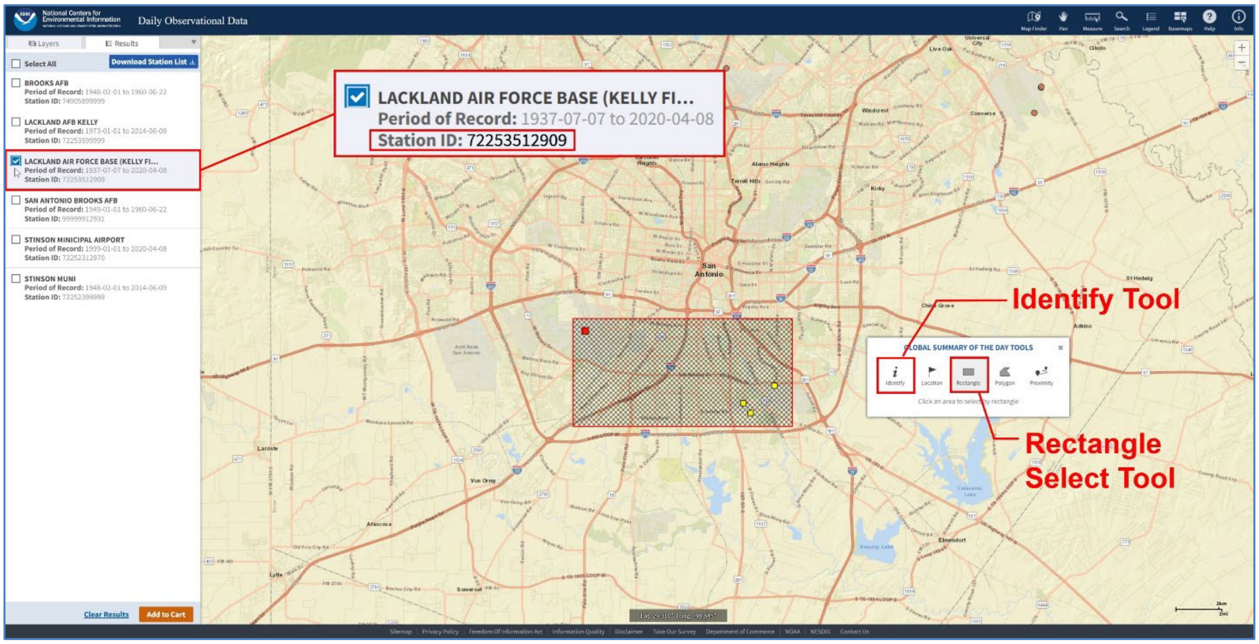
To download GSOD station data go to NOAA's Daily Observational Data map page at https://www.ncei.noaa.gov/maps/daily/ and select the Global Summary of the Day layer as shown in Figure A-9 to display GSOD station locations across the globe. The user may elect to show all GSOD stations including historical stations, or just the active stations using the settings icon beside the layer name.

Figure A-9 NOAA's Daily Observational Map Page – GSOD Layer

A-4.7.2.1 GSOD Specific Station Search.

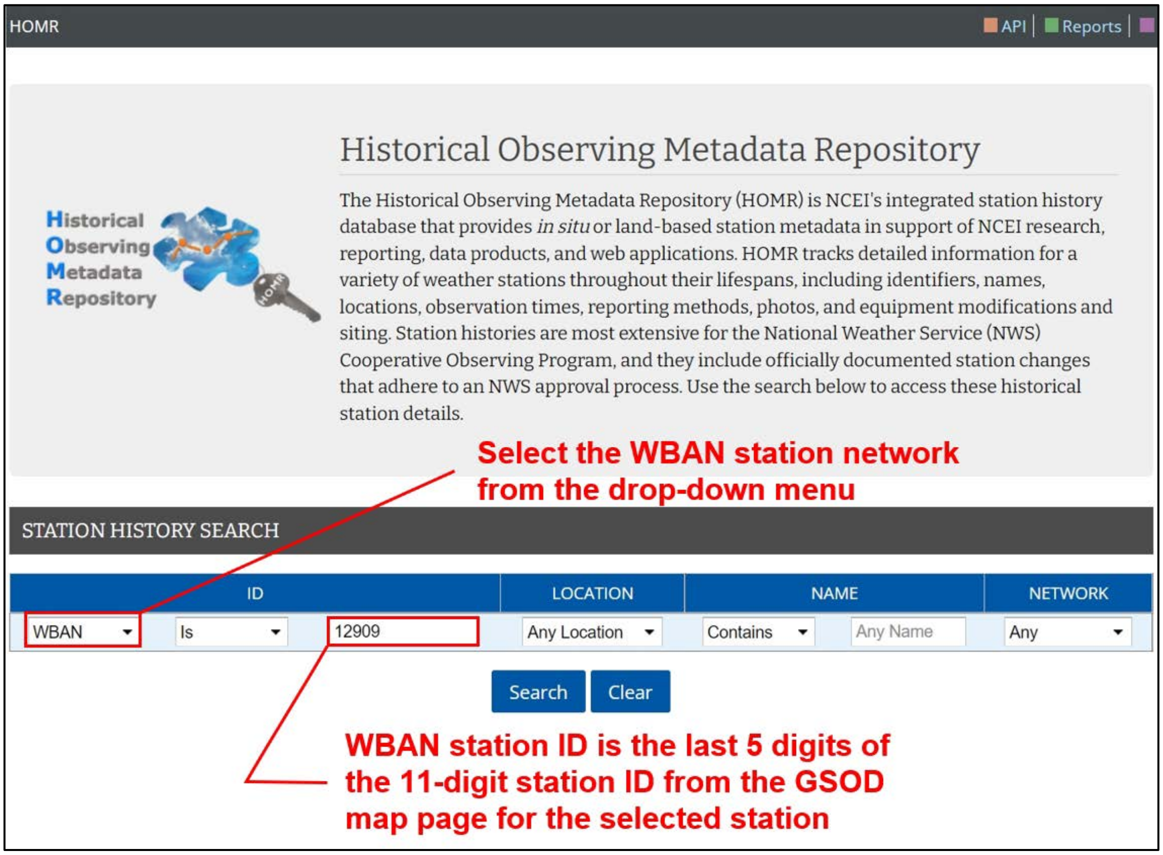
From the Daily Observational Data map page, users may zoom in and pan to a specific location, or search for a location or facility using the tools in the upper right of the page. Clicking on the Map Tools icon beside the layer name in the upper left allows the user to select an individual station using the identify tool, or multiple stations using the rectangle tool to draw a box around multiple stations as shown in Figure A-10. Station information for the selected station(s) will appear in the results tab to the left and includes the station name, station ID, and period of record.

Figure A-10 NOAA's Daily Observational Map Page



Unlike GHCN and WMO stations described in Section A-4.7.1.3, individual station details as shown in Figure A-4 are not linked to selected stations on the GSOD map page. Users must download and examine the data from a selected station to determine its completeness for a given period of record. Station history, if available, can be found on the NOAA website. The most efficient way to search for a GSOD station's history is from the Historic Observing Metadata Repository (HOMR) webpage at: https://www.ncei.noaa.gov/access/homr/;jsessionid=6C5634D8611E5A0E4F7FD2152BC1CE75. From the HOMR webpage, select WBAN from the drop-down menu for the network type as shown in Figure A-11. The WBAN station ID is the last five digits of the 11-digit station ID shown for a selected station on the GSOD map page.

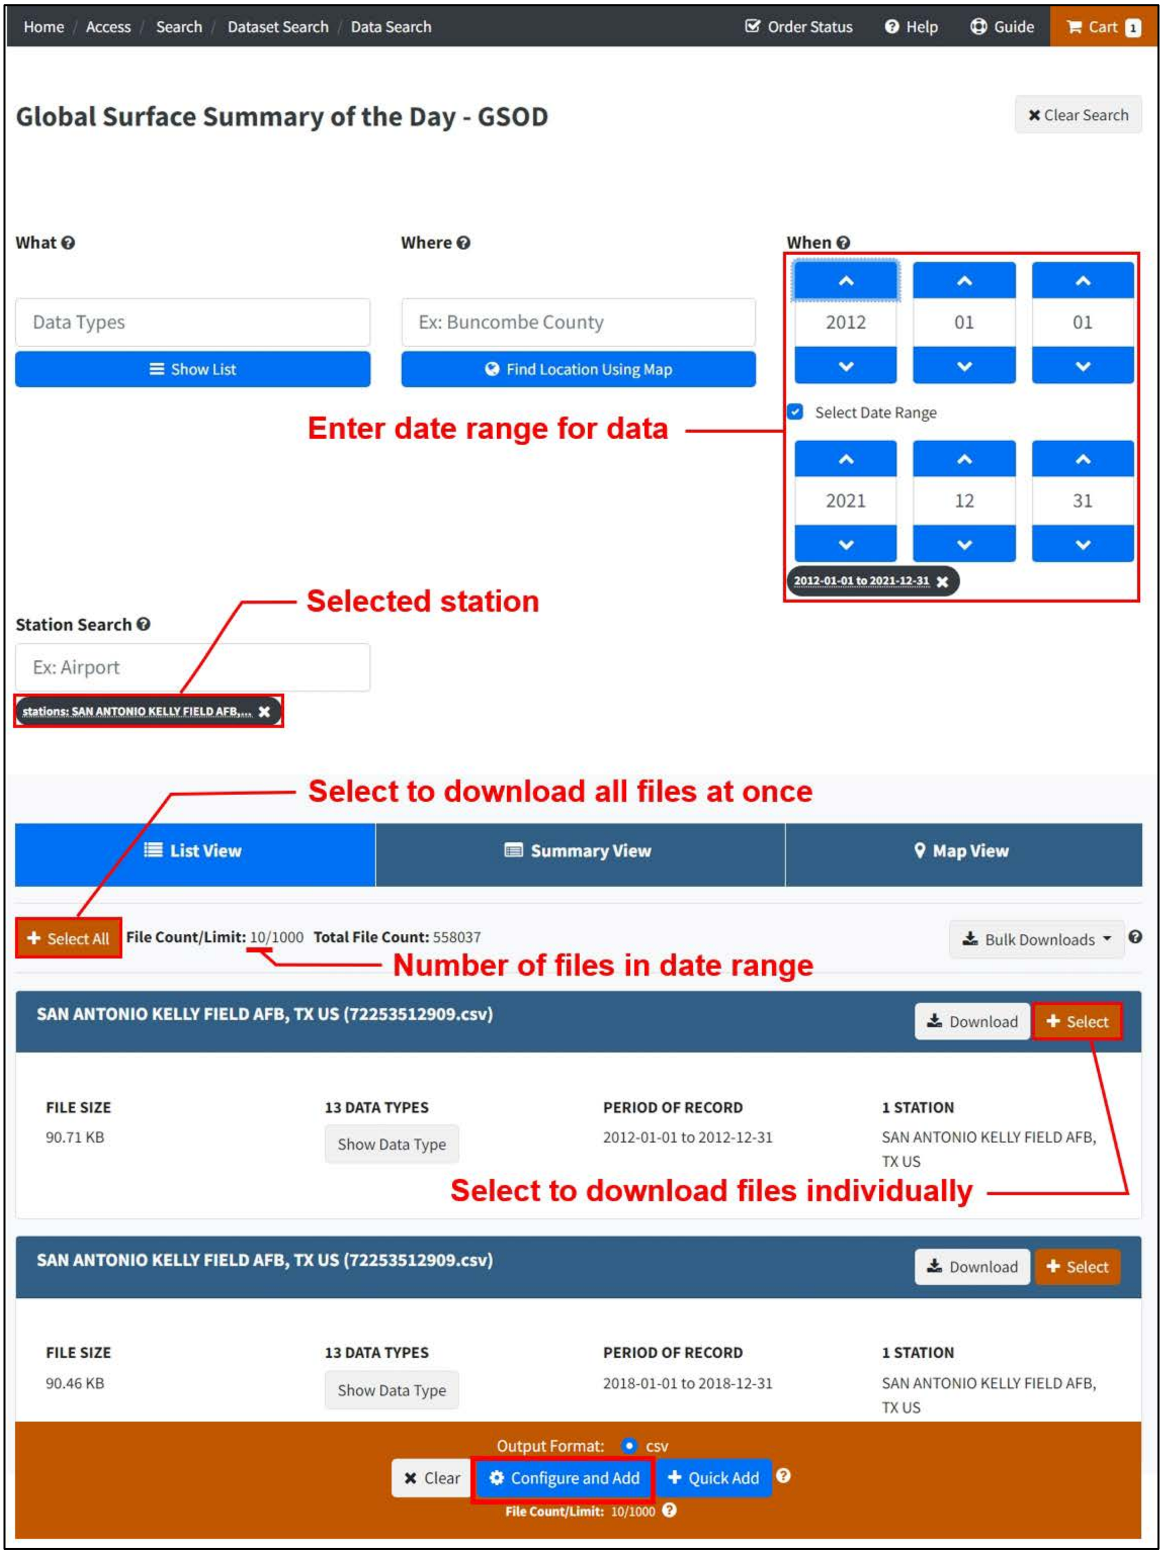
Figure A-11 GSOD Station History Search



A-4.7.2.2 Adding GSOD Data to Cart.

To download GSOD data after identifying a suitable station for analysis, select the station on the GSOD map page as shown in Figure A-10 and click “Add to Cart”. This will open a new webpage for the selected station as shown in Figure A-12 below. The selected station will be shown on the left side of the page below the station search bar.

Figure A-12 GSOD Data Selection



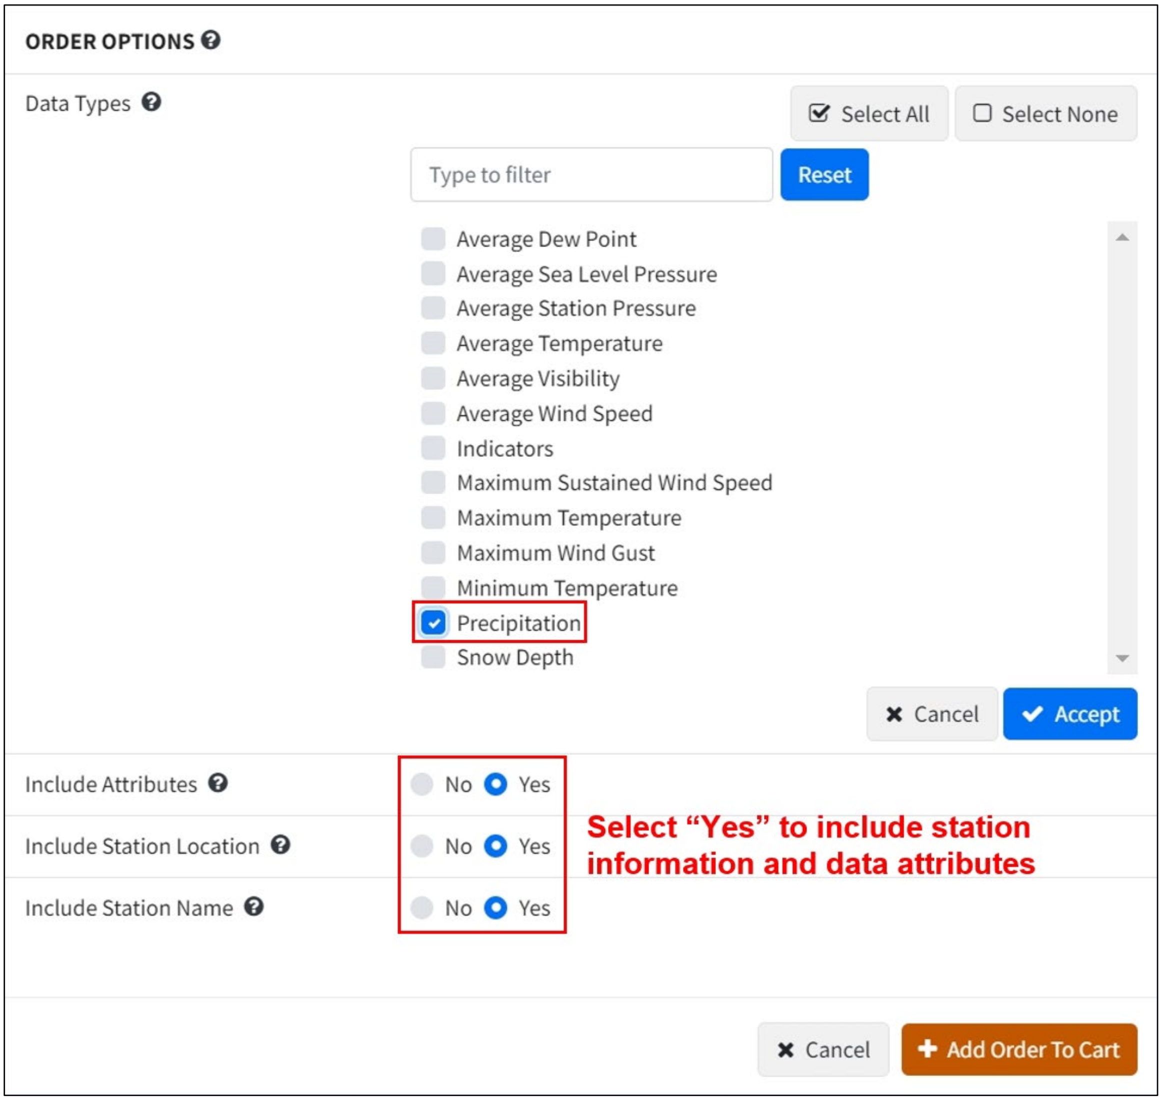
Below the station name, the number of files for the station will be displayed, with each file containing data for one calendar year. The default output file format for GSOD data is a comma separated values (.CSV) file. Before the user specifies a date range, the number of files for the station's entire period of record will be shown. Once a date range has been entered by the user, the number of files in the specified date range will be shown. The number of files should equal the number of years specified in the date range. When the number of files is fewer than years in the date range it indicates that data is missing for one or more years. The individual files for each year in the selected date range will be displayed at the bottom of the page and may continue on other pages depending on the length of the selected date range. Users can scroll down and look at the individual files to see which years are missing.

A-4.7.2.3 Options When Selecting GSOD Data.

Users may select and download the files individually, however the most efficient way to download the data is to click the "Select All" button on the left side of the page below the station name. This will select all the files for the specified date range and combine it into a single file for downloading. After the "Select All" button has been clicked, the user will see three options at the bottom of the page. The "Clear" button will unselect the files chosen for downloading but it does not clear the date range in the upper right of the page specified by the user. The "Quick Add" button automatically selects all data types collected by the station to include in the data download for each year in the date range and sends the request to the user's cart. However, this will include unneeded data such as wind speed, barometric pressure, etc. and will not include station information or data indicators with the data download.

Instead, users should select the "Configure and Add" button which lets them select or unselect the data types to be downloaded. More importantly, the station name and location, as well as data attributes, are not included with the data unless those items are selected. Figure A-13 below shows the order options for the GSOD data. Precipitation data attributes are listed in the GSOD data documentation and can be found at the following link https://www.ncei.noaa.gov/data/global-summary-of-the-day/doc/readme.txt. GSOD precipitation data is measured in inches to the nearest hundredth of an inch as stated in the GSOD data documentation linked above. Users should note that the units are not mentioned or shown on the download pages and are not listed with the downloaded data.

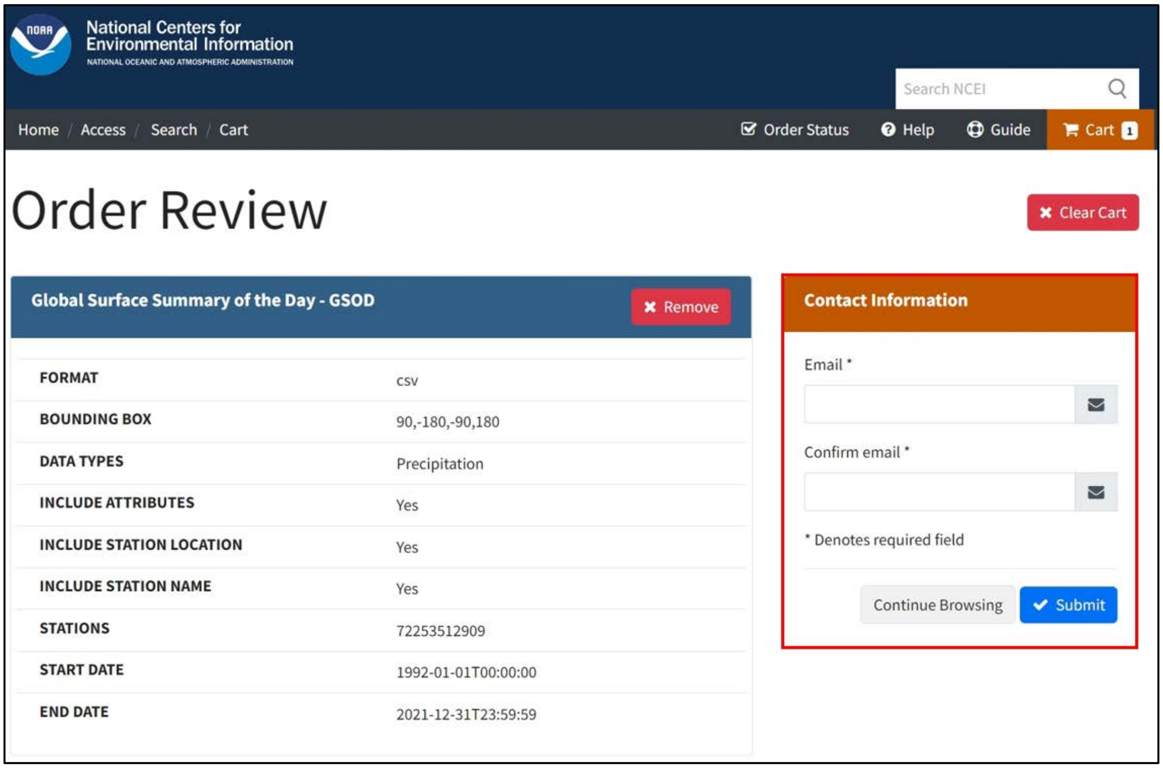
Figure A-13 GSOD Data – Order Options



A-4.7.2.4 Review of GSOD Data and Submit Order.

Once the data options have been selected, select "Add Order to Cart". This will take the user to the order review page shown in Figure A-14. After reviewing the order, the user must input and confirm their password before hitting the submit button to complete the data request.

Figure A-14 Order Review



After submitting the data request the user will receive an email from the NCEI at noreply@noaa.gov confirming the data request, followed by an email with a download link for the data. The time between placing an order and receiving the data link will vary but should not take more than a few minutes.

A-4.8 Procedure to Compute 95th Percentile Rainfall Event.

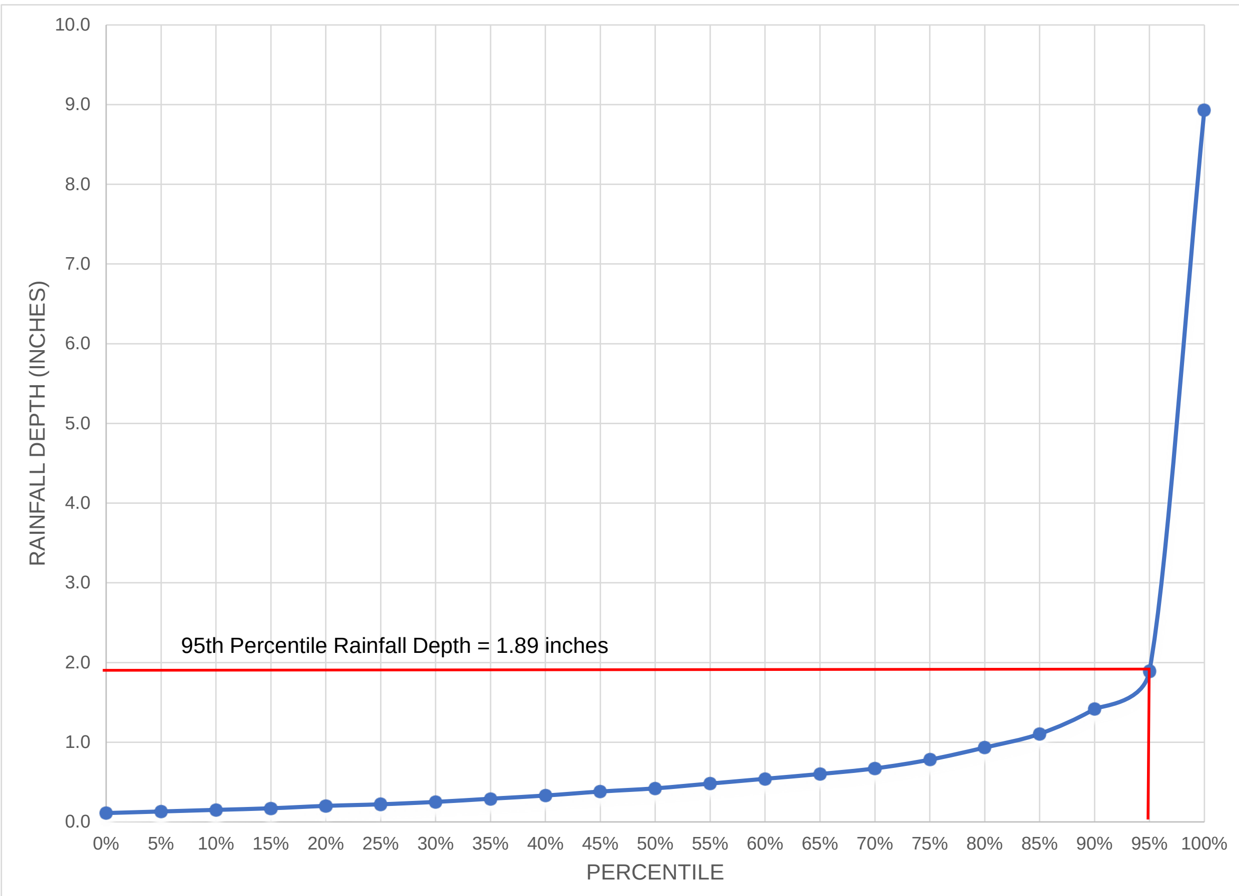
The design storm is the 95th percentile rainfall, described in Section 2-1.2. The step-by-step procedure for calculating the 95th percentile rainfall depth, using a spreadsheet, is summarized below:

1. Obtain a long-term rainfall record, in comma separated value or ".CSV" format, as detailed in Sections A-4.7.1 and A-4.7.2. These are daily or 24-hour rainfall records over the period.
2. Import the data into a spreadsheet. The daily precipitation data downloaded is typically arranged in a single column. If the original data set has multiple columns of daily precipitation data, then the user must rearrange the data into a single column.
3. Review the data for any anomalies or erroneous data points, measurement error flags (indicated in the precipitation data attributes) and remove this data from the list.
4. Remove data for small rainfall events that are 0.1 inch or less (≤ 0.1 inch) from the data set. These rainfall events (≤ 0.1 inch) are to be deleted since

they do not typically cause runoff and can potentially cause calculation of 95th percentile of runoff-causing rainfall event to be inaccurate.

5. It is preferable to sort the rainfall data (> 0.1 inch) from smallest value to highest value. The 95th percentile rainfall depth is calculated using the spreadsheet function PERCENTILE and specifying the range and percentile value (in this case it is 95th percentile and the value to be used in the spreadsheet function is 0.95). If MS Excel is used, the function attributes are [=PERCENTILE (precipitation data range, 0.95)]. Alternatively, the user can apply available statistical packages to determine the same.
6. A typical plot of rainfall depth versus percentile is shown in Figure A-15.

Figure A-15 Plot of Typical Rainfall Depth vs Percentile



A-5 LID DESIGN.

A-5.1 Introduction.

LID strategies provide decentralized hydrologic source control for stormwater. LID implementation centers around selecting LID features which are distributed small-scale controls that can closely maintain or replicate hydrological behavior of the natural system for a design storm event.

Standard BMPs may be used in conjunction with LID features, depending on site conditions, to handle the peak rate of discharge for flood control. Follow published design criteria relative to achieving, maintaining, and emphasizing a positive exterior visual environment applicable to military installations.

A-5.2 Hydrologic Analysis.

Table A-6 gives representative runoff curve numbers and the calculated initial abstractions for selected soil types. The runoff generated from a project site and the initial abstraction of the site does not have a linear relationship. For this reason, the required design storage of LID features is calculated using Equation 3-2 and Equation 3-3 discussed in Chapter 3.

Runoff curve numbers are determined by land cover type, hydrologic condition, antecedent runoff condition (ARC), and hydrologic soil group (HSG). Curve numbers for various land covers based on an average ARC can be found in the TR-55 manual.

Table A-6 Initial Abstraction for Indicated Soil Types

Existing Site Conditions	Curve Number (CN)	Initial Abstraction (inches)
Woods - good condition, HSG B	55	1.64
Woods - poor condition, HSG D	83	0.41
Pasture, grasslands - good condition, HSG B	61	1.28
Pasture, grasslands - fair condition, HSG C	79	0.53
Open space - lawns, park in fair condition, HSG B	69	0.90
Residential districts - 1/3 acre, 30% impervious, HSG B	72	0.78
Residential districts - 1/3 acre, 30% impervious, HSG C	81	0.47
Industrial area - 72% impervious, HSG B	88	0.27

A-5.2.1 Mimic Existing (Pre-Development) Hydrologic Conditions.

The preceding table shows that the hydrology of a naturally wooded environment in good condition provides a maximum retention that in turn increases the water quality treatment of stormwater runoff. For redevelopment, the site is not set at maximum retention, but to maintain pre-development levels. However, the typical site development project results in the following adverse environmental impacts:

- Changes to existing land-use and land cover

- Changes to natural drainage patterns
- Clear cutting of the native vegetation
- Soil compaction due to the use of heavy construction vehicles on-site
- Increase in impervious area
- Drainage systems that quickly move the water downstream.

It is recognized that there are very many different existing development conditions (including everything from leveling and fill, to existing conditions that bear no resemblance to what came before). As a result, the post-development hydrologic conditions are worsened, and in many cases, the damage becomes irreversible. The goal, however, is to document a return to a realistic natural pre-development condition for the particular locale and setting. LID techniques mimic the natural systems by capturing runoff in bio-infiltration practices (such as shown by Figure A-16 below), structural solutions, reuse, or footprint reduction for a design storm event. The pre-development condition is the typical condition of the project site just prior to the project. Apart from the potential increase in impervious area, the primary impacts due to man-made development are soil compaction, and increased efficiency of drainage patterns. The two land development conditions of concern are:

- Pre-Development Condition
- Post-Development Condition

Figure A-16 Typical Bio-infiltration 'Rain Garden'

Note curb cut inlet. Design should be based on regional plants and growing conditions.

A-5.2.2 Time of Concentration for Pre- and Post-Development Conditions.

In order to mimic natural hydrologic patterns, the site designer should provide features that limit the rate at which runoff leaves the site. Maintaining T_c close to pre-development conditions is critical because the peak runoff rate and thereby the volume of runoff from individual lots, is inversely proportional to the T_c. Manage T_c by utilizing strategies such as reduction of impervious areas, maintaining natural vegetation, siting of impervious areas in poor draining soils, and disconnecting impervious areas.

Using traditional site planning techniques, the post-development T_c is invariably reduced. This is due to the curbs, channels, and pipes causing quicker drainage, resulting in higher peak flow rates. In order to mimic the natural hydrologic pattern, the site designer needs to provide features that slow down the runoff from the site. To maintain the T_c, use the following site planning techniques:

- Maintaining or increasing pre-development sheet flow length
- Preserving natural vegetation
- Increasing surface roughness
- Detaining flows
- Disconnecting impervious areas

- Reducing longitudinal slopes of swales and ditches.

Achieving a T_c close to pre-development conditions is often an iterative process and requires analyzing different combinations of the appropriate techniques.

A-5.2.3 Stormwater Flow Segments.

TR-55 Curve Number Methodology is well documented and is used widely in engineering practice to determine the T_c. The method presumes that runoff from rainfall moves through a watershed as sheet flow, shallow concentrated flow, pipe flow, channel flow, or some combination of these. T_c is the sum of travel flow times calculated separately for the consecutive flow segments along the longest flow path. These three flow segments along with their implications on T_c are detailed in the TR-55 manual. The use of TR-55 is recommended for calculating T_c. Other methodologies in accordance with applicable state or local stormwater regulations and based on site specific conditions may also be used.

A-5.2.4 LID Design Storm Event.

Storm events are a complex natural phenomenon, and methods to predict and control their impacts rely upon empirical and mathematical modeling of the event. In previous versions of this document, three principal approaches were analyzed in selecting the 95th percentile design storm event – (a) Prince George's County Methodology; (b) EPA Methodology; and (c) First-Flush Water Quality Volume. Over the years, the EPA Methodology of using the 95th percentile rainfall depth as the design storm event for design of LID features has been widely accepted and is adopted herein. For details pertaining to this refer to Section A-4.8 or EPA 841-B-09-001 for the EPA Methodology for calculating the 95th percentile rainfall event.

A-5.2.4.1 Design Storage of LID Features.

For the 95th percentile design storm event, the LID volume is equal to or greater than the total net increase in runoff from the pre- to post-development states. Typically, the total volume of stormwater runoff generated during the post-development conditions exceeds the total volume of stormwater runoff generated from the site during the pre-development conditions. The design storage volume of LID features would be the difference in total volume of stormwater runoff generated between pre- and post-development conditions.

Table A-7 illustrates the total depth of increase in stormwater runoff for a hypothetical representative site. The depth of increase in stormwater runoff calculated will be used in designing the LID features to handle all of the net increases in stormwater runoff generated from a parcel being developed (using Equation 3-3).

A-5.3 Design Objective and Pre-Development Hydrology.

The LID Storage Volume assures the most practical solution and provides the maximum value for achieving an improved water quality discharge downstream. In certain geographical areas on optimal sites, the site designer will be able to improve the efficiency of the LID features to handle a portion of the flood control element of stormwater. For other rainfall events, which exceed normal intensities, the runoff will be collected and conveyed to the conventional SWM facilities. The conventional SWM facilities should be designed to discharge or outfall over a 24-hour period to reduce the peak flow rate below the pre-development outflow rate. Further, outfall water quality is improved through an additional treatment from conventional SWM facilities. To design the LID features for gross increases in stormwater runoff over a range of storm events, for less frequent or high return period storm events, would be impractical. Conventional SWM facilities may be needed in addition to LID features to meet with state/local stormwater requirements.

A-5.4 Design Considerations.

A few of the most relevant design considerations are listed below. For a more detailed list, the reader is referred to published literature given in the references.

It is important to note that holding excess rainwater on-site that would ordinarily end up as runoff can be detrimental in some cases. Rainfall that is retained in excess of the initial abstraction can destabilize certain soils on slopes, impact sensitive coastal tidal zones, increase the need for mosquito control, and in certain riparian or usufructuary rights create an infringement. In many areas where shallow groundwater aquifers are used for water supply or irrigation, the designer must consider contamination issues.

A-5.4.1 Develop LID Control Strategies.

Use hydrology as a design element. To minimize the runoff potential of the development, the hydrologic evaluation should be an ongoing part of the design process. An understanding of site drainage can suggest locations for both green areas and potential building sites. An open drainage system can help integrate the site with its natural features, creating a more aesthetically pleasing landscape.

a. Determine the state regulatory design storms. Regulatory requirements for design storms may also be stipulated in local ordinances, and these may limit or constrain the use of LID techniques or necessitate those structural controls be employed in conjunction with LID techniques.

b. Determine LID volumes using 95th percentile design storm and TR-55 Curve Number methodologies.

c. Evaluate current conditions. Analyze site with traditional hand methods or computer simulations. Use the results of modeling to estimate baseline values for the four evaluation measures: runoff volume, peak runoff rate, flow frequency and duration, and water quality.

d. Evaluate site planning benefits and compare with baseline values. The modeling analysis is used to evaluate the cumulative hydrologic benefit of the site planning process in terms of the four evaluation measures.

e. Evaluate the need for LID IMPs. If site planning is not sufficient to meet the site's LID objectives, additional hydrologic control needs may be addressed using LID features. After LID features are selected for the site, a second-level hydrologic evaluation can be conducted that combines the LID IMPs with the controls provided by the planning techniques. Results of this hydrologic evaluation are compared with the baseline conditions to verify that the site LID objectives have been achieved. If not, additional LID features are located on the site to achieve the optimal condition.

f. Evaluate supplemental needs. If supplemental control for either volume or peak flow is still needed after the use of LID IMPs, selection of additional management techniques should be considered. For example, where flood control or flooding problems are key design objectives, or where site conditions, such as poor soils or a high groundwater table limit the use of LID features, additional conventional end-of-pipe methods, such as large detention ponds or constructed wetlands, should be considered. In some cases, their capacity can be reduced significantly using LID features upstream. It may be helpful to evaluate several combinations of LID features and conventional stormwater facilities to determine which combination best meets the stated objectives. Use of hydrologic evaluations can assist in identifying the alternative solutions prior to detailed design and construction costs.

g. For residential areas, Prince George’s County, Maryland, has developed a detailed illustration of an approach for conducting a hydrologic evaluation based on the TR-55 method. The effect of LID features should be reflected in the curve numbers and times of concentration selected for the analysis. A full description of this process is available from Prince George’s County (*Low-Impact Development Hydrologic Analysis*)

A-5.4.2 LID Concept Design or Master Plan.

1. Maximize the efficiency of the existing site. Place impervious areas in poorer soils and retain existing trees where practical.
2. Sketch a design concept that distributes the LID practices appropriately around the project site. Keep in mind the multifunctional capability of LID technologies (that is, parking lot with detention facility underground).
3. Develop a master plan that identifies all key control issues (water quality, water quantity, water conservation) and implementation areas. Specify specific LID technologies and any connections they have to stormwater overflow units and subsurface detention facilities.

A-5.4.3 Develop Landscaping Plans to Maximize Efficiency of LID Features and Reduce Maintenance.

1. Hardy, native plantings should be used.
2. In areas where soils have low infiltration rates, as determined by percolation tests, average depth of bio-infiltration practices is determined such that the volume held would infiltrate within stated limits. For example, if the state criteria indicates 72 hours in soils with a low

permeability rate (hydrologic soil groups C and D) of 0.05 inches/hour (1.3 mm/hr), the depth of infiltration basin = 72 hrs x 0.05 in/hr (1.3 mm/hr) = 3.6 inches (93.6 mm). Conservatively, the designer may opt to restrict this depth to 3.0 inches (75 mm) and provide a larger area to satisfy the LID volume requirement. The designer may also want to incorporate other LID practices, such as footprint reduction of impervious surfaces and permeable pavers, in conjunction with sizing of bio-infiltration facilities. (Verify all actual design parameters with state BMP manual.)

3. Flood control is based on protecting life and property. Flood control criteria are ultimately determined locally based on drainage needs and flood risk of any particular area and may go beyond LID design criteria to achieve the necessary level of flood protection.
4. If project site has limited land area for bio-infiltration practices, in order to satisfy the LID volume criteria, a combination of structural practices such as rain barrels and cisterns may be employed in addition to bio-infiltration practices. At any time, the outflow from the structural practices should be controlled to the sum total of assimilating capacity of bio-infiltration practices provided downstream. For example, if a downstream bioretention facility is of size 600 sq.ft, in soil type C with an infiltration rate of 0.15 in/hr (3.8 mm/hr), then the cisterns or rain barrels provided on site will discharge into bioretention facility at a rate = 0.15 in/hr * 600 sq.ft /(12 in/ft * 3600 sec/hr) = 0.0021 cfs.
5. LID features should be incorporated into the site plan at locations as close as possible to the origin of surface runoff from impervious areas. For example, runoff from roof drains is to be collected around the building (minimum building offsets should comply with UFC 4-010-01), and runoff from parking lots will be held in traffic islands and along the perimeter.
6. Plant bioretention facilities with native vegetation; refer to Landscape Architect, local plant specialists, or horticulturists.
7. Design positive overflow system to capture excess rainfall-runoff.

A-5.4.4 Operation and Maintenance Procedures.

Operation and Maintenance Support Information documentation (OMSI) is critical to ensure LID features are maintained and continue to function properly. LID features should be viewed as environmental systems that have specific maintenance requirements. The O&M procedures for each of the LID practices implemented in the site plan should be provided as part of the OMSI documents. Different types of LID features will have different maintenance requirements, but some general principles will apply:

- Keep LID features and flow paths clear of debris and trash.
- Use native, drought-tolerant plantings that can tolerate periods of saturation. Vegetation should be watered regularly during dry periods. Use special care in selecting plants in areas of tidal influence.

- Consider impact on plants by road salts.
- Grassed areas should be mowed regularly using a longer length cut.
- Plantings should be pruned as needed.
- Deep raking and tilling of depression storage should be done on a yearly basis or as indicated.

A-5.5 Gaining Acceptance of LID Options.

A higher level of communication on LID projects should be maintained to keep stakeholders informed during the planning and design phase. From building tenant commands to O&M personnel, communicating intent and purpose is the key to successful LID implementation. In addition, for some period, feedback on implementation and program success of all new facilities may be required by the local Environmental Office.

Table A-7 Example Evaluations of Increased Post-Development Runoff Depth

Existing Site Conditions	Existing Site Composite CN	Design Storm Event 95th Percentile Rainfall EPA Methodology (inches)	Developed Conditions[2] Composite CN	Depth of Increase in Stormwater Runoff (inches)
Woods - good condition, HSG B	55	1.89[a]	76.5	0.37
Woods - poor condition, HSG D	83	1.38[b]	90.58	0.31
Pasture, grasslands - good condition, HSG B	61	1.89[a]	79.5	0.42
Pasture, grasslands - fair condition, HSG C	79	1.38[b]	88.5	0.31
Open space - lawns, park in fair condition, HSG B	69	1.89[a]	83.5	0.46
Residential districts - 1/3 acre, 30% impervious, HSG B	72	1.89[a]	85	0.47
Residential districts - 1/3 acre, 30% impervious, HSG C	81	1.38[b]	89.5	0.31
Industrial area - 72% impervious, HSG B	88	1.89[a]	93	0.34

1. In this example, regional refers to: a - Norfolk Region; b- Cincinnati Region.

2. The developed conditions composite curve number is calculated as equal to existing composite CN plus a 50% of maximum full development potential of the parcel. A full development potential is where the entire parcel is developed with impervious surface resulting in a composite curve number of 98. Here, it is assumed 50% of maximum full development and calculated as = existing CN+0.5*(98-existing CN).

Note: [1] See Table A-10 for DoDAAC installation address

[2] Average Annual Rainfall Depth (inches) is averaged over number of years rainfall data is available from 1992 - 2021. In computing the Annual Rainfall Depth, all daily rainfall events (> 0.0 in) are included.

[3] 95th Percentile Rainfall Depth is computed for the most recent 30-year period (from 1992-2021), where available. The calculating 95th percentile rainfall depth daily rainfall depths greater than 0.1" (> 0.1 in) are used. Small rainfall events (≤ 0.1 inch) are lost due to abstractions and typically do not result in runoff.

[4] Average Annual Rainfall Days (> 0.1 inch) is averaged over number of years rainfall data is available from 1992 - 2021.

Table A-9 Summary of Rainfall Analysis (1992 - 2021) – Overseas Locations

	Rainfall Station Name	State	Station ID: GHCND (or GSOD)	Applicable DoDAAC[1] Numbers												Annual Rainfall Depth[2] (inches)	95th Percentile[3] (inches)	Rainy Days[4] (>0.1")	Years of Available Record (1992-2021)

Note: [1] See Table A-10 for DoDAAC installation address

[2] Average Annual Rainfall Depth (inches) is averaged over number of years rainfall data is available from 1992 - 2021. In computing the Annual Rainfall Depth, all daily rainfall events (> 0.0 in) are included.

[3]95th Percentile Rainfall Depth is computed for the most recent 30-year period (from 1992-2021), where available. The calculating 95th percentile rainfall depth daily rainfall depths greater than 0.1" (> 0.1 in) are used. Small rainfall events (≤ 0.1 inch) are lost due to abstractions and typically do not result in runoff.

[4] Average Annual Rainfall Days (> 0.1 inch) is averaged over number of years rainfall data is available from 1992 - 2021.

[5] Bahrain average annual rainfall days (> 0.1 inch) = 4 days. For this reason, the 95th percentile rainfall depth computed is very high due to torrential storms that occur once or twice a year.

[6] Djibouti average annual rainfall days (> 0.1 inch) = 4 days. For this reason, the 95th percentile rainfall depth computed is very high due to torrential storms that occur once or twice a year.

B-2 DEFINITION OF TERMS.

95th Percentile Rainfall Event: The 95th percentile rainfall event represents a precipitation amount which 95 percent of all rainfall events for the period of record do not exceed. In more technical terms, the 95th percentile rainfall event is defined as the measured precipitation depth accumulated over a 24-hour period for the period of record that ranks as the 95th percentile rainfall depth based on the range of all daily event occurrences during this period.

The 24-hour period is typically defined as 12:00:00 am to 11:59:59 pm. In general, a 30-year period of rainfall data is recommended for such an analysis, with a required minimum period of 10 years. Small rainfall events that are 0.1 inch or less (that is, ≤ 0.1 inches) are excluded from the percentile analysis because this rainfall generally does not result in any measurable runoff due to absorption, interception, and evaporation by permeable, impermeable, and vegetated surfaces.

Building: DODI 4165.14, Enclosure 2, defines a building as: A roofed and floored facility enclosed by exterior walls and consisting of one or more levels that is suitable for single or multiple functions and that protects human beings and their properties from direct harsh effects of weather such as rain, wind, sun, etc.

Federal Facility: Section 401(8) of EISA states: The term “Federal facility” means any building that is constructed, renovated, leased, or purchased in part or in whole for use by the Federal Government.

Low Impact Development (LID): LID is a stormwater management strategy designed to maintain site hydrology and mitigate the adverse impacts of stormwater runoff and nonpoint source pollution.

LID actively manages stormwater runoff by mimicking a project site’s pre-development hydrology using design techniques that infiltrate, store, and evaporate runoff close to its source of origin. LID strategies provide decentralized hydrologic source control for stormwater runoff. In short, LID seeks to manage the rain, beginning at the point where it falls. The LID features are distributed small-scale controls that closely mimic the hydrological behavior of the pre-project sites for a design storm event.

Pre-Development: pre-project conditions that exist at the beginning of design. Where phased development occurs, the existing conditions at the time prior to the first phase being submitted will establish pre-development conditions.

Record of Changes (changes are indicated by **1**\ ... /**1**/)

Change No.	**Date**	**Location**
1	11/03/2021	Update to referenced International Building Code 2018 (IBC 2018) as implemented by UFC 1-200-01. Clarifications to requirements not addressed by the current Building Code. Appendix A, B, C, and D updated links.
2	10/17/2024	Update to reference the International Building Code 2021 (IBC 2021) as implemented by UFC 1-200-01. Update to Chapter 2-1.1 to clarify requirements of individuals responsible for design and studies. Update to Chapter 2-4.2.5 to include use of geophysics. Update Chapter 2-4.2.9 to address effects of site grade changes.

This UFC supersedes UFC 3-220-01, dated 1 November 2012.

FOREWORD

The Unified Facilities Criteria (UFC) system is prescribed by MIL-STD 3007 and provides planning, design, construction, sustainment, restoration, and modernization criteria, and applies to the Military Departments, the Defense Agencies, and the DoD Field Activities in accordance with USD (AT&L) Memorandum dated 29 May 2002. UFC will be used for all DoD projects and work for other customers where appropriate. All construction outside of the United States is also governed by Status of Forces Agreements (SOFA), Host Nation Funded Construction Agreements (HNFA), and in some instances, Bilateral Infrastructure Agreements (BIA.) Therefore, the acquisition team must ensure compliance with the most stringent of the UFC, the SOFA, the HNFA, and the BIA, as applicable.

UFC are living documents and will be periodically reviewed, updated, and made available to users as part of the Services' responsibility for providing technical criteria for military construction. Headquarters, U.S. Army Corps of Engineers (HQUSACE), Naval Facilities Engineering Systems Command (NAVFAC), and Air Force Civil Engineer Center (AFCEC) are responsible for administration of the UFC system. Defense agencies should contact the preparing service for document interpretation and improvements. Technical content of UFC is the responsibility of the cognizant DoD working group. Recommended changes with supporting rationale may be sent to the respective DoD working group by submitting a Criteria Change Request (CCR) via the Internet site listed below.

UFC are effective upon issuance and are distributed only in electronic media from the following source:

- Whole Building Design Guide web site http://www.wbdg.org/ffc/dod.

Refer to UFC 1-200-01, *DoD Building Code*, for implementation of new issuances on projects.

UNIFIED FACILITIES CRITERIA (UFC)
REVISION SUMMARY SHEET

Document: UFC 3-220-01, *Geotechnical Engineering*

Superseding: UFC 3-220-01, *Geotechnical Engineering,* dated 1 November 2012.

Description of Changes: This UFC adopts and modifies the provisions of the International Building Code 2021 (IBC 2021) consistent with the scope of current military requirements and procedures.

Reasons for Changes:

- The updated UFC is designed to be consistent with and to supplement the guidance contained in the IBC 2021 as modified and implemented by UFC 1-200-01.

- Clarification of requirements not addressed by IBC 2021 are added and use additional industry standards.

Impact: Changes to this document further reduce interpretation and ambiguity that could potentially lead to design and construction conflicts. Increase to costs of DoD facilities are not expected as a result of these changes.

Unification Issues: There are no unification issues.

TABLE OF CONTENTS

TABLES

CHAPTER 1 INTRODUCTION

1-1 BACKGROUND.

UFC 1-200-01, "DoD Building Code" adopts and modifies **\2** International Building Code 2021 (IBC 2021) as the building code for DoD. This UFC adopts the updated International Building Code 2021 (IBC 2021) as the basis for use in geotechnical engineering design requirements. Chapter 2 of this UFC further modifies the IBC for specific geotechnical engineering design requirements and is organized by the IBC chapter that each section modifies. The required IBC 2021 section modifications are one of four actions, according to the following legend:

> **[Addition]** – New section added, includes new section number not shown in IBC 2021.
>
> **[Deletion]** – Delete referenced IBC 2021 section.
>
> **[Replacement]** – Delete referenced IBC 2021 section or noted portion and replace it with the narrative shown.
>
> **[Supplement]** – Add narrative shown as a supplement to the narrative shown in the referenced section of IBC 2021. ***/2/***

Effort has been made to adopt non-government standards to the greatest practical extent when they appear to cover the topics and/or the information contained in the former manuals, or when they provide new and innovative methods for geotechnical engineering practices. When non-government criteria does not exist or there is insufficient coverage of the topic in the non-government criteria and where there are unique Department of Defense (DoD) requirements, the existing government criteria from DoD publications are either referenced or have been inserted totally in the document.

1-2 PURPOSE AND SCOPE.

This Unified Facilities Criteria (UFC) provides technical guidance and minimum technical requirements for geotechnical engineering and design of DoD facilities worldwide for all service elements. This guidance and the technical requirements are based on the IBC **\2** 2021 ***/2/*** and the requirements in UFC 1-200-01. This UFC shall be used by geotechnical engineers to develop military construction contract documents for design and construction of DoD facilities. Project conditions may dictate the need for designs that exceed these requirements. This document shall not supersede higher level mandates such as Public Laws (PL), Executive Orders (E.O.), Regulations (CFR), DoD Directives (DoDD) and DoD Instructions (DoDI) unless a specific exemption has been obtained. If a condition or application occurs for which guidance is not provided, the *registered design professional* shall obtain guidance from the *building official* at the earliest stage of design and prior to commission of any act not easily revise without cost to the Government.

1-3 REISSUES AND CANCELS.

This UFC reissues and cancels UFC 3-220-01, Change 1, 3 November 2021.

1-4 APPLICABILITY.

This UFC applies to all service elements and contractors involved in the planning, design and construction of DoD facilities worldwide. For construction outside of the U.S., the design shall comply with the more stringent of the UFC and the Host Nation requirements and regulations.

1-5 GENERAL BUILDING REQUIREMENTS.

UFC 1-200-01, "DoD Building Code," provides applicability of model building codes and government-unique criteria for typical design disciplines and building systems, as well as for accessibility, antiterrorism, security, sustainability, and safety. Use this UFC in addition to UFC 1-200-01 and the UFCs and government criteria referenced therein. In addition, comply with all contract documents specific requirements.

1-6 REFERENCES.

Appendix A contains a list of references used in this document. The publication date of the code or standard is not included in this document. In general, the latest available issuance of the reference is to be used.

1-7 BEST PRACTICES.

Appendix B identifies background information and practices considered by the DoD as being acceptable for accomplishing certain geotechnical design and engineering services. The Engineer of Record (EoR) or Designer of Record (DoR) is expected to review and interpret this guidance as it conforms to criteria and contract requirements and apply the information according to the needs of the project. If a Best Practices document has guidelines or requirements that differ from the UFGS or Unified Facilities Criteria, the UFGS and the UFC shall prevail.

1-8 SUPPLEMENTAL RESOURCES.

Appendix C provides a list of reliable sources for information on subjects related to geotechnical engineering, design and construction. These resources are valuable tools to the geotechnical engineer for additional information on topics pertinent to and affiliated with geotechnical engineering.

The glossary in Appendix D contains acronyms, abbreviations, and definitions for terms used in this document.

CHAPTER 2 MODIFICATIONS TO IBC

2-1 CHAPTER 2 DEFINITIONS.

2-1.1 Section 202 DEFINITIONS. [Replacement]

Replace the

\1 Registered Design Professional: A registered design professional, as referred to in this document, is an individual licensed to practice engineering in the project area, knowledgeable in soil mechanics and experienced with the geotechnical conditions and construction practices in the project vicinity. This is the individual referred to as the Engineer of Record (EoR) or Designer of Record (DoR) for the geotechnical portion of the design in other Department of Defense construction requirement documents. **/1/ \2** Under special circumstances, such as conducting engineering or scientific studies not directly related to design, an expert in the field of study who is not licensed in the project jurisdiction may be utilized provided that the individual's credentials are submitted and approved in advance by the *building official*. **/2/**

2-2 CHAPTER 16 STRUCTURAL DESIGN.

2-2.1 Section 1613 EARTHQUAKE LOADS.

2-2.1.1 1613.1 Scope. [Supplement]

Insert the following after the first sentence:

Unless approved by the *building official*, the assessment of liquefaction potential must be based on the Summary Report and supporting documentation contained in NCEER-97-0022, Proceedings of the NCEER Workshop on Evaluation of Liquefaction Resistance of Soils. An acceptable factor of safety associated with liquefaction potential shall meet or exceed those listed in TABLE 2-1 below or conform to local code requirements, whichever is greater. Risk Category is as indicated in Table 1604.5 of IBC **\2** 2021 **/2/**.

TABLE 2-1 MINIMUM FACTOR OF SAFETY FOR LIQUEFACTION

Risk Category	Factor of Safety
I & II	1.0
III & IV	1.1

Factor of safety values stated for risk categories I & II are to prevent structural collapse. Factor of safety values stated for risk categories III & IV are to prevent major non-repairable structural damage. Factor of safety values stated are minimums for an extreme event and some structures or conditions may require a factor of safety in excess of those indicated.

2-2.1.2 1613.2.2 Site class definitions. [Replacement]

Replace the following sentence:

“Where the soil properties are not known in sufficient detail to determine the site class, Site Class D, subjected to the requirements of Section 1613.2.3, shall be used unless the *building official* or geotechnical data determines that Site Class E or F soils are present at the site.”

With:

If the *building official* does not provide an assumed site class, or where the soil properties are not known in sufficient detail to determine the site class, Site Class D shall be assumed for preliminary purposes. However, the registered design professional shall be responsible for verification of the site class used for design. **\1** Verify the site class by assessing the strength and stiffness of the subsurface profile to a depth of 30.5 m (100 ft) using one or more methods specified in ASCE 7. Use applicable data to assess liquefaction potential.

Further, the new ‘requirements’ of IBC **\2** 2021 **/2/** Section 1613.2.3, read “Where Site Class D is selected as the default site class per Section 1613.2.2, the value of Fa shall be not less than 1.2. Where the simplified design procedure of ASCE 7 Section 12.14 is used, the value of Fa shall be determined in accordance with ASCE 7 Section 12.14.8.1, and the values of Fv, SMS and SM1 need not be determined.” These requirements should be included in the replacement. **/1/**

2-3 CHAPTER 17 SPECIAL INSPECTIONS AND TESTS. [REPLACEMENT]

Replace all paragraphs in this chapter relating to soils and foundations with the following:

All special inspections and testing shall be performed and documented as prescribed in the contract documents.

2-4 CHAPTER 18 SOILS AND FOUNDATIONS.

2-4.1 Section 1801 GENERAL.

2-4.1.1 1801.1 Scope. [Replacement]

Replace the current paragraph with the following:

The provisions of this chapter shall apply to Geotechnical Engineering for construction of military facilities. All exceptions must be approved by the *building official* (as defined in UFC 1-200-01). NAVFAC projects shall also conform to the provisions contained in

FC 1-300-09N, Navy and Marine Corps Design Procedures. If conflicts occur with the requirements in this document, the requirements of this document shall take precedence.

2-4.2 Section 1803 GEOTECHNICAL INVESTIGATIONS.

2-4.2.1 1803.1 General. [Supplement]

Add the following after the first sentence:

In addition: All site work, including topographic/hydrographic and soil surveys, shall be coordinated with representatives of the Public Works, Utilities and Energy team, base engineering and other design personnel. During execution of field investigation work, the *registered design professional* shall be responsible for obtaining necessary permits, and complying with applicable laws, codes, and regulations, including OSHA regulations. **\1** The exact location of the geotechnical excavation, whether by drilling or digging, shall be approved by the appropriate authorities, be it the local utility service or by a company hired by the geotechnical engineering firm to locate or “scope” utilities. **/1/** The *registered design professional* shall be responsible for all damages to persons and property that occur as a result of their fault or negligence. The *registered design professional* shall take proper safety precautions to protect all persons and property from physical hazards and unsafe conditions. Upon completion of field investigation, return the property to its original condition except as released in writing by the client activity.

Add the following to the end of the paragraph:

The qualifications of the geotechnical testing laboratory and personnel shall meet ASTM D3740, “Minimum Requirements for Agencies Engaged in the Testing and/or Inspection of Soil and Rock as Used in Engineering Design and Construction”. Adherence to the requirements in the ASTM D420, “Standard Guide to Site Characterization for Engineering Design and Construction Purposes” shall be required for all foundation and soils investigations. See IBC Section 1613 for requirements and procedure to determine site class. **\1** Follow IBC revisions contained within this UFC document. **/1/**

2-4.2.2 1803.2 Investigations required. [Supplement]

Add the following to the end of the paragraph:

Investigations and evaluations (including soil borings, test pits, ground penetrating radar surveys, seismic refraction surveys, and electrical resistivity testing, laboratory testing) shall be in accordance with ASTM D420 and other applicable ASTM standards to the fullest practical extent. The soil classification and investigation shall be supervised by a registered professional engineer. Where ASTM methods are not applicable, procedures and apparatus used shall be in accordance with generally accepted engineering practice.

2-4.2.3 1803.3.1 Scope of Investigation. [Supplement]

Add the following to the end of the paragraph:

Architecture and engineering firms preparing, planning or designing documents shall contact the *building official* to determine if there are files pertaining to the existing geotechnical and seismic conditions or past design approaches for facilities, structures, or pavements that are applicable to the current project. For Design-Build contracts, any relevant Government provided geotechnical or pavement information that is available will be furnished in the Design-Build RFP. Unless approved otherwise by the *building official*, Cone Penetration Test (CPT) holes shall be performed in accordance with ASTM D5778, “Standard Test Method for Electronic Friction Cone and Piezocone Penetration Testing of Soils” and the soil classification shall be substantiated by visual and laboratory testing of samples recovered from ASTM D1586, “Standard Penetration Test (SPT) and Split-Barrel Sampling of Soils” **\1** and ASTM D1587, "Standard Practice for Thin-Walled Tube Sampling of Fine-Grained Soils", ASTM D3550, “Thick Wall, Ring-Lined, Split Barrel, Drive Sampling of Soils” soil borings. SPT tests and tube samples must be conducted continuously to a depth of 3.7m (12 ft), or 3.7m (12 ft) below the lowest floor elevation, foundation, whichever is greater. Investigate to a depth of 6.2m (20 ft) below the lowest anticipated deep foundations or deeper as determined by the registered design professional. ***/1/*** If geophysical methods including seismic (sonic) methods, electrical and electro-magnetic procedures, gravitational field techniques, and magnetic field methods, are contemplated; then a site visit is required by the *registered design professional* early in the site characterization process.

2-4.2.4 1803.5.4 Ground-water table. [Replacement]

Replace the paragraph with the following:

When encountered, provide the stabilized groundwater elevation with the anticipated variation with the local causes for variation (e.g., seasonal, tidal, etc.). The stabilized groundwater elevation will be measured after 24 hours unless determined otherwise by the *registered design professional*. If drilling techniques are used that prevent the measurement of the water table levels, the Contractor shall install at least two piezometers per drilling site to more accurately measure the depth to the water table. A sufficient number of readings (locations) shall be obtained to establish a representative groundwater depth profile for the project site. Piezometers are required for storm water pond investigations. Piezometers are not required if the ground water levels can be accurately measured during drilling operations or there is good evidence that the water table is not within the depth of the borings or zone of influence for the foundation or structure.

2-4.2.5 1803.5.6 Rock strata. [Supplement]

Add the following to the end of the paragraph:

Limestone areas suspected of containing solution channels or cavities or other areas suspected to have karst topography or subsurface voids shall be investigated by **\2** a combination of boring, probing, test pits and geophysical methods /**2**/ as determined by the *registered design professional*. A sufficient number of borings, probes and/or test pits shall be performed to verify the subsurface conditions as being adequate to support foundations. Unless specified otherwise in the contract requirements, the investigation shall determine, (a) the depth of overburden in areas of foundations and excavations; (b) the type and hardness of material encountered; and (c) the degree of difficulty expected to be encountered in excavation. Design of foundations in rock shall include bearing capacity, settlement, sliding stability analyses and consideration of the effects of seepage and grouting to prevent seepage. Rock- Mass Classification shall be determined by one of the systems proposed in ASTM D5878, "Standard Guides for Using Rock-Mass Classification Systems for Engineering Purposes".

2-4.2.6 1803.5.11 Seismic Design Categories C through F. [Supplement]

Add the following to the end of the paragraph:

\1 Refer to UFC 3-301-02 for Risk Category V structures, and to UFC 3-301-01 for all other structures. **/1/**

2-4.2.7 1803.5.12 Seismic Design Categories D through F. [Supplement]

Add the following to the end of the paragraph:

\1 Refer to UFC 3-301-02 for Risk Category V structures, and to UFC 3-301-01 for all other structures. **/1/**

2-4.2.8 1803.6 Reporting. [Replacement]

Replace the first paragraph with the following:

A geotechnical report must be provided to the *building official* by the *registered design professional* on all contracts unless waived by the *building official*. Unless directed otherwise, provide the report electronically in PDF format and two (2) print copies of the report. The PDF copy of the report shall be produced directly from the report's authoring software. All Geotechnical Reports shall be signed and sealed by the *registered design professional*. **\1** Include in-situ testing data source files with the electronic submittal of the geotechnical report. **/1/**

Replace item 1 with the following:

Plot(s) indicating the location of all testing, samples or investigations. The plot(s) shall be to scale and shall clearly indicate the location of each test, etc. on the project site as well as the location of the project on the facility.

Replace item 4 with the following:

When encountered, provide the stabilized groundwater level and identify any factors that influence the groundwater elevation (i.e., tidal or seasonal variation, etc.) and any potential influence of groundwater on the project during both design and during construction.

2-4.2.9 1803.6 Reporting. [Supplement]

Add the following to the end of the section:

11. Seismic site classification and liquefaction potential.
12. Global Positioning System (GPS) coordinates, with an accuracy of at least 3 feet (1 m) for each soil boring, coring or test pit location, referenced to the datum and stated in coordinates required by the *building official*. Reference WGS84 and state in degrees of latitude and longitude for Navy projects.
13. Gradation, moisture content and/or Atterberg tests results per stratum exceeding 1.5 m (5 ft) thickness.
14. Soil corrosivity test results with recommended mitigation construction practices.
15. Observed indication of soil or groundwater contamination.
16. Structural properties tests (i.e. hydraulic conductivity, consolidation, shear strength, triaxial shear, collapse/swell potential, etc.) and dynamic tests (cyclic loading, resonant column, ultrasonic pulse, etc.) when required to support particular design problems.
17. The professional seal and signature of the *registered design professional*.
18. For Cone Penetration Tests (CPT), presentation of results shall include soil stratigraphy in a manner discernable in black and white prints, similar to those provided for soil borings, unless otherwise stated in the contract documents. Include tabulated CPT data.
19. Report the occurrence of permafrost and the accommodations that must be made for the design of the project.
20. When rock is encountered, classify rock in accordance with ASTM D5878, “Standard Guide for Using Rock-Mass Classification Systems for Engineering Purposes” and report the characteristics determined for the specific engineering purpose of the investigation.
21. Provide hammer type used for SPT testing (i.e. manual or automatic) and corrected “N” values with uncorrected values in parenthesis. Supporting information must include energy ratio and supporting calibration data.
22. Provide written and graphic subsurface profiles. Profiles must indicate the elevation of features and based on the report data. Profiles must provide soil and rock stratigraphy, groundwater data, penetration resistance data and all other pertinent data.
23. Site preparation recommendations with any special precautions (e.g., soft soil conditions, high groundwater, etc.) including any equipment limitations and any special requirements (e.g., over-excavation and replacement) and any special

precautions. **\2** Address the effects of site grade increases/decreases. **/2/**

24. Recommended pavement section(s) with a discussion of the variables (e.g., subgrade CBR and modulus k) used to determine the pavement section(s).

25. **\1** Calculations to support all conclusions, recommendations, and analyses. Include references, factor of safety used, soil model, etc. **/1/**

2-4.3 Section 1804 EXCAVATION, GRADING AND FILL.

2-4.3.1 1804.1 Excavation near foundations. [Supplement]

Add at the end of this paragraph:

There shall be no excavation in the proximity of an existing foundation without approval of the *building official*. Prior to excavation, provide calculations verifying there will be no loss of support for all excavations closer than the excavation depth to an existing foundation.

2-4.4 Section 1805 DAMPPROOFING AND WATERPROOFING.

2-4.4.1 1805.1.3 Ground-water control. [Replacement]

Replace the first sentence with the following:

Where the ground-water table is lowered and maintained at an elevation 12 inches (305 mm) or more below the bottom of the lowest floor or working level, the floor and walls shall be dampproofed in accordance with Section 1805.2.

Add the following to the end of the paragraph:

Since permanent groundwater control systems must operate continuously without interruption, they shall be conservatively designed and mechanically simple to avoid the need for complicated control equipment subject to failure and the need for operation personnel. When temporary dewatering is required during construction, the dewatering shall be in accordance with UFC 3-220-05, “Dewatering and Groundwater Control” and the groundwater shall be maintained a minimum of 12 inches (305 mm) below the working level or base of the excavation. The *registered design professional* shall provide all documentation required by the *building official* to ensure the dewatering procedure does not cause damage to any existing structures, utilities or pavements and ensure the process complies with applicable safety requirements.”

2-4.4.2 1805.4.3 Drainage discharge. [Supplement]

Add the following to the end of the paragraph:

Sedimentation and erosion control shall be incorporated in all new construction projects.

2-4.5 Section 1806 PRESUMPTIVE LOAD-BEARING VALUES OF SOILS.

2-4.5.1 1806.1 Load combinations. [Supplement]

Add to the beginning of the paragraph:

Unless otherwise provided or required in the contract documents, load bearing values shall be based on site specific analysis determined by a *registered design professional* as a result of a geotechnical investigation for all structures except minor construction such as equipment or storage sheds less than 55.75 sq m (600 sf). Use the factors of safety provided in Tables 2-2 and 2-3 in developing the allowable bearing values for site specific designs.

TABLE 2-2 MINIMUM FACTORS OF SAFETY (FS) FOR FOUNDATIONS IN ROCK

LOADING CONDITION		FACTOR OF SAFETY (FS)
Bearing		
	Structural Foundations (DL+LL)	3.0
Sliding		
	Dams, Basin Walls	2.5
	Static Loading	2.0
	Seismic Loading	1.3
	Retaining Walls on Rock	1.5
Rock Slopes		
	Severe Consequence of Failure	2.0
	Minor Consequence of Failure	1.3
	Seismic Loading	1.1
Rock Anchorage		
	Based on Unit Weight of Rock Mass	1.5
	Based on Rock Mass Cohesion Intercept	4.0
\1\Pile Foundations Anchored in Rock /1/		
	For pile groups, end bearing piles resting in bedrock may have an efficiency of 1. Buoyancy should be considered in tensile resistance to pull out. The possibility of buckling below the mudline should be evaluated for high capacity piles driven through soft soils to bedrock.	3
\1\ Drilled Shafts/Piers/ Caissons Anchored in Rock /1/		
	Socket into the rock effects the load transfer. Inspection of the bottom of the hole may be needed to ensure the bearing stratum is what was anticipated. For piers extending into Rock assume no load transfer takes place along the soil pier interface. For piers likely to be subjected to tensile loads, reinforcement should be continued for the entire length of the pier.	2.5-4 Depending on uncertainties in loading, stratification, and verification testing.

TABLE 2-3 MINIMUM FACTORS OF SAFETY (FS) FOR FOUNDATIONS IN SOIL

STRUCTURE		FACTOR OF SAFETY (FS)*
Retaining		
	Walls	3.0
	Temporary Braced Excavations	>2
Bridges		
	Railway	4.0
	Highway	3.5
Buildings		
	Silos	2.5
	Warehouse	2.5*
	Apartments, Office	3.0
	Light Industrial, Public	3.5
Footings, Other		3
Mats		>3
\1\ Deep Foundations /1/		
	With static load tests	2
	With dynamic pile analysis including signal matching	2.25 (Compression) 3.0 (Tension)

Notes for Table 2-3:

* Use FS >3 for projects that require extreme limitations on total and differential movements such as super-flat warehouse floors that are needed to accommodate modern transport equipment.

These FS's are conservative and will generally limit settlement to acceptable values, but economy may be sacrificed in some cases.

FS selected for design depends on the extent of data available on subsoil characteristics and their variability. A thorough and extensive subsoil investigation and extensive testing may permit use of a smaller FS. Use of a FS less than the minimum listed above requires formal approval by the Building Official.

FS should generally be $\geq$ 2.5 and never less than 2.

2-4.5.2 1806.2 Presumptive load-bearing values. [Deletion]

Delete the exception statement at the end of this paragraph.

2-4.6 Section 1807 FOUNDATION WALLS, RETAINING WALLS AND EMBEDDED POSTS AND POLES.

2-4.6.1 1807.1.3 Rubble Stone Foundation Walls. [Replacement]

Replace the paragraph with the following:

Rubble stone foundation walls are not allowed.

2-4.6.2 1807.1.4 Permanent Wood Foundation Systems. [Replacement]

Replace the paragraph with the following:

Permanent wood foundation systems are not allowed. **\1** Timber piles are allowed where deemed appropriate by the *registered design professional* and approved by the *building official*. **/1/**

2-4.6.3 1807.2.3 Safety factor. [Replacement]

Replace last sentence in paragraph with the following:

The factor of safety against sliding, calculated as the ratio of forces resisting movement to the horizontal component of earth plus water pressure on the back wall, whether in soil or rock shall be not less than 2.0. In rock, the sliding seismic loading factor of safety is 1.3.

2-4.6.4 1807.3.2.3 Vertical load. [Replacement]

Replace the paragraph with the following:

The resistance to vertical loads shall be determined by the *registered design professional* based on an analysis of the site soil conditions. The presumptive allowable soil-bearing pressures set forth in Table 1806.2 may be used for preliminary design purposes and for minor construction (e.g., non-critical equipment pad or shed, etc.) where a site investigation is not warranted.

2-4.7 Section 1808 FOUNDATIONS.

2-4.7.1 1808.2 Design for capacity and settlement. [Supplement]

Add the following at the end of this paragraph:

The ultimate bearing capacity shall be evaluated using the results from the geotechnical investigation and appropriate in-situ and laboratory analyses.

\1 Foundation settlements shall be estimated using deformation analyses based on the results of laboratory or in situ testing. The soil parameters used in the analyses shall be chosen to reflect the loading history of the ground, the construction sequence and the effect of soil layering. Both total and differential settlements, including time effect, shall be considered. Ultimate bearing capacity and settlement analysis shall be performed using a minimum of three (3) widely accepted methods of analysis. The guidance provided in Appendix B shall be utilized for the determination of widely accepted methods of analysis. **/1/** Foundations shall be designed such that the net allowable bearing capacity of the soil is not exceeded, and that total and differential settlement is limited to acceptable values, as defined below. Except for minor construction (e.g., equipment sheds, storage sheds, etc. less than 55.75 sq m (600 sf)) minimum width of individual column or pier foundations shall be 610 mm (24 inches) and continuous footings shall be 457 mm (18 inches) wide or 203 mm (8 inches) wider than the supported wall, whichever is greater.

Design of foundations in rock shall include bearing capacity, settlement and sliding stability analyses, and consider the effects of seepage and grouting to control seepage.

Using statistical analyses, compute total settlement at a sufficient number of points to establish the overall settlement pattern. In no case shall total settlement be computed at less than two (2) points. Determine the greatest difference in settlement between adjacent foundation units from this pattern. Designs shall incorporate measures that limit total and differential settlement to levels that prevent structural or cosmetic damage or impairment of the serviceability and function of the facility or structures, including affected drainage and utilities.

\1 Unless approved by the *building official*, total post construction settlement may not exceed tolerable limits based on building type and dimension, or 25.4 mm (1 in.), whichever is less. Differential settlements shall not result in an angular distortion in excess of 1/500. The angular distortion is defined as the difference in settlement between two points divided by the distance between the points. Acceptable values for total and differential settlement shall give consideration to the purpose and design life of the facility, the materials used for construction, the conditions (environmental, subsurface and external forces) that the facility will be exposed to, and any project-specific requirements. Reference guidance in Appendix B-3.7 for typical limits based on building type and materials. **/1/**

Slab-on-grade concrete floors shall be designed so that any settlement of the floor shall not result in harmful distortion of the floor or misalignment of the floor with any other building components (such as doorways, trenches or structural elements) or building utilities.

2-4.7.2 1808.3 Design loads. [Supplement]

Add the following to the end of the paragraph:

Consideration of possible future events such as dewatering and flooding due to storms is also required.

2-4.7.3 1808.4 Vibratory loads. [Supplement]

Add the following to the end of the paragraph:

Design foundations in accordance with ACI 351.3R, “Foundations for Dynamic Equipment” and ACI 350.4R, “Design Considerations for Environmental Engineering Concrete Structures”.

2-4.7.4 1808.6 Design for expansive soils. [Supplement]

Add the following to the end of the first paragraph:

Surface soils shall be examined for gilgai whenever expansive soils are suspected.

2-4.7.4.1 1808.6.2 Slab-on-ground foundations. [Supplement]

Add the following at the end of this paragraph:

Structurally supported slabs cast on the ground or above ground shall provide support for all under slab utilities to accommodate their in-service dead and live load using structurally supported trenches and/or stainless steel hangars.

2-4.7.4.2 1808.6.4 Stabilization. [Supplement]

Add the following to the end of the paragraph:

Construction techniques that promote a constant moisture regime in the foundation soils during and following construction shall be used.

2-4.7.5 1808.7.5 Alternate setback and clearance. [Replacement]

Replace the paragraph with the following:

Alternate setback and clearances are permitted subject to the approval of the *building official*. For consideration, the contractor must provide the recommendation of a *registered design professional* substantiated with the results of an investigation that demonstrates the intent of this section has been satisfied.

2-4.7.6 1808.8.6 Seismic requirements. [Deletion]

Delete exceptions at end of paragraph.

2-4.7.7 1808.8.7 Concrete reinforcement. [Addition]

For footings over 0.914 m (3 ft) thick, the minimum ratio of reinforcement area to gross concrete area in each direction shall be 0.0015, with not less than one-half nor more than two-thirds of the total reinforcement required placed in any one face. Minimum bar size shall be #13M (No. 4) with a maximum spacing of 305 mm (12 inches).

2-4.8 Section 1809 SHALLOW FOUNDATIONS.

2-4.8.1 1809.4 Depth and width of footings. [Replacement]

Replace the paragraph with the following:

The minimum depth of footings below the finished ground surface shall be 457 mm (18 inches). Spacing between footings shall be at least 1.5 times the width of the larger foundation to minimize any reduction in bearing capacity due to overlapping zones of influence. The most appropriate foundation types shall be designed, in a preliminary manner and foundation type selection based on a detailed cost comparison of these designs. The minimum footing size shall be as indicated in paragraph 1808.2 revisions in this UFC.

2-4.8.2 1809.5 Frost Protection. [Deletion]

Delete the exception statements at the end of this paragraph.

2-4.8.3 1809.5 Frost Protection. [Replacement]

Replace the last sentence of the paragraph with the following:

Shallow foundations shall not bear on frozen soil unless such frozen condition is of a permanent character and specifically allowed by the contract documents.

2-4.8.3.1 1809.5.1 Frost line depth. [Addition]

Depths to the frost line at specific locations within the United States, its territories and possessions, and at specific locations outside of the United States are identified in UFC 3-301-01, "Structural Engineering". At locations where frost depths are not provided, use the more stringent of the nearest listed location and the local building code requirement. Conflicts shall be brought to the *building official*'s attention at the earliest stage of design. Additional guidance on frost depth determination and design can be found in Appendix B.

2-4.8.4 1809.9 Masonry-unit footings. [Replacement]

Replace this subsection paragraph with the following sentence:

Masonry-unit footings are not permitted.

2-4.8.5 1809.11 Steel grillage footings. [Replacement]

Replace this subsection paragraph with the following sentence:

Steel grillage footings are not permitted.

2-4.8.5.1 1809.12 Timber footings. [Replacement]

Replace this subsection paragraph with the following sentence:

Timber footings are not permitted. **\1** Treated timber piling is allowed. **/1/**

2-4.9 Section 1810 DEEP FOUNDATIONS.

2-4.9.1 1810.1 General. [Supplement]

Add the following to the end of this paragraph:

Applied loads shall not cause excessive vertical and lateral displacements of the pile or drilled shaft. See Section 1808.2 including revisions in this UFC.

2-4.9.2 1810.2 Analysis. [Supplement]

Add the following to the end of this paragraph:

Applied loads shall not cause excessive vertical and lateral displacements of the pile or drilled shaft. See Section 1808.2 including revisions in this UFC.

2-4.9.3 1810.2.5 Group effects. [Supplement]

Add the following at the end of this paragraph:

See Section 1808.2 including revisions in this UFC.

2-4.9.4 1810.3.2.1 Concrete. [Supplement]

Insert the following statement at the end of this paragraph:

Material specifications shall conform to ACI 543R, "Guide to Design, Manufacture, and Installation of Concrete Piles".

2-4.9.5 1810.3.2.5 Protection of materials. [Replacement]

Replace the first sentence of the paragraph to read:

Where boring records or site conditions indicate possible deleterious action on the materials used in deep foundation elements because of soil constituents, changing water levels or other factors, the *registered design professional* and/or the *Designer of Record* shall evaluate materials, methods or processes to adequately protect these foundation materials and provide recommendations for approval by the *building official*.

2-4.9.6 1810.3.3.1.6 Uplift capacity for grouped deep foundation elements. [Supplement]

After ". . . largest single element", add the following:

"with the optimum pile spacing being 3 to 3.5B (Vesic 1967) or greater than 0.02L + 2.5B, where L is the pile length in feet and B equals the least horizontal dimension of the largest single deep foundation element."

2-4.9.7 1810.4.4 Pre-excavation. [Replacement]

Replace first sentence in the paragraph to read:

The use of jetting, augering or other methods of pre-excavation shall be evaluated by the *registered design professional* and subject to the approval of the *building official*.

2-4.9.8 1810.4.13 Noise. [Addition]

The entire matter of allowable noise disturbance is subjective and shall be carefully evaluated before seeking special methods to reduce its effect.

2-1.1.1.1 1810.4.14 Airfield Clearance. [Addition]

Cranes and other tall equipment used to install deep foundations or site improvement features (e.g., wicks, sand drains, etc.) shall comply with the requirements of UFC 3-260-01, "Airfield and Heliport Planning and Design" including equipment height, clearance and marking requirements.

2-4.10 Section 1811 SLOPE STABILITY. [Addition]

2-4.10.1 1811.1 General. [Addition]

Slopes shall be designed and constructed in accordance with Section 1811.2.

2-4.10.2 1811.2 Geotechnical Investigations and stability analyses. [Addition]

Follow guidelines established in Section1803 as modified herein and with special emphasis on ground water and seepage site information. Liquefaction is a major concern for slope stability and shall be investigated thoroughly. Several methods of stability analyses shall be employed to ensure greater accuracy and safety in final design. Structural properties testing shall be accomplished for slopes where consequences of failure endanger human life and/or high value structures. Safety factors used in design of new construction or evaluation of existing conditions shall be evaluated by the *registered design professional* and subject to the approval of the *building official* at the earliest stages of the design/evaluation. Acceptable values for factors of safety shall be derived from guidance in Best Practices document EM 1110-2-1902, "Slope Stability", and evaluation of the conditions (environmental, subsurface and external forces) that the facility will be exposed to, and any project-specific requirements.

2-4.11 Section 1812 GEOSYNTHETICS. [Addition]

2-4.11.1 1812.1 General. [Addition]

Applications using geosynthetics shall be designed and constructed using the most current industry accepted practices and standards, along with applicable guidance from Best Practices document UFC 3-220-08FA, "Engineering Use of Geotextiles". Safety factors shall be applied as stated herein for the type of structure being designed.

2-4.11.2 1812.2 Geosynthetics design and use in construction. [Addition]

Geosynthetics functions include pavement reinforcement, separation, filtration (water and gases), drainage, reinforced embankments, impermeable liners, railroads, erosion and sediment control, and earth retaining walls. **\1** For landfill design and construction, follow guidance from applicable Environmental Protection Agency (EPA) and Geosynthetic Research Institute (GRI) publications. **/1/**

Geosynthetics must be manufactured for the purpose intended, whether woven, non-woven, method of bonding, whether made from polypropylene, polyester, polyethylene, polyamide (nylon), polyvinylidene chloride, fiberglass or bonded with clay. Strength considerations vary from very low as in non-woven fabrics to very high tensile strength as geogrids. Durability must be considered in exposure to sunlight, ground water, chemicals (landfill liners), asphalt (pavement applications), and temperature of the environment. In drainage design the apparent opening size is important in maintaining drainage and filtration. In construction, important factors are making connections whether in overlapping edges and ends or sewing seams at these intersections and the exposure to sunlight before and after installation.

2-5 CHAPTER 33 SAFEGUARDS DURING CONSTRUCTION.

2-5.1 Section 3304 SITE WORK. [Replacement]

Replace this section with the following:

All site work shall be performed and documented as prescribed in the approved contract documents.

\1 Designer must consider the differential settlement of the site in relation to the structure or critical areas to ensure that utility connections will not fail. **/1/**

APPENDIX B BEST PRACTICES

B-1 INTRODUCTION.

This appendix identifies background information and practices considered by the DoD as being acceptable for accomplishing certain geotechnical design and engineering services. The Designer of Record (DoR) is expected to review and interpret this guidance and apply the information according to the needs of the project. If a Best Practices document has guidelines or requirements that differ from the UFGS or Unified Facilities Criteria, the UFGS and the UFC shall prevail.

B-2 WHOLE BUILDING DESIGN GUIDE.

The Whole Building Design Guide provides additional information and discussion on practice and facility design, including a holistic approach to integrated design of facilities.

The WBDG website provides access to all Construction Criteria Base (CCB) criteria, standards and codes for the DoD Military Departments, National Aeronautics and Space Administration (NASA), and others. These include, Unified Facilities Criteria (UFC), Unified Facilities Guide Specifications (UFGS) and other construction criteria. For approved Government employees, it also provides access to non-government standards.

B-3 GEOTECHNICAL ENGINEERING RELATED GUIDANCE.

The following documents provide guidance on the specific topics indicated. Obtain the indicated UFC documents from the WBDG, the EM documents from http://publications.usace.army.mil/publications/ and ETL documents from https://www.publications.usace.army.mil/USACE-Publications/Engineer-Technical-Letters/.

This UFC supersedes TM 5-818-4, dated 1 June 1983. The format of this UFC does not conform to UFC 1-300-01; however, the format will be adjusted to conform at the next revision. The body of this UFC is the previous TM 5-818-4, dated 1 June 1983.

FOREWORD

\1\
The Unified Facilities Criteria (UFC) system is prescribed by MIL-STD 3007 and provides planning, design, construction, sustainment, restoration, and modernization criteria, and applies to the Military Departments, the Defense Agencies, and the DoD Field Activities in accordance with USD(AT&L) Memorandum dated 29 May 2002. UFC will be used for all DoD projects and work for other customers where appropriate. All construction outside of the United States is also governed by Status of forces Agreements (SOFA), Host Nation Funded Construction Agreements (HNFA), and in some instances, Bilateral Infrastructure Agreements (BIA.) Therefore, the acquisition team must ensure compliance with the more stringent of the UFC, the SOFA, the HNFA, and the BIA, as applicable.

UFC are living documents and will be periodically reviewed, updated, and made available to users as part of the Services' responsibility for providing technical criteria for military construction. Headquarters, U.S. Army Corps of Engineers (HQUSACE), Naval Facilities Engineering Command (NAVFAC), and Air Force Civil Engineer Support Agency (AFCESA) are responsible for administration of the UFC system. Defense agencies should contact the preparing service for document interpretation and improvements. Technical content of UFC is the responsibility of the cognizant DoD working group. Recommended changes with supporting rationale should be sent to the respective service proponent office by the following electronic form: Criteria Change Request (CCR). The form is also accessible from the Internet sites listed below.

UFC are effective upon issuance and are distributed only in electronic media from the following source:

- Whole Building Design Guide web site http://dod.wbdg.org/.

Hard copies of UFC printed from electronic media should be checked against the current electronic version prior to use to ensure that they are current.

LIST OF TABLES

CHAPTER 1

INTRODUCTION

1-1. Background. Military facilities for the Army and Air Force have included construction of buildings and other structures partially below ground surface. In more recent years, missile launching and support structures, fallout and blast-protection shelters, and command-control centers have been constructed below ground surface. Many of these structures were constructed using cut-and-cover procedures and required backfilling within confined areas using various types of soil.

a. Numerous deficiencies in backfilling operations occurred in some of the earlier missile-launch construction programs and caused conditions that jeopardized the proper functioning of those structures. Measures to correct deficiencies were both time consuming and costly. It was recognized that critical areas must be delineated and the causes of the deficiencies be determined and corrected.

b. Measures were taken to alleviate the overall backfilling problems. These measures were progressive modification of design and configuration of structures, more detailed instructions to the construction personnel, and close control during construction to ensure that proper construction practices were being followed.

(1) Some of the problem areas were eliminated by modification of design and configuration of structures to allow easier placement of backfill and to permit access of compaction equipment so that required densities could beachieved.

(2) Construction personnel were issued more detailed field directives covering some of the particularly difficult phases of backfill placement.

(3) Inspector training programs were conducted to point out critical areas and emphasize proper backfill procedures and the need for continuous surveillance and close control.

c. The advent of energy efficient structures, partially embedded below ground level, had increased the use of backfill. In addition, the ever increasing need for fuel conservation requires maximum use of all excavated or onsite materials for backfill to reduce fuel needed for hauling in better materials from offsite. Thus, innovative planning and design and good construction control using rapid check tests are imperative for all backfill operations.

1-2. Purpose and scope. This manual is for the guidance of designers, specification writers, and especially field personnel engaged in designing, planning, and conducting earthwork operations around major deep-seated or subsurface structures.

a. The greatest deficiencies in earthwork operations around deep-seated or subsurface structures occur because of improper backfilling procedures and inadequate construction control during this phase of the work. Therefore, primary emphasis in this manual is on backfilling procedures. Design and planning considerations, evaluation and selection of materials, and other phases of earthwork construction are discussed where pertinent to successful backfill operations.

b. Although the information in this manual is primarily applicable to backfilling around large and important deep-seated or buried structures, it is also applicable in varying degrees to backfilling operations around all structures, including conduits.

CHAPTER 2

PLANNING AND DESIGN OF STRUCTURES AND EXCAVATIONS TO ACCOMMODATE BACKFILL OPERATIONS

2-1. General. Many earthwork construction problems can be eliminated or minimized through proper design, thorough planning, and recognition of problem areas effecting backfill operations. Recognition and consideration must be given in planning to design features that will make backfilling operations less difficult to accomplish. Examples of problem areas and how forethought in design and planning can help to eliminate backfill deficiencies are presented in the following paragraphs.

2-2. Effect of excavation and structural configuration on backfill operations. Some of the problems encountered in earthwork construction are related to the excavation and the configuration of the structures around which backfill is to be placed. It is the designer's responsibility to recognize these problems and to take the necessary measures to minimize their impact on the backfill operations.

a. *Open zones.* An open zone is defined as a backfill area of sufficient dimensions to permit the operation of heavy compaction equipment without endangering the integrity of adjacent structures around which compacted backfill operations are conducted. Figure 2-1 shows examples of open zones. In these zones where large compaction equipment, can operate, it is generally not too difficult to obtain the desired density if appropriate materials and proper backfill procedures are used. For areas that can be economically compacted by heavy equipment, the designer can avoid problems by including in the design provisions sufficient working space between structures or between excavation slopes and structures to permit access by the heavy compaction equipment. Generally, a working space of at least 12 feet between structure walls and excavation slopes and at least 15 feet between structures is necessary for heavy equipment to maneuver. In addition to maneuvering room, the designer must also consider any adverse loading caused by the operation of heavy equipment too close to structure walls, as discussed in paragraph *2-3d.*

b. Confined zones. Confined zones are defined as areas where backfill operations are restricted to the use of small mechanical compaction equipment (fig. 2-2) either because the working room is limited or because heavy equipment (fig. 2-1) would impose excessive soil pressures that could damage the structure. Most deficiencies in compacted backfill around subsurface structures have occurred in confined zones where required densities are difficult to achieve because of restricted working room and relatively low compaction effort of equipment that is too lightweight. The use of small equipment to achieve required compaction is also more expensive than heavy equipment since thinner lifts are required. However, because small compaction equipment can operate in spaces as narrow as 2 feet in width, such equipment is necessary to achieve the required densities in some areas of most backfill projects. Therefore, the designer should plan structure and excavation areas to minimize the use of small compaction equipment.

c. Structure configuration. The designer familiar with backfilling operations can avoid many problems associated with difficult to reach confined zones, which are created by structural shapes obstructing the placement and compaction of backfill, by considering the impact of structural shape on backfill operations. In most cases, structural shapes and configurations that facilitate backfill operations can be used without significantly affecting the intended use of the structure.

(1) *Curved bottom and wall structures.* Areas below the spring line of circular, elliptical, and similar shaped structures are difficult to compact backfill against because compaction equipment cannot get under the spring line. If possible, structures should be designed with continuously curved walls and flat floors such as in an igloo-shaped structure. For structures where a curved bottom is required to satisfy the intended function, it may be advisable for the designer to specify that a template shaped like the bottom of the structure be used to guide the excavation below the spring line so that uniform foundation support will be provided.

(2) Complex structures. Complex structures have variable shaped walls and complex configurations in plan and number of levels. These structures can also be simple structures interconnected by access shafts, tunnels, and utility conduits. Because of their irregular shapes and configurations the different types of structures significantly increase excavation and backfill problems.

(a) Typical examples of complex structures are stepped multilevel structures and multichambered structures with interconnecting corridors (fig. 2-3). Complex structures are generally more difficult to

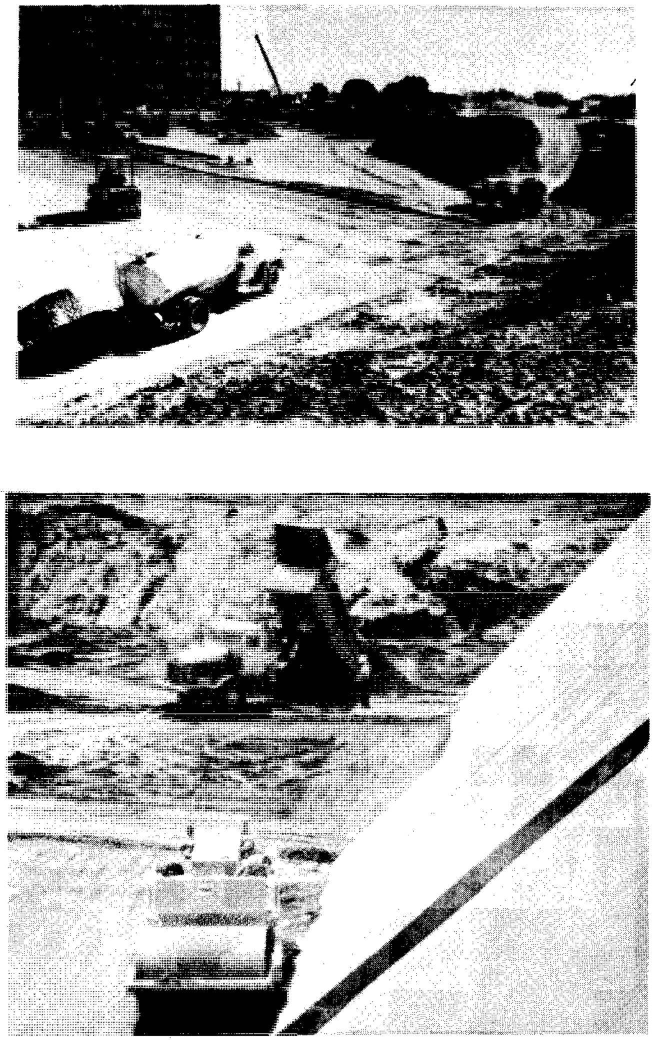

Figure 2- 1. Open backfill zones.

compact backfill around and are more likely to have settlement problems (para 2-3a). Although the multi-level step structure (fig. 2-3a) is not particularly difficult to compact backfill around, at least for the first level, the compaction of backfill over the offset structure will generally require the use of small equipment. Small equipment will also be required for compaction of backfill around and over the access corridor and between the two chambers (fig. 2-3b). Where possible, the design should accommodate intended functions into structures with uniformly shaped walls and a simple configuration.

(b) Where structures of complex configurations are necessary, construction of a three-dimensional model during the design and planning phases will be extremely beneficial. From the model, designers can more easily foresee and eliminate areas in which it would be difficult to place and compact backfill.

d. Service conduits. Since compaction of backfill is difficult around pipes and conduits, utility lines should be grouped together or placed in a single large conduit where feasible rather than allowed to form a haphazard maze of pipes and conduits in the backfill. Utility lines should be run either horizontally or vertically wherever possible. Plans for horizontally run appurtenances, such as utility lines, access tunnels, and blast-delay tubing, should be coordinated with the excavation plans so that wherever feasible these appurtenances can be supported by undisturbed soils rather than by compacted backfill.

e. Excavation plans. The excavation plans should be developed with the backfill operations and the structure configurations in mind. The excavation and all completed structures within the excavation should be conducive to good backfill construction procedures, and access should be provided to all areas so that compaction equipment best suited to the size of the area can be used. The plans for excavation should also provide for adequate haul roads and ramps. Positive excavation slopes should be required in all types of soil de-

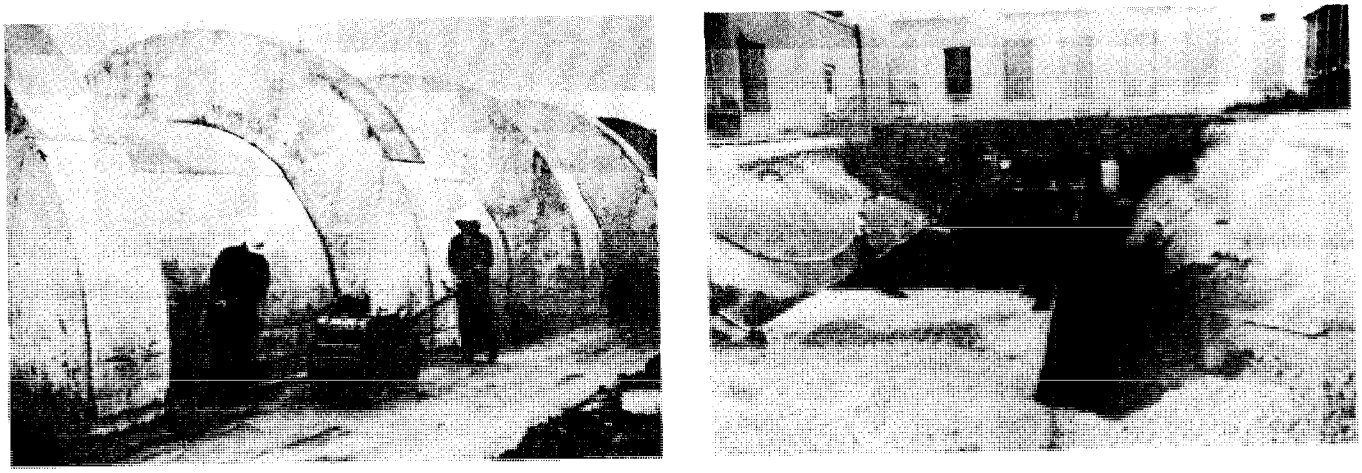

Figure 2-2. Confined backfield zones.

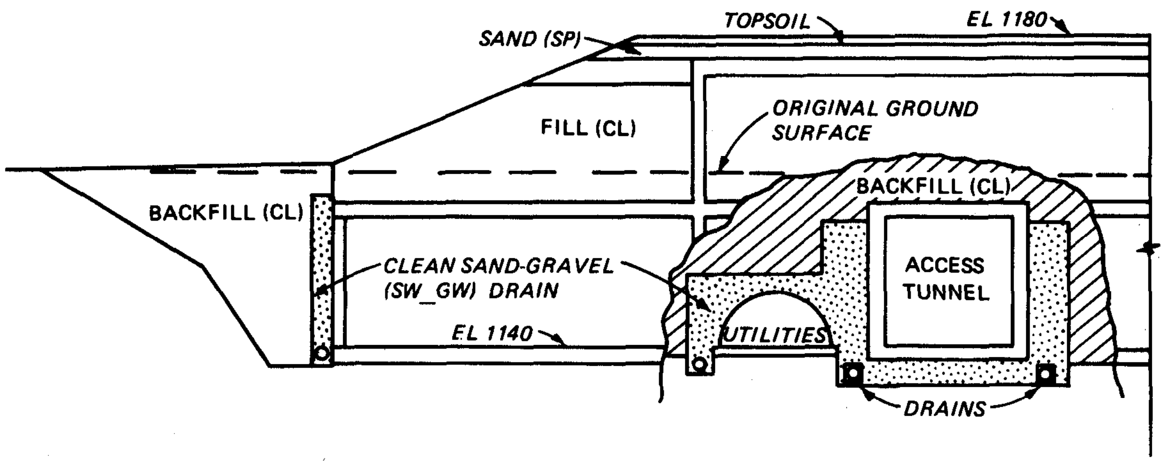
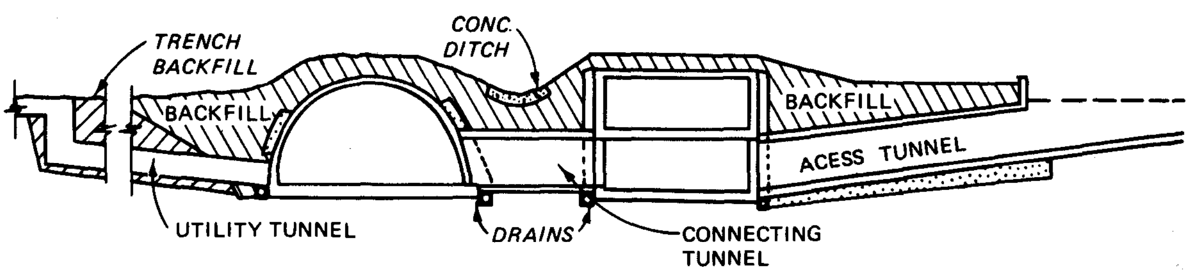


(a) TWO-STORY STRUCTURE



(b) CONNECTING STRUCTURES

Figure 2-3. Complex structures.

posits to facilitate compaction of backfill against the slope and to ensure good bond between the backfill and the excavation slopes. Loose material should be removed from the excavation slopes; in some cases, benches may be required to provide a firm surface to compact backfill against.

f. Lines and grades. Care should be exercised in planning lines and grades for excavation to ensure that uniform, adequate support is provided at the foundation level of important structures. Generally, foundations consisting of part backfill and part undisturbed materials do not provide uniform bearing and should be avoided wherever possible. The foundation should be overexcavated where necessary, and backfilled with compacted select material to provide uniform support for the depth required for the particular structure. Where compacted backfill is required beneath a structure, the minimum depth specified should be at least 18 inches.

g. Thin- walled metal structures. Thin-walled, corrugated metal structures are susceptible to deflections of structural walls when subjected to backfill loads. Adverse deflections can be minimized by planning backfill operations so that compacted backfill is brought up evenly on both sides of the structure to ensure uniform stress distribution. Temporary surcharge loads applied to the structure crown may also be required to prevent vertical distortions and inward deflection at the sides.

2-3. Backfill problem areas. Other features that have the potential to become problem areas are discussed in the following paragraphs. These potential problem areas have to be considered during the planning and design phases to minimize deficiencies in structure performance associated with backfill placement and to make backfilling operations less difficult.

a. Settlement and downdrag. In the construction of underground structures and particularly missile-launch-site facilities, tolerances to movement are often considerably less than those in normal construction. The design engineer must determine and specify allowable tolerances in differential settlement and ensure that differential settlement is minimized and/or accommodated. Settlement analysis procedures are outlined in TM 5-818-l/AFM 88-3, Chapter 7. See appendix A, References.

(1) *Critical zones.* Critical backfill zones are those immediately beneath most structures. Consolidation and swelling characteristics of backfill materials should be thoroughly investigated so that materials having unfavorable characteristics will not be used in those zones. Some settlement can be expected to take place, but it can be minimized by requiring a higher than normal compacted density for the backfill. Cohesive backfill compacted at a water content as little as 3 to 4 percentage points below optimum may result in large settlements caused by collapse of nonswelling soil material or heave of swelling materials upon saturation after construction. Compacting cohesive backfill material at optimum water content or slightly on the wet side of optimum generally will reduce the amount of settlement and swelling that would occur. The reduction should be confirmed by consolidation and swell tests on compacted specimens (para 3-2b(4)).

(2) *Service conduits.* Settlement within the backfill around structures will also occur. A proper design will allow for the estimated settlement as determined from studies of consolidation characteristics of the compacted backfill. Where service conduits, access corridors, and similar facilities connect to the structure oversize sleeves, flexible connections and other protective measures, as appropriate, may be used to prevent damage within the structure.

(3) *Differential settlement.* Complex structures are more susceptible to differential settlement because of the potential for large variations in loads carried by each component foundation. In the multilevel stepped structure (fig. 2-3a), the foundation supporting the lower level offset component must also support the volume of backfill over that part of the structure. Measures must be taken to ensure that the proper functioning of all elements is not hampered by differential settlement. The increased cost of proper design and construction where unusual or difficult construction procedures are required is insignificant when compared with the cost of the structure. The cost of remedial measures to correct deficiencies caused by improper design and construction usually will be greater than the initial cost required to prevent the deficiencies.

(4) *Downdrag.* In addition to conventional service loads, cut and cover subsurface structures are susceptible to downdrag frictional forces between the structure and the backfill that are caused by settlement of the backfill material adjacent to and around the structure. Downdrag loads can be a significant proportion of the total vertical load acting on the structure and must be considered in the structure settlement analysis. Structure-backfill friction forces may also generate significant shear forces along the outer surface of structures with curve-shaped roofs and walls. The magnitude of the friction forces depends upon the type of backfill, roughness of the structure's surface, and magnitude of earth pressures acting against the structure. Techniques for minimizing downdrag friction forces generally include methods that reduce the structure surface roughness such as coating the structure's outer surface with asphalt or sandwiching a layer of polyethylene sheeting between the structure's outer surface and fiberboard (blackboard) panels. Backfill settlement and associated downdrag can also be mini-

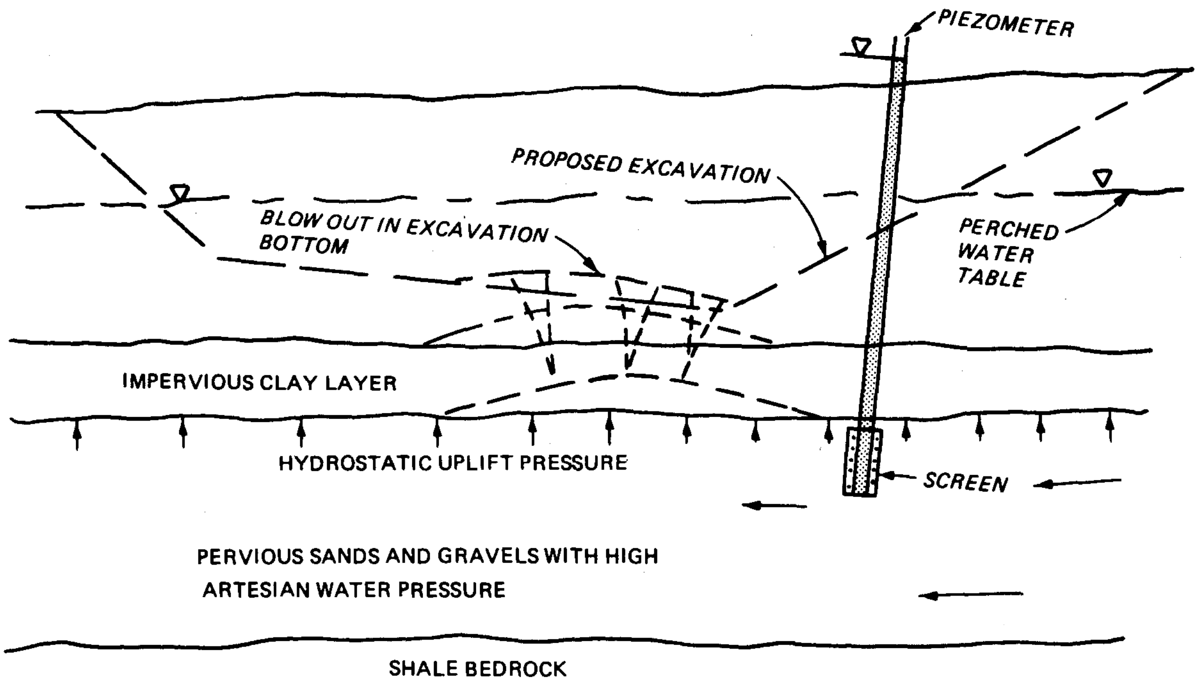


Figure 2-4. Excavation subject to bottom heave.

mized by requiring higher backfill densities adjacent to the structure.

b. Groundwater. Groundwater is an important consideration in planning for construction of subsurface structures. If seepage of groundwater into the excavation is not adequately controlled, backfilling operations will be extremely difficult. The groundwater level must be lowered sufficiently (at least 2 to 3 feet for granular soils and as much as 5 to 10 feet for fine-grained soils below the lowest level of backfilling) so that a firm foundation for backfill can be established. If the level is not lowered, the movement of hauling or compaction equipment may pump seepage water through the backfill, or the initial backfill layers may be difficult to compact because of an unstable foundation. Since the proper water content of the backfill is essential for achieving proper compaction, prevention of groundwater seepage into the excavation during backfilling operations is mandatory. Figure 3-14 of EM 1110-2-1911 shows a method for dewatering rock foundations.

(1) The contractor is generally responsible for the design, installation, and operation of dewatering equipment. The Corps of Engineers is responsible for specifying the type of dewatering system and evaluating the contractor's proposed dewatering plan. Since the dual responsibility of the contractor and the Corps relies on a thorough understanding of groundwater conditions, inadequate dewatering efforts can be minimized by adequate planning and implementation of groundwater investigations.

(2) The possibility of hydraulic heave in cohesive material must also be investigated to ensure stability of the excavation floor. Hydraulic heave may occur where an excavation overlies a confined permeable stratum below the groundwater table (fig. 2-4). If the upward hydrostatic pressure acting at the bottom of the confining layer exceeds the weight of overburden between the bottom of the excavation and the confining layer, the bottom of the excavation will rise bodily even though the design of the dewatering system is adequate for control of groundwater into the excavation. To prevent heave, the hydrostatic pressure beneath the confined stratum must be relieved.

(3) Subsurface structures located in part or wholly below the groundwater table require permanent protection against groundwater seepage. The type of protection may range from simple impermeable barriers to complex permanent dewatering systems.

(4) Dewatering and groundwater control procedures are described in TM 5-818-5/NACFAC P-418/AFM 88-5, Chapter 6.

c. Gradation and filter criteria for drainage materials. Groundwater control is often accomplished by ditches positioned to intercept the flow of groundwater and filled with permeable granular material. The water is generally collected in perforated pipes located at the bottom of the ditch and pumped to a suitable discharge area. Such drainage systems are referred to as filter drains. The gradation of the granular filter material is critical for the functioning of the system. Selection of the proper gradation for the filter material is dependent upon the gradation of the material that is being drained. Drainage of silts and clays usually requires a graded filter made up of several layers of granular material with each layer having specific requirements for maximum grain size and gradation. Details on the design of filter drains are presented in TM 5-818-5/NAVFACP-418/AFM 88-5, Chapter 6.

(1) *Selected material.* If materials at the jobsite do not meet the designed filter requirements, select material must be purchased from commercial sources and shipped to the jobsite. Filter material must be stockpiled according to gradation. For graded filter systems, the materials must be placed with care to minimize mixing of individual components.

(2) *Filter cloths.* Both woven and nonwoven filter cloths, which have been found satisfactory for use as a filter media for subsurface drains, are available. When granular filter materials are not economically available, a single wrap of filter cloth around a pipe may be used in lieu of a coarser backfill. When available granular filter material is too coarse to satisfy filter criteria for the protected soil, a single layer of filter cloth may be used adjacent to the protected soil. To reduce the chance of clogging, no filter cloth should be specified with an open area less than 4 percent and or equivalent opening size (EOS) of less than the No. 100 sieve (0.0059 inch). A cloth with openings as large as allowable should be specified to permit drainage and prevent clogging. Additional information on airfield drainage is contained in TM 5-820-2/AFM 88-5, Chapter 2.

(3) *Other uses.* Filter cloth can also provide protection for excavated slopes and serve as a filter to prevent piping of fine-grained soils. In one project, sand was not available for backfill behind a wall and coarse gravel had to be used to collect seepage. The filter cloth used to protect the excavated slope served as a filter against piping of the natural silty clay under seepage gradients out of the excavated slope after the coarse gravel backfill was placed.

d. Earth pressures. The rationale design of any structure requires the designer to consider all loads acting on the structure. In addition to normal earth pressures associated with the effective pressure distribution of the backfill materials, subsurface cut-and-cover structures may also be subjected to surcharge loads caused by heavy equipment operating close to the structure and by increased permanent lateral earth pressures caused by compaction of backfill material with heavy equipment. Procedures for predicting normal earth pressures associated with the effective pressure of backfill materials are discussed in TM 5-818-1/AFM 88-3, Chapter 7, EM 1110-2-2902, and EM 1110-2-2502.

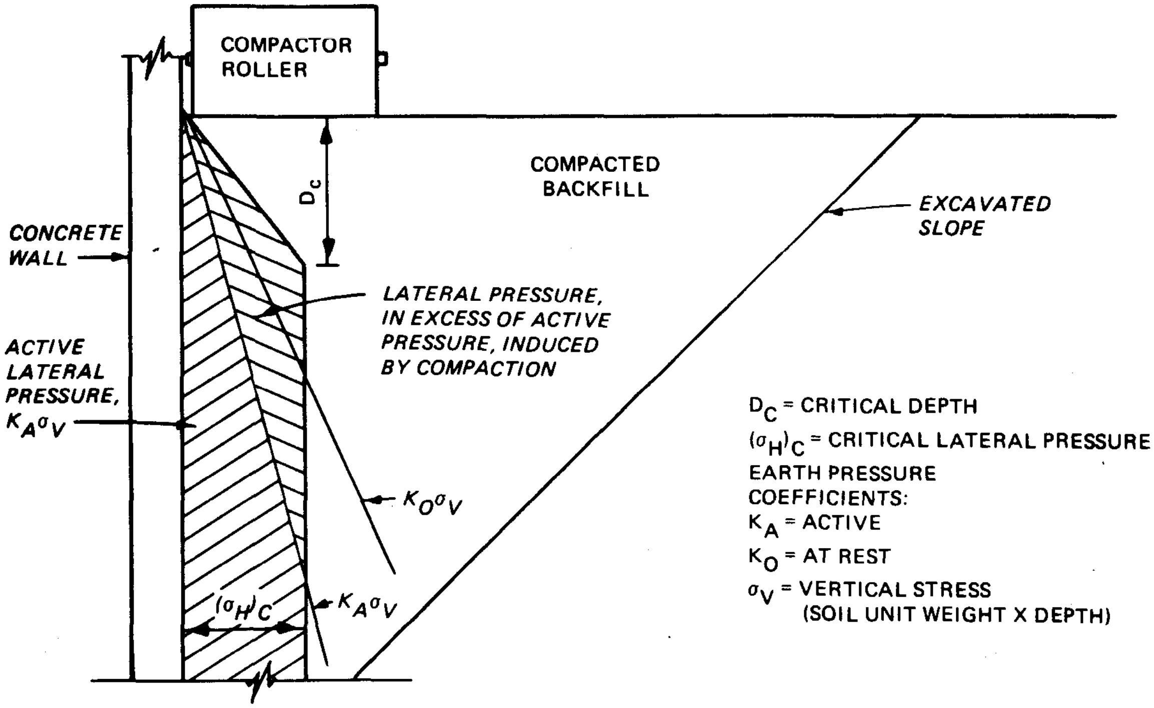
(1) Exact solutions for surcharge earth pressures generated by heavy equipment (or other surcharge loads) do not exist. However, approximations can be made using appropriate theories of elasticity such as Boussinesq's equations for load areas of regular shape or Newmark's charts for irregular shaped load areas as given in NAVFAC DM-7. As a conservative guide, heavy-equipment surcharge earth pressures may be minimized by specifying that heavy compaction equipment maintain a horizontal distance from the structure equivalent to the height of the backfill above the structure's foundation.

(2) Compaction-induced earth pressures can cause a significant increase in the permanent lateral earth pressures acting on a vertical wall of a structure (fig. 2-5a). This diagram is based on the assumption that the equipment can operate to within 6 inches of the wall. Significant reductions in lateral pressures occur as the closest allowable distance to the wall is increased (fig. 2-5b). For an operating distance 5 feet from the wall, the induced horizontal earth pressure is much less than that caused by the backfill. The magnitude of the increase in lateral pressure is dependent, among other factors, on the effective weight of the compaction equipment and the weight, earth pressure coefficient, and Poisson's ratio of the backfill material. Compaction-induced earth pressures against walls are also described in TM 5-818-l/AFM 88-3, Chapter 7, and EM 1110-2-2502.

(3) The designer must evaluate the economics of the extra cost of structures designed to withstand very close-in operation of heavy compaction equipment versus the extra cost associated with obtaining required compaction of backfill in thin lifts with smaller compaction equipment. A more economical alternative might be to specify how close to the walls different weights of compaction equipment can be operated.

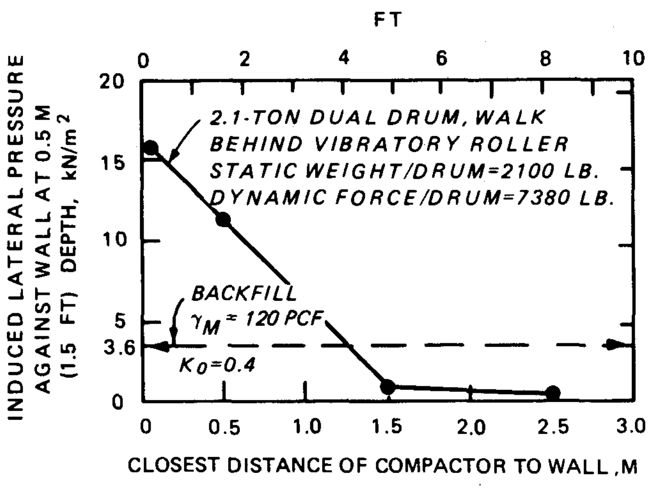
(4) One method of reducing lateral earth pressures behind walls has been to use about 4 feet of uncompacted granular (sand or gravel) backfill above the base of the wall. Soil backfill can then be compacted in layers above the granular backfill. Compression of the granular material prevents the buildup of excessive lateral pressures against the wall.

e. Structural backfill. Structural backfill is defined as the compacted backfill required over and around a structure to prevent damage from heavy equipment operating over or near the structure. This backfill must be compacted using small compaction equipment, such as mechanical rammers or vibratory-plate compactors, or intermediate size equipment such as walk-behind, dual-drum vibratory rollers. The horizontal and vertical distances from the structure for which structural backfill is required should be deter-



COMPACTION EQUIPMENT	CRITICAL DEPTH D_c, FT	$(\sigma_H)_c$ psf
10–TON SMOOTH WHEEL ROLLER	1.9	420
3.2–TON VIBRATORY ROLLER	1.7	400
1.4–TON VIBRATORY ROLLER	1.2	260
400–KG VIBRATORY PLATE	1.5	340
120–KG VIBRATORY PLATE	1.0	240

a. MAXIMUM INDUCED LATERAL PRESSURES



b. EFFECT OF DISTANCE FROM WALL

Figure 2-5. Excess lateral pressure against vertical walls induced by compaction.

mined from estimates of loads acting on the structure caused by heavy equipment and on the strength of the embedded structure members as discussed in *d* above. A 2-foot cover over small utility conduits and pipes is adequate protection where proper bedding procedures are followed. The minimum cover requirements over larger diameter (6 inches or greater), rapid and flexible pipes are presented in appendix II of TM 5-820-4/AFM 88-5, Chapter 4.

f. Slopes and bracing. Where open excavation is planned, consideration should be given to the slopes to which the materials to be encountered can be cut and remain stable. The stability analysis should include the strength of the materials, groundwater conditions, and any surcharge load that may be imposed as the result of stockpiles being placed or equipment operating near the crest of the excavation. Slope stability evaluation procedures are described in TM 5-818-1/AFM 88-3, Chapter 7. Shoring and bracing should be used to support excavation slopes where it is not feasible to excavate to stable slopes (TM 5-818-l/AFM 88-3, Chapter 7). Requirements for shoring and bracing safety are presented in EM 385-l-l.

g. Bedding for curved-bottom structures. Foundations for pipes, conduits, access tunnels, fuel and water storage tanks, and other curved-bottom structures constructed within the backfill are considered critical zones that require special attention. Any bedding material used should be free of stones or other large particles that would lead to nonuniform bearing. One of the most important functions of any bedding procedure is to provide firm support along the full length of the structure. For areas where it is difficult to perform field density control tests because of limited working space, a procedure to ensure that proper compaction is obtained must be employed. Several methods of obtaining adequate bedding are discussed in paragraph 5-1c (2).

h. Cold weather construction. Cold weather can have a very adverse effect on backfilling operations and can cause considerable delay. If possible, the project should be planned to complete backfilling operations prior to any extended period of freezing temperatures. The contractor and the resident engineer must keep up to date with weather data so that the contractor can plan the equipment and construction force required to meet the construction schedule and to protect the work already accomplished.

(1) The designer must establish definite limitations and requirements regarding placement of backfill when the ambient temperature is below freezing. Most inorganic soils, particularly silts and lean clays, containing 3 percent, by weight, or more of particles finer than 0.02 millimetre in diameter are frost susceptible. Such soils, when frozen in the presence of an available source of water, develop segregated ice in the form of lenses, layers, veins, or masses commonly, but not always oriented normal to the direction of heat loss. The expansion of the soil mass resulting from ice segregation is called frost heave. Frost heave of soil under and against structures can cause detrimental effects, which can be compounded during subsequent thawing by differential movement, loss of density, and loss of shear strength. Soils of this type should not be placed during or immediately prior to freezing temperatures and must not be placed in critical areas. Nonfrost susceptible soils should be used at the finished grade to the depth of frost penetration when the finished grade serves as a load-bearing surface.

(2) Additives, such as calcium chloride, can be used to lower the freezing temperature of soil water, but such additives will ordinarily also change the compaction and water content requirements. Therefore, additives must not be used without prior investigation to determine their effect on compaction and water content requirements. Dry sand or sand-gravel mixtures can be placed satisfactorily when temperatures are below freezing without serious effects.

(3) Protection must be provided for in-place permanent backfill in critical areas, such as those around and under structures and embedded items already placed. To preclude structural damage from possible frost heave, backfill materials around such structures should be insulated with a protective covering of mulch, hay, or straw. In some instances, loose lifts of soil can be used for insulation. However, rock or sand is too porous to provide sufficient insulation and too permeable to resist water penetration. If soil is to be used as an insulating material, a material completely foreign to the permanent fill, such as straw or building paper, should be laid down prior to placement of the insulation fill so that there will be a marked distinction between the permanent and the temporary insulation fills. In this way, when the insulation fill is removed, the stripping limits can be readily discerned.

(4) Flooding of the excavation has also been used successfully to prevent frost penetration of the in-place permanent backfill. However, consideration must be given to possible detrimental effects of saturating in-place backfill and the delay of removing the water at the beginning of the next construction season if it freezes into a solid mass of ice.

(5) Concrete walls and floors of completed structures provide poor insulation for the fill around and beneath these structures. Therefore, these structures should be enclosed as much as possible and kept closed during the winter when construction is halted because of adverse freezing weather. Reinforcing steel protruding from a partially completed structure will conduct cold through the concrete and increase the rate and depth of frost penetration beneath the structure.

Every effort should be made to schedule construction so that this condition will be kept to a minimum, and protection must be required where necessary.

i. Seismic zones. The design considerations for subsurface structures subjected to dynamic loads caused by seismic activity or explosive devices are beyond the scope of this manual. Design details are provided in TM 5-818-1/AFM 88-3, Chapter 7, and ER 1110-2-1806. Specific problems relating to backfill operations are primarily limited to possible potential for dynamically induced liquefaction. Certain materials are particularly susceptible to liquefaction; these include saturated gravels, sands, silts, and clayey sands and gravel. Where these materials are used as backfill, the potential for liquefaction can be minimized by requiring a high degree of compaction, particularly in critical areas such as beneath footings and under the spring line of curved wall structures. The requirements for materials susceptible to liquefaction are discussed in paragraph 3 - 3d.

2-4. Instrumentation. For important structures of unique design or for structures where the potential for postconstruction distress exists, instrumentation of the structure should be considered. The instrumentation program may include monitoring the amount and rate of settlement, movement of retaining walls and other structural elements, development of stresses within the structure, and development of hydrostatic and earth pressures against the structure. Analysis of the data will furnish a check on design assumptions and indicate what measures must be taken to relieve or correct undesirable conditions before distress develops. Information of this nature can also be of significant value in future design and construction.

a. Requirements. Specific requirements for instruments are ruggedness, reliability over the projected service life, and simplicity of construction, installation, and observation. Other important considerations in selecting the type of instruments are cost and availability. Manufacturers of devices considered for installation should be asked to provide a list of projects on which their devices have been installed, and previous users of new equipment should be contacted to ascertain their operating experiences.

b. Installation and observation of instrumentation. A rational instrumentation program must use the proper type of instruments and have the instruments installed properly at critical locations. Valid readings often depend on techniques and procedures used in installing and observing the instrumentation.

(1) Schedules for observations are generally established by the design office. Initial observations should be checked to assure their validity and accuracy, since these readings usually form the basis to which subsequent observations are related. Observations should be plotted immediately after each set of readings is taken and evaluated for reasonableness against previous sets of readings. In this way, it is often possible to detect errors in readings and to obtain check readings before significant changes in field conditions occur.

(2) EM 1110-2-1908 discusses in detail various types of instrumentation devices; procedures for installation, observation, and maintenance; collection, recording, analysis, and reporting of data; and possible source of error and causes of malfunctions.

2-5. Optimum cost construction. The designer should consider all details of the construction process to ensure a safe and operational facility at the lowest possible cost.

a. Energy requirements. The consideration of energy requirements is important not only for economical reasons but also for the critical need to conserve energy wherever possible. It should not be the intent of the design engineer to unduly restrict the competitive nature of current contractural procedures. Nevertheless, there are certain alternatives that the designer may specify that potentially could lead to more energy efficient construction with cost saving being reflected in bid prices. Some of the possible alternatives that should be considered are discussed below.

(1) Sources of suitable select backfill material should be located as close to the project site as possible. The source may be either a borrow area or a commercial vendor.

(2) Hauling routes to and from the source of backfill and the project site should follow the most direct route.

(3) Only compaction equipment that will compact the specific backfill to the required density in an efficient manner should be approved for use. For large projects, the designer may require that the contractor demonstrate the capabilities of the equipment he intends to use prior to construction.

(4) If possible, material from excavations or within the immediate vicinity of the project site should be used as backfill, even though such material may be marginally suitable. The engineering characteristics of marginal material may be enhanced by the use of additives (para 3-3d).

(5) The energy requirements for adequate cold weather protection of construction personnel and structures can be considerable. For project sites subject to seasonal cold weather, construction should not, if possible, be scheduled during extreme cold weather periods.

b. Value engineering. Potential cost savings may be realized by encouraging the contractor to participate in value engineering, whereby the contractor shares any project saving derived from realistic cost-saving suggestions submitted.

CHAPTER 3

EVALUATION, DESIGN, AND PROCESSING OF BACKFILL MATERIALS

3-1. General. The evaluation, design, and proper processing of backfill materials are extremely important phases of the preconstruction operations. The purpose of the evaluation phase is to determine the engineering characteristics of potential backfill materials. The design phase must take into account the engineering characteristics required of the backfill and specify materials that, when compacted properly, will have these characteristics. Proper processing of the backfill material will ensure that desirable engineering. characteristics will be obtained as the material is placed.

3-2. Evaluation of backfill materlals. Evaluation of backfill materials consists of exploration, sampling, and laboratory testing to determine the engineering characteristics of potential backfill materials. Detailed instructions for exploration, sampling, laboratory testing, and foundation design are presented in TM 5-818-1/AFM 88-3, Chapter 7. However, to emphasize the need for an adequate investigation, some aspects of planning and investigation that should be considered are discussed in the following paragraphs.

a. Field exploration and sampling. Field exploration and sampling are extremely important to the design of foundations, selection of backfill, and planning for construction. A great amount of material will be available from required excavations, and the investigation for foundation conditions should include the sampling and evaluation of these materials for possible use as backfill. Where an adequate volume of suitable backfill cannot be obtained from the construction excavation, the exploration and sampling program must be expanded to find other sources of suitable material whether from nearby borrow areas or commercial sources.

(1) The purpose of the investigation is to delineate critical conditions and provide detailed information on the subsurface deposits so that proper design and construction, including backfilling operations, can be accomplished with minimum difficulty. Thus careful planning is required prior to the field exploration and sampling phase of the investigation. Available geologic and soil data should be studied, and if possible, preliminary borings should be made. Once a site has been tentatively selected, orientation of the structure to the site should be established. The engineer who plans the detailed field exploration program must have knowledge of the structure, i.e., its configuration and foundation requirements for design loads and settlement tolerances. The planning engineer should also know the type and quantity of backfill required. The importance of employing qualified field exploration personnel cannot be overemphasized. The exploration crews should be supervised in the field by a soils engineer or geologist familiar with the foundation and backfill requirements so that changes can be made in the exploration program where necessary to provide adequate information on subsurface conditions.

(2) The field engineer should also know the location of significant features of the structure so that sampling can be concentrated at these locations. In addition, he should have an understanding of the engineering characteristics of subsurface soil and rock deposits that are important to the design of the structure and a general knowledge of the testing program so that the proper type and quantity of samples will be obtained for testing.

(3) From the samples, the subsurface deposits can be classified and boring logs prepared. The more continuous the sampling operation, the more accurate will be the boring logs. All borings should be logged with the description of the various strata encountered as discussed in TM 5-818-1/AFM 88-3, Chapter 7. Accurate logging and correct evaluation of all pertinent information are essential for a true concept of subsurface conditions.

(4) When the exploratory borings at the construction site have been completed, the samples and logs of borings should be examined to determine if the material to be excavated will be satisfactory and in sufficient quantity to meet backfill requirements. Every effort should be made to use the excavated materials; however, if the excavated materials are not satisfactory or are of insufficient quantity, additional exploration should be initiated to locate suitable borrow areas. If borrow areas are not available, convenient commercial sources of suitable material should be found. Backfill sources, whether excavation, borrow, or commercial, should contain several times the required volume of compacted backfill.

(5) Groundwater studies prior to construction of subsurface structures are of the utmost importance, since groundwater control is necessary to provide a dry excavation in which construction and backfilling

operations can be properly conducted. Data on groundwater conditions are also essential for forecasting construction dewatering requirements and stability problems. Groundwater studies must consist of investigations to determine: groundwater levels to include any seasonal variations and artesian conditions; the location of any water-bearing strata; and the permeability and flow characteristics of water-bearing strata. Methods for investigating groundwater conditions are described in TM 5-818-1/AFM 88-3, Chapter 7, and TM 5-818-5/NAVFACP-418/AFM 88-5, Chapter 6.

b. Laboratory testing. The design of any foundation is dependent on the engineering characteristics of the supporting media, which may be soil or rock in either its natural state or as compacted backfill. The laboratory testing program will furnish the engineer information for planning, designing, and constructing sub surface structures. Laboratory testing programs usually follow a general pattern and to some extent can be standardized, but they should be adapted to particular problems and soil conditions. Special tests and research should be utilized when necessary to develop needed information. The testing program should be well planned with the engineering features of the structure and backfill in mind; testing should be concentrated on samples from areas where significant features will be located but should still present a complete picture of the soil and rock properties. The laboratory test procedures and equipment are described in TM 5-818-1/AFM 88-3, Chapter 7, EM 1110-2-1906, and MIL-STD-621.

(1) *Identification and classification of soils. The* Unified Soil Classification System used for classifying soils for military projects (MIL-STD-619 and TM 5-818-1/AFM 88-3, Chap. 7) is a means of identifying a soil and placing it in a category of distinctive engineering properties. Table 3-1 shows the properties of soil groups pertinent to backfill and foundations. Using these characteristics, the engineer can prepare preliminary designs based on classification and plan the laboratory testing program intelligently and economically.

(a) The Unified Soil Classification System classifies soils according to their grain-size distribution and plasticity characteristics and groups them with respect to their engineering behavior. With experience, the plasticity and gradation properties can be estimated using simple, expedient tests (see table 2-2 and 2-3 of TM 5-818-1/AFM 88-3, Chap. 7 or AFM 89-3, Chap. 2) and these estimates can be confirmed using simple laboratory tests. The principal laboratory tests performed for classification are grain-size analyses and Atterberg limits.

(b) The engineering properties in table 3-1 are based on “Standard Proctor” (CE 25) maximum density except that the California Bearing Ratio (CBR) and the subgrade modulus are based on CE 55 maximum density. This information can be used for initial design studies. However, for final design of important structures, laboratory tests are required to determine actual performance characteristics, such as CE 55 compaction properties, shear strength, permeability, compressibility, swelling characteristics, and frost susceptibility where applicable, under expected construction conditions.

(c) The Unified Soil Classification System is particularly useful in evaluating, by visual examination, the suitability of potential borrow materials for use as compacted backfill. Proficiency in visual classification can be developed through practice by comparing estimated soil properties with results of laboratory classification tests.

(2) *Compaction testing.* Compaction test procedures are described in detail in MIL-STD-621 and ASTM D 1557 (app. A). It is important that the designer and field inspection personnel understand the basic principles and fundamentals of soil compaction. The principles of soil compaction are discussed in appendix B of this manual.

(a) The purpose of the laboratory compaction tests are to determine the compaction characteristics of available backfill materials. Also, anticipated field density and water content can be approximated in lab oratory-compacted samples in order that other engineering properties, such as shear strength, compressibility, consolidation, and swelling, can be studied. For most soils there is an optimum water content at which a maximum density is obtained with a particular compaction effort. A standard five-point compaction curve relating density and water content (fig. B-1, app. B) can be developed by the procedures outlined in MIL-STD-621.

(b) The impact compaction test results normally constitute the basis on which field compaction control criteria are developed for inclusion in the specifications. However, for some cohesionless soils, higher densities can be obtained by the vibratory compaction method (commonly referred to as maximum relative density), described in appendix XII of EM 1110-2-1906. The required field compaction is generally specified as a percentage of laboratory maximum dry density and referred to as percent CE 55 maximum density. Water content is an important controlling factor in obtaining proper compaction. The required percentage of maximum dry density and the compaction water content should be selected on the basis of the engineering characteristics, such as compression moduli, settlement, and shear strength, desired in the compacted backfill. It should be noted that these characteristics could be adversely effected by subsequent increases in

water content after placement. This situation could result from an increase in the groundwater level after construction.

(c) Density control of placed backfill in the field can be facilitated by the use of rapid compaction check tests (para 7-5c). A direct rapid test is the one-point impact compaction test. Rapid indirect tests, such as the Proctor needle penetration for cohesive soils or the cone resistance load for cohesionless soils, can also be used when correlations with CE 55 maximum density have been established.

(3) *Shear strength testing.* When backfill is to be placed behind structure walls or bulkheads or as foundation support for a structure, and when fills are to be placed with unrestrained slopes, shear. tests should be performed on representative samples of the backfill materials compacted to expected field densities and water contents to estimate as-constructed shear strengths. The appropriate type of test required for the conditions to be analyzed is presented in TM 5-818-1/AFM 88-3, Chapter 7. Procedures for shear strength testing are described in EM 1110-2-1906.

Table 3-1. Typical Engineering Properties of Compacted Materials[a]

Group Symbol	Soil Type	Range of Maximum Dry Unit Weight, pcf	Range of Optimum Water, Content Percent	Typical Value of Compression At 2.5 ksf (20 psi) Percent of Original Height	At 7.2 ksf (50 psi)	Typical Strength Characteristics Cohesion (As Compacted) psf	Cohesion (Saturated) psf	φ (Effective Stress Envelope) deg	Typical Coefficient of Permeability ft/min	Range of CBR Values	Range of Subgrade Modulus k lb/cu in. ML-CL	Mixture of inorganic silt and clay	100-120	22-12	1.0	2.2	1350	460	32	5×10^{-7}	—	100-200	
CL	Inorganic clays of low to medium plasticity	95-120	24-12	1.3	2.5	1800	270	28	10^{-7}	15 or less	50-200	Medium to high
OL	Organic silts and silt-clays, low plasticity	80-100	33-21	—	—	—	—	—	—	5 or less	50-100	Medium to high
MH	Inorganic clayey silts, elastic silts	75-95	40-24	2.0	3.8	1500	420	25	5×10^{-7}	10 or less	50-100	Medium to very high
CH	Inorganic clays of high plasticity	80-105	36-19	2.6	3.9	2150	230	19	10^{-7}	15 or less	50-150	Medium
OH	Organic clays and silty clays	75-100	45-21	--	—	—	—	—	—	5 or less	25-100	Medium

Notes: 1. All properties are for condition of "standard Proctor" maximum density, except values of k and CBR which are for CE55 maximum density.
2. Typical strength characteristics are for effective strength envelopes and are obtained from USBR data.
3. Compression values are for vertical loading with complete lateral confinement.
4. (>) indicates that typical property is greater than the value shown. (—) indicates insufficient data available for an estimate.

[a] After DM-7.
[b] From TM 5-818-2/AFM 88-6, Chapter 4.

(4) *Consolidation and swell testing.* The rate and magnitude of consolidation under a given load are influenced primarily by the density and type of soil and the conditions of saturation and drainage. Fine-grained soils generally consolidate more and at a slower rate than coarse-grained soils. However, poorly graded, granular soils and granular soils composed of rounded particles will often consolidate significantly under load but usually at a relatively fast rate.

(a) The procedure for the consolidation test is outlined in EM 1110-2-1906. The information obtained in this test can be used in settlement analyses to determine the total settlement, the time rate of settlement, and the differential settlement under varying loading conditions. Consolidation characteristics are important considerations in selection of backfill materials. The results of consolidation tests performed on laboratory compacted specimens of backfill material can be used in determining the percent compaction to be required in the specifications.

(b) Swelling characteristics can be determined by a modified consolidation test procedure. The degree of swelling and swelling pressure should be determined on all backfill and foundation materials suspected of having swelling characteristics. This fact is particularly important when a considerable overburden load is removed by excavation or when the compacted backfill with swelling tendencies may become saturated upon removal of the dewatering system and subsequent rise of the groundwater level. The results of swelling tests can be used to determine the suitability of material as backfill. When it is necessary to use backfill materials that have a tendency to swell upon saturation because more suitable materials are unavailable, the placement water content and density that will minimize swelling can be determined from a series of tests. TM 5-818-1/AFM 88-3, Chapter 7, and FHWA-RD-79-51 (app. A) provide further information applicable to compacted backfills.

(5) *Permeability tests.* Permeability tests to determine the rate of flow of water through a material can be conducted in the laboratory by procedures described in EM 1110-2-1906. Permeability characteristics of fine-grained materials at various densities can also be determined from consolidation tests.

(a) Permeability characteristics for the design of permanent drainage systems for structures founded below the groundwater level must be obtained from laboratory tests. The tests should be performed on representative specimens of backfill materials compacted in the laboratory to densities expected in the field.

(b) In situ material permeability characteristics for the design of construction excavation dewatering systems can also be approximated from laboratory tests on representative undisturbed samples. Laboratory permeability tests on undisturbed samples are less expensive than in situ pumping tests performed in the field; however, laboratory tests are less accurate in predicting flow characteristics.

(6) *Slake durability of shales.* Some clay shales tend to slake when exposed to air and water and must be protected immediately after they are exposed. The extent of slaking also governs the manner in which they are treated as a backfill material (para 3-3c). Slaking characteristics can be evaluated by laboratory jar-slake tests or slake-durability tests.

(a) The jar-slake test is qualitative with six descriptive degrees of slaking determined from visual observation of ovendried samples soaked in tap water for as long as 24 hours. The jar-slake test is not a standardized test. One version of the jar-slake test is discussed in FHWA-RD-78-141. Six suggested values of the jar-slake index I_J are listed below:

I_J	Behavior
1	Degrades into pile of flakes or mud
2	Breaks rapidly and forms many chips
3	Breaks rapidly and forms few chips
4	Breaks slowly and forms several fractures
5	Breaks slowly and develops few fractures
6	No change

Shales with I_J values of 1 to 3 should be protected when occurring in excavated slopes and compacted as soil if used for backfill.

(b) The slake-durability test is a standardized test that gives a quantitative description in percent by weight of material remaining intact at the conclusion of the test. Details of the test are presented in FHWA-RD-78-141.

(7) *Dynamic tests for special projects.* The dynamic analysis of projects subject to seismic or blast induced loading conditions requires special dynamic tests on both in situ and backfill materials. Tests required for dynamic analysis include: cyclic triaxial tests; in situ density measurements; and tests to determine shear wave velocities, shear modulus, and damp ing (ER 1110-2-1806).

(8) *In situ water content.* The in situ water content, including any seasonal variation, must be determined prior to construction for materials selected for use as backfill. Natural in situ water contents will determine the need for wetting or drying the backfill material before placement to obtain near optimum water contents for placement and compaction. ASTM D 2216 discusses the test method for determining water content.

3-3. Selection of backfill materials. Selection of backfill materials should be based upon the engineering properties and compaction characteristics of the materials available. The results of the field exploration and laboratory test programs should provide adequate information for this purpose. The materials may come from required excavation, adjacent borrow pits, or commercial sources. In selecting materials to be used, first consideration should be given to the maximum use of materials from required excavation. If the excavated materials are deficient in quality or quantity, other sources should be considered. Common backfill having the desired properties may be found in borrow areas convenient to the site, but it may be necessary to obtain select backfill materials having particular gradation requirements, such as filter sands and gravels and pipe or conduit bedding materials from commercial sources.

a. Primary considerations. Primary considerations for borrow material sources are suitability and quantity. Accessibility and proximity of the borrow area to the jobsite should also be considered. The water contents of the borrow area material should be determined seasonally, and a source of water should be located if the natural water contents are considerably less than the required placement water content. If several sources of suitable backfill are available, other factors to be considered in selecting the borrow materials are ease of loading and spreading and the means for adding or reducing water. The need for separating or mixing soil strata from excavation or borrow sources should be considered if necessary to provide reasonably uniform engineering properties throughout the compacted backfill.

b. Compaction characteristics. If compaction characteristics of the major portion of the backfill are relatively uniform, problems of controlling placement of backfill will be significantly reduced since the inspector will be able to develop more rapidly the ability to recognize the adequacy of the compaction procedures. In addition, the frequency of testing for compaction control could be reduced. When available backfill materials are unusual, test sections of compacted backfill are sometimes justified to develop placement procedures and to determine the engineering characteristics to be expected in field-compacted materials.

c. Workability. An important factor in choosing backfill materials is the workability or ease with which the soil can be placed and compacted. Material characteristics that effect workability include: the ease of adjusting water contents in the field by wetting or aeration; the sensitivity to the compaction water content with respect to optimum; and the amount of compaction effort required to achieve specified densities.

d. Types of backfill material. A discussion of the many types of backfill and their compaction characteristics is beyond the scope of this manual since soil types will vary on each project. However, the compaction characteristics of several rather broad categories of backfill (table 3-1) are discussed briefly. MIL-STD-619 should be studied for more detailed information.

(1) *Coarse-grained soils.* Coarse-grained soils include gravelly and sandy soils and range from clayey sands (SC) through the well-graded gravels of gravel-sand mixtures (GW) with little or no fines (table 3-l). They will exhibit slight to no plasticity. All of the well-graded soils falling in this category have fairly good compaction characteristics and when adequately compacted provide good backfill and foundation support.

(a) One difficulty that might arise with soils in this category would be in obtaining good compaction of the poorly graded sands and gravels. These poorly graded materials may require saturation with downward drainage and compaction with greater compaction effort to achieve sufficiently high densities. Also, close control of water content is required where silt is present in substantial amounts. Coarse-grained materials compacted to a low relative density are susceptible upon saturation to liquefaction under dynamic loads.

(b) For sands and gravelly sands with little or no fines, good compaction can be achieved in either the air-dried or saturated condition. Downward drainage is required to maintain seepage forces in a downward direction if saturation is used to aid in compaction. Consideration may be given to the economy of adding cement to stabilize moist clean sands that are particularly difficult to compact in narrow confined areas. However, the addition of cement may produce zones with greater rigidity than untreated adjacent backfill and form “hard spots” resulting in nonuniform stresses and deformations in the structure.

(c) Cohesionless materials are well suited for placement in confined areas adjacent to and around structures where heavy equipment is not permitted and beneath and around irregulary shaped structures, such as tunnels, culverts, utilities, and tanks. Clean, granular, well-graded materials having a maximum size of 1 inch with 95 percent passing the No. 4 sieve and 5 percent or less passing the No. 200 sieve are excellent for use in these zones. However, a danger exists of creating zones where seepage water may accumulate and saturate adjacent cohesive soils resulting in undesirable consolidation or swelling. In such cases, provisions for draining the granular backfill, sealing the surface, and draining surface water away from the structure are necessary.

(2) *Fine-grained soils of low to medium plasticity.* Inorganic clays (CL) of low to medium plasticity (gravelly, sandy, or silty clays and lean clays) and inorganic silts and very fine sands (ML) of low plasticity (silty or clayey fine sands and clayey silts) are included in this category. The inorganic clays are relatively impervious and can be compacted fairly easily with heavy compac-

tion equipment to provide a good stable backfill. Soils in the CL group can be compacted in confined areas to a fairly high degree of compaction with proper water content and lift thickness control. The clayey sands of the SC group and clayey silts of the ML group can be compacted to fairly high densities, but close control of water content is essential and sometimes critical, particularly on the wet side of optimum water content. Some ML soils, if compacted on the dry side of optimum, may lose considerable strength upon saturation after compaction. Considerable settlement may occur. Caution must therefore be exercised in the use of such soils as backfill, particularly below the groundwater level. Also, saturated ML soils are likely to be highly susceptible to liquefaction when dynamically loaded. Where such soils are used as backfill in seismic prone areas, laboratory tests should be conducted to determine their liquefaction potential (see para. 17-5 and 17-6, TM 5-818-1/AFM 88-3, Chap. 7).

(3) *Rock.* The suitability of rock as backfill material is highly dependent upon the gradation and hardness of the rock particles. The quantity of hard rock excavated at most subsurface structure sites is relatively small, but select cohesionless materials may be difficult to find or may be expensive. Therefore, excavated hard rock may be specified for crusher processing and used as select cohesionless material.

(4) *Shale.* Although shale is commonly referred to as rock, the tendency of some shales to breakdown under heavy compaction equipment and slake when exposed to air or water after placement warrants special consideration.

(a) Some soft shales break down under heavy compaction equipment causing the material to have entirely different properties after compaction than it had before compaction. This fact should be recognized before this type of material is used for backfill. Establishing the proper compaction criteria may require that the contractor construct a test fill and vary the water content, lift thickness, and number of coverages with the equipment proposed for use in the backfill operation. This type of backfill can be used only in unrestricted open zones where heavy towed or self-propelled equipment can operate.

(b) Some shales have a tendency to break down or slake when exposed to air. Other shales that appear rock-like when excavated will soften or slake and deteriorate upon wetting after placement as rockfill. Alternate cycles of wetting and drying increases the slaking process. The extent of material breakdown determines the manner in which it is treated as a backfill material. If the material completely degrades into constituent particles or small chips and flakes, it must be treated as a soil-like material with property characteristics similar to ML, CL, or CH materials, depending upon the intact composition of the parent material. Complete degradation can be facilitated by alternately wetting, drying, and disking the material before compaction A detailed discussion on the treatment of shales as a fill material is given in FHWA-RD-78-141.

(5) *Marginal materials.* Marginal materials are these materials that because of either their poor compaction, consolidation, or swelling characteristics would not normally be used as backfill if sources of suitable material were available. Material considered to be marginal include fine-grained soils of high plasticity and expansive clays. The decision to use marginal materials should be based on economical and energy conservation considerations to include the cost of obtaining suitable material whether from a distant borrow area or commercial sources, possible distress repair costs caused by use of marginal material, and the extra costs involved in processing, placing, and adequately compacting marginal material.

(a) The fine-grained, highly plastic materials make poor backfill because of the difficulty in handling, exercising water-content control, and compacting. The water content of highly plastic fine-grained soils is critical to proper compaction and is very difficult to control in the field by aeration or wetting. Furthermore, such soils are much more compressible than less-plastic and coarse-grained soils; shear strength and thus earth pressures may fluctuate between wide limits with changes in water content; and in cold climates, frost action will occur in fine-grained soils that are not properly drained. The only soil type in this category that might be considered suitable as backfill is inorganic clay (CH). Use of CH soils should be avoided in confined areas if a high degree of compaction is needed to minimize backfill settlement or to provide a high compression modulus.

(b) The swelling (and shrinking) characteristics of expansive clay vary with the type of clay mineral present in the soil, the percentage of that clay mineral, and the change in water content. The active clay minerals include montmorillonite, mixed-layer combinations of montmorillonite and other clay minerals, and under some conditions chlorites and vermiculites. Problems may occur from the rise of groundwater, seepage, leakage, or elimination of surface evaporation that may increase or decrease the water content of compacted soil and lead to the tendency to expand or shrink. If the swelling pressure developed is greater than the restraining pressure, heave will occur and may cause structural distress. Compaction on the wet side of optimum moisture content will produce lower magnitudes of swelling and swell pressure. Expansive clays that exhibit significant volume increases should not be used as backfill where the potential for structural damage might exist. Suitability should be based upon laboratory swell tests (TM 5-818-1/AFM 88-3, Chapter 7).

(c) Additives, such as hydrated lime, quicklime, and fly ash, can be mixed with some highly plastic clays to improve their engineering characteristics and permit the use of some materials that would otherwise be unacceptable. Hydrated lime can also be mixed with some expansive clays to reduce their swelling characteristics (TM 5-818-1/AFM 88-3, Chapter 7). Lab oratory tests should be performed to determine the amount of the additive that should be used and the characteristics of the backfill material as a result of using the additive. Because of the complexity of soil-additive systems and the almost complete empirical nature of the current state of the art, trial mixes must be varified in the field by test fills.

(6) *Commercial by-products. The* use of commercial by-products, such as furnace slag or fly ash as backfill material, may be advantageous where such products are locally available and where suitable natural materials cannot be found. Fly ash has been used as a lightweight backfill behind a 25-foot-high wall and as an additive to highly plastic clay. The suitability of these materials will depend upon the desirable characteristics of the backfill and the engineering characteristics of the products.

3-4. Processing of backfill materials. The construction of subsurface structures often requires the construction of elements of the structure within or upon large masses of backfill. The proper functioning of these elements are often critically affected by adverse behavioral characteristics of the backfill. Behavioral characteristics are related to material type, water content during compaction, gradation, and compaction effort. While compaction effort may be easily controlled during compaction, it is difficult to control material type, water content, and gradation of the material as it is being placed in the backfill; control criteria must be established prior to placement.

a. Material type. Backfill material should consist of a homogeneous material of consistent and desirable characteristics. The field engineer must ensure that only the approved backfill material is used and that the material is uniform in nature and free of any anomalous material such as organic matter or clay pockets. Stratified material should be mixed prior to placing to obtain a uniform blend. Excavated material to be used as backfill should be stockpiled according to class or type of material.

b. Water content. While water content can be adjusted to some extent after placing (but before compacting), it is generally more advantageous to adjust the water content to optimum compaction conditions before placing. Adjustment of water content can be accomplished by aeration (disking or turning) or sprinkling the material in 12- to 18- inch layers prior to placing or stockpiling. If the material is stockpiled, provisions should be made to maintain a constant moisture content during wet or dry seasons.

c. Ensuring gradation. Some backfill materials consisting of crushed rock, gravel, or sand require limitations on maximum and minimum particle-size or gradation distributions. Where materials cannot be located that meet gradation criteria, it may be advantageous to require processing of available material by sieving to obtain the desired gradation.

CHAPTER 4

EARTHWORK: EXCAVATION AND PREPARATION FOR FOUNDATIONS

4-1. Excavation.

a. General. In general, excavation for subsurface structures will consist of open excavation and shaft and tunnel excavation. Where excavation to great depths is required, a variety of soils and rock may be encountered at a single site. Soils may range through a wide spectrum of textures and water contents. Rock encountered may vary from soft rock, very similar to a firm soil in its excavation requirements, to extremely hard rock requiring extensive blasting operations for removal. Groundwater may or may not be present. The groundwater conditions and the adequacy of groundwater control measures are important factors in excavation, in maintaining a stable foundation, and in backfilling operations. The extent to which groundwater can be controlled also influences the slopes to which the open excavation can be cut, the bracing required to support shaft and tunnel excavation, and the handling of the excavated material.

b. Good construction practices, and problems. A majority of the problems encountered during excavation are related to groundwater conditions, slope stability, and adverse weather conditions. Many of the problems can be anticipated and avoided by preconstruction planning and by following sound construction practices.

(1) *Groundwater.* Probably the greatest source of problems in excavation operations is groundwater. If the seepage of groundwater into an excavation is adequately controlled, other problems will generally be minor and can be easily handled. Several points should be recognized that, if kept in mind, will help to reduce problems attributable to groundwater. In some instances, groundwater conditions can be more severe than indicated by the original field exploration investigation since field explorations provide information only for selected locations and may not provide a true picture of the overall conditions.

(a) If groundwater seepage begins to exceed the capacity of the dewatering system, conditions should not be expected to improve unless the increased flow is known to be caused by a short-term condition such as heavy rain in the area. If seepage into the excavation becomes excessive, excavation operations should be halted until the necessary corrective measures are determined and effected. The design and evaluation of dewatering systems require considerable experience that the contractor or the contracting office often do not possess, and the assistance of specialists in this field should be obtained.

(b) Groundwater without significant seepage flow can also be a problem since excess hydrostatic pressures can develop below relatively impervious strata and cause uplift and subsequent foundation or slope instability. Excess hydrostatic pressures can also occur behind sheet pile retaining walls and shoring and bracing in shaft and tunnel excavations. Visual observations should be made for indications of trouble, such as uncontrolled seepage flow, piping of material from the foundation or slope, development of soft wet areas, uplift of ground surface, or lateral movements.

(c) Accurate daily records should be kept of the quantity of water removed by the dewatering system and of the piezometric levels in the foundation and beneath excavation slopes. Separate records should be kept of the flow pumped by any sump-pump system required to augment the regular dewatering system to note any increase of flow into the excavation. Flowmeters or other measuring devices should be installed on the discharge of these systems for measurement purposes (TM 5-818-5/NAVFAC P-418/AFM 88-5, Chap. 6). These records can be invaluable in evaluating "Changed Condition" claims submitted by the contractor. The contractor should be required to have "standby" equipment in case the original equipment breaks down.

(2) *Surface water.* Sources of water problems other than groundwater are surface runoff into the excavation and snow drifting into the excavation. A peripheral, surface-drainage system, such as a ditch and berm, should be required to collect surface water and divert it from the excavation, In good weather there is a tendency for the contractor to become lax in maintaining this system and for the inspection personnel to become lax in enforcing maintenance. The result can be a sudden filling of the excavation with water during a heavy rain and consequent delay in construction. The surface drainage system must be constantly maintained until the backfill is complete. Drifting snow is a seasonal and regional problem, which can best be controlled by snow fences placed at strategic locations around the excavation,

(3) *Slope integrity.* Another area of concern during excavation is the integrity of the excavation

slopes. The slopes may be either unsupported or supported by shoring and bracing. The lines and grades indicated in the plans should be strictly adhered to. The contractor may attempt to gain additional working room in the bottom of the excavation by steepening the slopes; this change in the plans must not be allowed.

(a) Where shoring and bracing are necessary to provide a stable excavation, and the plans and specifications do not provide details of these requirements, the contractor should be required to submit the plans in sufficient detail so that they can be easily followed and their adequacy checked. The first principle of excavation stabilization, using shoring and bracing, is that the placing of supports should proceed with excavation. The excavation cut should not be allowed to yield prior to placing of shoring and bracing since the lateral pressures to be supported would generally be considerably greater after yield of the unshored cut face than if no movement had occurred prior to placement of the shoring. Excavation support systems are discussed in TM 5-818-1/AFM 88-3, Chapter 7. All safety requirements for shoring and bracing as contained in EM 385-1-1 should be strictly enforced.

(b) The inspector must be familiar with stockpiling requirements regarding the distance from the crest of the excavation at which stockpiles can be established and heavy equipment operated without endangering the stability of the excavation slopes. He must also know the maximum height of stockpile *or* weight of equipment that can be allowed at this distance.

(c) Excessive erosion of the excavation slopes must not be permitted. In areas subject to heavy rainfall, it may be necessary to protect excavation slopes with polyethylene sheeting, straw, silt fences, or by other means to prevent erosion. Excavation slopes for large projects that will be exposed for several seasons should be vegetated and maintained to prevent erosion.

(4) *Stockpiling excavated material.* Generally, procedures for stockpiling are left to the discretion of the contractor. Prior to construction, the contractor must submit his plans for stockpiling to the contracting officer for approval. In certain cases, such as where there are different contractors for the excavation and the backfill phases, it may be necessary to include the details for stockpiling operations in the specifications. In either case, it is important that the stockpiling procedures be conducive to the most advantageous use of the excavated materials.

(a) As the materials are excavated, they should be separated into classes of backfill and stockpiled accordingly. Thus the inspection personnel controlling the excavation should be qualified to classify the material and should be thoroughly familiar with backfill requirements. Also, as the materials are placed in stockpiles, water should be added or the materials should be aerated as required to approximate optimum water content for compaction. Field laboratory personnel can assist in determining the extent to which this is necessary. The requirements of shaping the stockpile to drain and sealing it against the entrance of undesirable water by rolling with spreading equipment or covering with polyethylene sheeting should be enforced. This step is particularly important for cohesive soils that exhibit poor draining characteristics and tend to remain wet if once saturated by rains. Stockpiles must be located over an area that is large enough to permit processing and where they will not interfere with peripheral drainage around the excavation and will not overload the slopes of the excavation.

(b) In cases where significant energy and cost saving can be realized, special stockpiling requirements should be implemented. An example would be *a* large project consisting of a number of excavation and backfilling operations. The excavation material from the first excavation could be stockpiled for use as backfill in the last excavation. The material from the intermediate excavations could in turn be immediately used as backfill for the first, second, etc., phases of the project and thereby eliminate double handing of excavated backfill for all but the first-phase excavation.

(5) *Protection of exposed material.* If materials that are exposed in areas, such as walls of a silo shaft, foundation support, or any other area against which concrete will be placed, are susceptible to deterioration or swell when exposed to the weather, they should be properly protected as soon after exposure as possible. Depending on the material and protection requirements, this protection may be pneumatic concrete, asphalt spray, or plastic membrane (TM 5-818-1/AFM 88-33, Chap. 7). In the case of a foundation area, the contractor is required to underexcavate leaving a cover for protection, as required, until immediately prior to placement of the structure foundation. Any frost-susceptible materials encountered during excavation should be protected (para 2-3h (3) and (4)) if the excavation is to be left open during an extended period of freezing weather.

(6) *Excavation record.* As the excavation progresses, the project engineer should keep a daily record of the type of material excavated and the progress made. This record would be of value if subsequent claims of "Changed Conditions" are made by the contractor.

4-2. Foundation preparation.

a. General. In this manual, preparation applies to foundations for backfill as well as those for structures to be placed in the excavation. Generally, if proper excavation procedures have been followed, very little additional preparation will be required prior to backfill placement.

b. Good construction practices, and problems. As mentioned previously, the problems associated with foundation preparation are greatly reduced by following such proper excavation procedures as maintaining a dry excavation and planning ahead. The principles of good foundation preparation are simple, but enforcing the provisions of the specifications concerning the work is more difficult. Inspection personnel must recognize the importance of this phase of the work since, if not properly controlled, problems can result.

(1) It is most important that a stable foundation be provided. Thus it may be necessary, particularly in the case of sensitive fine-g-rained materials, to require that the final excavation for footings be carefully done with hand tools and that no equipment be allowed to operate on the final cut surface. To provide a working platform on which to begin backfill placement on these sensitive materials, it may be necessary to place an initial layer of granular material.

(2) If the foundation is to be supported on rock, the soundness of the exposed rock should be checked by a slaking test (soaking a piece of the rock in water to determine the resulting degree of deterioration (para 3-2b (6)) and visual observation to determine if the rock is in a solid and unshattered condition. If removal of rock below the foundation level is required, the space should be filled with concrete. A qualified geological or soils engineer should inspect the area if it is suspected that the material will deteriorate or swell when exposed to the weather. If necessary, the materials must be protected from exposure using the methods previously discussed in paragraph 4-1b (5).

(3) Before placement of any structure foundation is begun, the plans should be rechecked to ensure that all required utilities and conduits under or adjacent to the foundation have been placed, so that excavating under or undermining the foundation to place utilities and conduits will not become necessary later.

(4) Occasionally, it may be found upon completion of the excavation that if a structure were placed as shown on the plans, it would be supported on two materials with drastically different consolidation charactertistics, such as rock and soil, rock and backfill, or undisturbed soil and backfill. This situation could occur because the predesign subsurface information was inadequate, because the structure was relocated or reoriented by a subsequent change in the plans, because of an oversight of the design engineer, or because of the excavation procedures followed by the contractor. Regardless of the reason, measures such as overexcavation and placement of subsequent backfill should be taken, where possible, and in coordination with the design office to provide a foundation of uniform material. Otherwise, the design office should evaluate the differences in foundation conditions for possible changes to the structural foundation elements.

(5) Preparing the area to receive the backfill consists of cleaning, leveling, and compacting the bottom of the excavation if the foundation is in soil. All debris and foreign material, such as trash, broken concrete and rock, boulders, and forming lumber, should be removed from the excavation. All holes, depressions, and trenches should be filled with the same material as that specified to be placed immediately above such a depression, unless otherwise designated, and compacted to the density specified for the particular material used. If the depression is large enough to accommodate heavy compacting equipment, the sides of the depression should have a positive slope and be flat enough for proper operation of compaction equipment. After the area is brought to a generally level condition by compacting in lifts in accordance with specifications, the entire area to receive backfill should be sacrificed to the depth specified, the water content adjusted if necessary, and the area compacted as specified. If the foundation is in rock, the area should be leveled as much as possible and all loose material removed.

(6) All work in the excavation should be accomplished in the dry; therefore, the dewatering system should be operated for the duration of this work. Under no circumstances should the contractor be allowed to dry an area by dumping a thick layer of dry material over it to blot the excess water. If soil exists at the foundation level and becomes saturated, it cannot be compacted. The saturated soil will have to be removed and replaced or drained sufficiently so that it can be compacted. Any frozen material in the foundation should be removed before placement of concrete footings or compacted backfill.

CHAPTER 5

BACKFILL OPERATIONS

5-1. Placement of backfill.

a. General. Backfill construction is the refilling of previously excavated space with properly compacted material. The areas may be quite large, in which case the backfilling operation will be similar to embankment construction. On the other hand, the areas may be quite limited, such as confined areas around or between and beneath concrete or steel structures and areas in trenches excavated for utility lines. Prior to construction of the backfill, the inspection personnel should become thoroughly familiar with the various classes of backfill to be used. They should be able to readily identify the materials on sight, know where the various types of material should be placed, and be familiar with the compaction characteristics of the soil types. Compaction characteristics of various soil types are discussed in appendix B.

b. Good construction practices, and problems. Problems with placement of backfill will vary from one construction project to another. The magnitude of the problems will depend on the type of materials available such as backfill, density requirements, and the configuration of the areas in which compaction is to be accomplished. Problems should be expected during the initial stages of backfill compaction unless the contractor is familiar with compaction characteristics of backfill materials. The inspector can be of great assistance to the contractor during this period by performing frequent water content and density checks. The information from these checks will show the contractor the effects of the compaction procedures being used and point out any changes that should be made.

(1) *Backfilling procedures.* Problems associated with the compaction of backfill can be minimized by following good backfilling procedures. Good backfilling procedures include: processing the material (para. 3-4) before it is placed in the excavation; placing the material in a uniformly spread loose lift of the proper thickness suited to the compaction equipment and the type of material to be used; applying the necessary compaction effort to obtain the required densities; and ensuring that these operations are not performed during adverse weather. Proper bond should be provided between each lift and also between the backfill and the sides of the excavation.

(2) *Compaction equipment, backfill material,* and *zones.* The type of compaction equipment used. to achieve the required densities will usually depend upon the type of backfill material being compacted and the type of zone in which the material is placed.

(a) In open zones, coarse-grained soils that exhibit slight plasticity (clayey sands, silty sands, clayey gravels, and silty gravels) should be compacted with either sheepsfoot or rubber-tired rollers; close control of water content is required where silt is present in substantial amounts. For sands and gravelly sands with little or no fines, good compaction results are obtained with tractor compaction. Good compaction can also be achieved in gravels and gravel-sand mixtures with either a crawler tractor or rubber-tired and steel-wheeled rollers. The addition of vibration to any of the means of compaction mentioned above will usually improve the compaction of soils in this category. In confined zones, adequate compaction of cohesionless soils in either the air-dried or saturated condition can be achieved by vibratory-plate compactors with a static weight of at least 100 pounds. If the material is compacted in the saturated condition, good compaction can be achieved by internal vibration (for example, by using concrete vibrators). Downward drainage is required to maintain seepage forces in a downward direction if the placed material is saturated to aid in compaction.

(b) Inorganic clays, inorganic silts, and very fine sands of low to medium plasticity are fairly easily compacted in open zones with sheepsfoot or rubber-tired rollers in the 15,000-pound and above wheel-load class. Some inorganic clays can be adequately compacted in confined zones using rammer or impact compactors with a static weight of at least 100 pounds provided close control of lift thickness and water content is maintained.

(c) Fine-grained, highly plastic materials, though not good backfill materials, can best be compacted in open zones with sheepsfoot rollers. Sheepsfoot rollers leave the surface of the backfill in a rough condition, which provides an excellent bond between lifts. In confined areas the best results, which are not considered good, are obtained with rammer or impact compactors.

(3) *Lift thickness.* The loose-lift thickness will depend on the type of backfill material and the compaction equipment to be used.

(a) As a general rule, a loose-lift thickness that will result in a 6-inch lift when compacted can be al-

lowed for most sheepsfoot and pneumatic-tired rollers. Cohesive soils placed inapproximately lo-inch loose lifts will compact to approximately 6 inches, and cohesionless soils placed in approximately 8-inch base lifts will compact to 6 inches. Adequate compaction can be achieved in cohesionless materials of about 12- to 15-inch loose-lift thickness if heavy vibratory equipment is used. The addition of vibration to rolling equipment used for compacting cohesive soils generally has little effect on the lift thickness that can be compacted, although compaction to the desired density can sometimes be obtained by fewer coverages of the equipment.

(b) In confined zones where clean cohesionless backfill material is used, a loose-lift thickness of 4 to 6 inches and a vibratory plate or walk-behind, dual-drum vibratory roller for compaction is recommended. Where cohesive soils are used as backfill in confined zones, use of rammer compactors and a loose-lift thickness of not more than 4 inches should be specified. Experience has shown that "two-by-four" wood rammers, or single air tampers (commonly referred to as "powder puffs" or "pogo sticks") do not produce sufficient compaction.

(4) *Density requirements.* In open areas of backfill where structures will not be constructed, compaction can be less than that required in more critical zones. Compaction to 90 percent of CE 55 maximum dry density as obtained by MIL-STD-621 should be adequate in these areas. If structures are to be constructed on or within the backfill, compaction of cohesionless soils to within 95 to 100 percent of CE 55 maximum dry density and of cohesive soils to at least 95 percent of CE 55 should be required for the full depth of backfill beneath these structures. The specified degree of compaction should be commensurate with the tolerable amount of settlement, and the compaction equipment used should be commensurate with the allowable lateral pressure on the structure. Drainage blankets and filters having special gradation requirements should be compacted to within 95 to 100 percent of CE 55 maximum dry density. Table 5-1 gives a summary of type of compaction equipment, number of coverages, and lift thickness for the specified degree of compaction of various soil types (TM 5-818-1/AFM 88-3, Chap. 7).

(5) *Cold weather.* In areas where freezing temperatures either hamper or halt construction during the winter, certain precautions can and should be taken to prevent damage from frost penetration and subsequent thaw. Some of these precautions are presented below.

(a) Placement of permanent backfill should be deferred until favorable weather conditions prevail. However, if placement is an absolute necessity during freezing temperatures, either dry, cohesionless, non-frost-susceptible materials or material containing additives, such as calcium chloride, to lower the freezing temperature of the soil water should be used. Each lift should be checked for frozen material after compaction and before construction of the next lift is begun. If frozen material is found, it should be removed; it should not be disked in place. Additives should not be used indiscriminately since they will ordinarily change compaction and water content requirements. Prior laboratory investigation should be conducted to determine additive requirements and the effect on the compaction characteristics of the backfill material.

(b) Under no circumstances should frozen material, from stockpile or borrow pit, be placed in backfill that is to be compacted to a specified density.

(c) Prior to halting construction during the winter, the peripheral surface drainage system should be checked and reworked where necessary to provide positive drainage of surface water away from the excavation.

(d) Foundations beneath structures and backfill around structures should not be allowed to freeze, because structural damage will invariably develop. Structures should be enclosed as much as possible and heated if necessary. Construction should be scheduled so as to minimize the amount of reinforcing steel protruding from a partially completed structure since steel will conduct freezing temperatures into the foundation.

(e) Permanent backfill should be protected from freezing as discussed in paragraphs 2-3h (3) and (4). Records should be made of all temporary coverings that must be removed before backfilling operations are resumed. A checklist should be maintained to ensure that all temporary coverings are removed at the beginning of the next construction season.

(f) During freezing weather, records should be kept of the elevation of all critical structures to which there is the remotest possibility of damage or movement due to frost heave and subsequent thaw. It is important that frost-free bench marks be established to which movement of any structure can be referenced. Bench marks also should be established on the structures at strategic locations prior to freezing weather.

(g) At the beginning of the following construction season and after the temporary insulating coverings are removed, the backfill should be checked for frozen material and ice lenses, and the density of the compacted material should be checked carefully before backfilling operations are resumed. If any backfill has lost its specified density because of freezing, it should be removed.

(6) *Zones having particular gradation requirements.* Zones that have particular gradation requirements include those needed to conduct and control seepage, such as drainage blankets, filters, and zones

Table 5-1. Summary of Compaction Criteria [a]

Soil Group	Soil Types		Degree of Compaction	Equipment	No. of Passes or Coverages	Comp. Lift Thick., in.	Placement Water Content	Field Control
				Fill and Backfill — Typical Equipment and Procedures for Compaction				
Pervious (Free-Draining)	GW GP SW SP	Compacted	90 to 95% of CE 55 maximum density; 75 to 85% of relative density	Vibratory rollers and compactors	Indefinite	Indefinite	Saturate by flooding	Control tests at intervals to determine degree of compaction or relative density
				Rubber-tired roller[b]	2-5 coverages	12		
				Crawler-type tractor[c]	2-5 coverages	8		
				Power hand tamper[d]	Indefinite	6		
		Semicompacted	85 to 90% of CE 55 maximum density; 65 to 75% of relative density	Rubber-tired roller[b]	2-5 coverages	14	Saturate by flooding	Control tests as noted above, if needed
				Crawler-type tractor[c]	1-2 coverages	10		
				Power hand tamper[d]	Indefinite	8		
				Controlled routing of construction equipment	Indefinite	8-10		
Semipervious and Impervious	GM GC SM SC ML CL OL OH MH CH OH	Compacted	90 to 95% of CE 55 maximum density	Rubber-tired roller[b]	2-5 coverages	8	Optimum water content	Control tests at intervals to determine degree of compaction
				Sheepsfoot roller[e]	4-8 passes	6		
				Power hand tamper[d]	Indefinite	4		
		Semicompacted	85 to 90% of CE 55 maximum density	Rubber-tired roller[b]	2-4 coverages	10	(A) Optimum water content (B) By observation; wet side-maximum water content at which material can satisfactorily operate, dry side-minimum water content required to bond particles and which will not result in voids or honeycombed material	(A) Control tests as noted above, if needed (B) Field control exercised by visual inspection of action of compacting equipment
				Sheepsfoot roller[e]	4-8 passes	8		
				Crawler-type tractor[c]	3 coverages	6		
				Power hand tamper[d]	Indefinite	6		
				Controlled routing of construction equipment	Indefinite	6-8		

Note: The above requirements will be adequate in relation to most construction. In special cases where tolerable settlements are unusually small, it may be necessary to employ additional compaction equivalent to 95 to 100% of compaction effort. A coverage consists of one application of the wheel of a rubber-tired roller or the threads of a crawler-type tractor over each point in the area being compacted. For a sheepsfoot roller, one pass consists of one movement of a sheepsfoot roller drum over the area being compacted.

a From TM 5-818-1.
b Rubber-tired rollers having a wheel load between 18,000 and 25,000 lb and a tire pressure between 80 and 100 psi.
c Crawler-type tractors weighing not less than 20,000 lb and exerting a foot pressure not less than 6-1/2 psi.
d Power hand tampers weighing more than 100 lb; pneumatic or operated by gasoline engine.
e Sheepsfoot rollers having a foot pressure between 250 and 500 psi and tamping feet 7 to 10 in. in length with a face area between 7 and 16 sq in.

susceptible to frost penetration. Drainage zones are often extremely important to the satisfactory construction and subsequent performance of the structure. To maintain the proper functioning of these zones, care must be taken to ensure that the material placed has the correct gradation and is compacted according to specifications.

c. Special problems. In open zones, compaction of backfill will not generally present any particular problems if proper compaction procedures normally associated with the compaction of soils are exercised and the materials available for use, such as backfill, are not unusually difficult to compact. The majority of the problems associated with backfill will occur in confined zones where only small compaction equipment producing a low compaction effort can be used or where because of the confined nature of the backfill zone even small compaction equipment cannot be operated effectively.

(1) Considerable latitude exists in the various types of small compaction equipment available. Unfortunately, very little reliable information is available on the capabilities of the various pieces of equipment. Depending upon the soil type and working room, it may be necessary to establish lift thickness and compaction effort based essentially on trial and error in the field. For this reason, close control must be maintained particularly during the initial stages of the backfill until adequate compaction procedures are established.

(2) Circular, elliptical and arched walled structures are particularly difficult to adequately compact backfill beneath the under side of haunches because of limited working space. Generally, the smaller the structure the more difficult it is to achieve required densities. Rock, where encountered, must be removed to a depth of at least 6 inches below the bottom of the structure and the overdepth backfilled with suitable material before foundation bedding for the structure is placed. Some alternate bedding and backfill placement methods are discussed below.

(a) One method is to bring the backfill to the planned elevation of the spring line using conventional heavy compaction equipment and methods. A template in the shape of the structure to be bedded is then used to reexcavate to conform to the bottom contours of the structure. If the structure is made of corrugated metal, allowance should be made in the grade for penetration of the corrugation crests into the backfill upon application of load. Success of this method of bedding is highly dependent on rigid control of grade during reexcavation using the template. This procedure is probably the most applicable where it is necessary to use a cohesive backfill.

(b) Another method of bedding placement is to sluice a clean granular backfill material into the bed after the structure is in place. This method is particularly adapted to areas containing a maze of pipes or conduits. Adequate downward drainage, generally essential to the success of this method, can be provided by sump pumps or, if necessary, by pumping from well points. Sluicing should be accompanied by vibrating to ensure adequate soil density. Concrete vibrators have been used successfully for this purpose. This method should be restricted to areas where conduits or pipes have been placed by trenching or in an excavation that provides confining sides. Also, this method should not be used below the groundwater table in seismic zones, since achieving densities high enough to assure stability in a seismic zone is difficult.

(c) Another method is to place clean, granular bedding material with pneumatic concrete equipment under the haunches of pipes, tunnels, and tanks. The material is placed wet and should have an in-place water content of approximately 15 to 18 percent. A nozzle pressure of 40 pounds per square inch is required to obtain proper density. Considerable rebound of material (as much as 25 percent by volume when placed with the hose nozzle pointed vertically downward and 50 percent with the nozzle pointed horizontally) occurs at this pressure. Rebound is the material that bounces off the surface and falls back in a loose state. However, the method is very satisfactory if all rebound material is removed. The material can be effectively removed from the backfill by dragging the surface in the area where material is being placed with a flat-end shovel. Two or three men will be needed for each gunite hose operated.

(d) For structures and pipes that can tolerate little or no settlement, lean grouts containing granular material and various cementing agents, such as portland cement or fly ash, can be used. This grout may be placed by either method discussed in (b) and (c) above. However, grouts may develop hard spots (particularly where the sluice method is used that could cause segregation of the granular material and the cementing agent), which could generate stress concentrations in rigid structures such as concrete pipes. Stress concentrations may be severe enough to cause structural distress. If lean grouts are used as backfill around a rigid structure, the structure must be designed to withstand any additional stress generated by possible hard spots.

5-2. Installation of instruments. Installation of instrumentation devices should be supervised, if not actually done, by experienced personnel from within the Corps of Engineers or by firms that specialize in instrumentation installation. The resident engineer staff must be familiar with the planned locations of all instruments and necessary apparatus or structures (such as trenches and terminal houses) so that necessary arrangements and a schedule for installation can be made with the contractor and with the office or firm that will install the devices. Inspectors should inspect any instrumentation furnished and installed by the contractor. Records must be made of the exact locations and procedures used for installation and initial observations. Inspectors should ensure that necessary extensions are added for the apparatus (such as lead lines and piezometer tubes) installed within the backfill as the backfill is constructed to higher elevations. Care must be used in placing and compacting backfill around instruments that are installed within or through backfill. Where necessary to prevent damage to instruments, backfill must be placed manually and compacted with small compaction equipment such as rammers or vibratory plates.

5-3. Postconstruction distress. Good backfill construction practices and control will minimize the potential for postconstruction distress. Nevertheless, the possibility of distress occurring is real, and measures must be taken to correct any problems before they become so critical as to cause functional problems with the facility. Therefore, early detection of distress is essential. Some early signs of possible distress include: settlement or swelling of the backfill around the structure; sudden or gradual change of instrumentation data; development of cracks in structural walls; and adverse seepage problems. Detailed construction records are important for defining potential distress areas and assessing the mechanisms causing the distress.

CHAPTER 6

SPECIFICATION PROVISIONS

6-1. General.

a. The plans and specifications define the project in detail and show how it is to be constructed. They are the basis of the contractor's estimate and of the construction contract itself. The drawings show the physical characteristics of the structure, and the specifications cover the quality of materials, workmanship, and technical requirements. Together they form the guide and standard of performance that will be required in the construction of the project. Once the contract is let, the plans and specifications are binding on both the Contracting Officer and the contractor and are changed only by written agreement. For this reason, it is essential that the contractor and the Contracting Officer's representative anticipate and resolve differences that may arise in interpreting the intent and requirements of the specifications. The ease with which this can be accomplished will depend on the clarity of the specifications and the background and experience of the individuals concerned. Understanding of requirements and working coordination can be improved if unusual requirements are brought to the attention of prospective bidders and meetings for discussion are held prior to construction. Situations will undoubtedly arise that are not covered by the specifications, or conditions may occur that are different from those anticipated. Close cooperation is required between the contractor and the inspection personnel in resolving situations of this nature; if necessary, to be fair to both parties a change order should be issued.

b. Preparation of contract specifications is easier if an outline of general requirements is available to the specification writer. However, it would be virtually impossible to prepare a guide specification that anticipates all problems that may occur on all projects. Therefore, contract specifications must be written to satisfy the specific requirement of each project. Some alternate specification requirements that might be considered for some projects are discussed below.

6-2. Excavation. The section of the specifications dealing with excavation contains information on drainage, shoring and bracing, removal and stockpiling, and other items, and refers to the plans for grade requirements and slope lines to be followed in excavating overburden soils and rock.

a. Drainage. For some projects the specifications will require the contractor to submit a plan of his excavation operations to the Contracting Officer for review. The plans and specifications will require that the excavation and subsequent construction and backfill be carried out in the dry. To meet this requirement, a dewatering system based on the results of groundwater studies may be included in the plans. Also, for some projects the specifications may require the contractor to submit his plan for controlling groundwater conditions. The specifications should likewise indicate the possibility of groundwater conditions being different from those shown in the subsurface investigation report due to seasonal or unusual variations or insufficient information, since the contractor will be held responsible for controlling the groundwater flow into the excavation regardless of the amount. To this end, the specifications should provide for requiring the contractor to submit a revised dewatering plan for review where the original dewatering plan is found to be inadequate.

b. Shoring and bracing. The specifications either will require the contractor to submit for review his plans for the shoring and bracing required for excavation or will specify shoring and bracing required by subsurface and groundwater conditions and details of the lines and grades of the excavation. In the latter case, the contractor may be given the option to submit alternate plans for shoring and bracing for review by the Contracting Officer. The plans will present the necessary information for the design of such a system if the contractor is allowed this option.

c. Stockpiling. Provisions for stockpiling materials from required excavation according to type of backfill may or may not be included in the specifications. Generally, procedures for stockpiling are left to the discretion of the contractor, and a thorough study should be made to substantiate the need for stockpiling before such procedures are specified. There are several conditions under which inclusion of stockpiling procedures in the specifications would be desirable and justified. Two such conditions are discussed in the following paragraphs.

(1) Under certain conditions, such as those that existed in the early stages of missile base construction where time was an important factor, it may be necessary or desirable to award contracts for the work in phases. As a result, one contractor may do the excavat-

ing and another place the backfill. It is probable that the excavation contractor will have little or no interest in stockpiling the excavated materials in a manner conducive to good backfilling procedures. When such a situation can be foreseen, the specifications should set forth stockpiling procedures. The justification for such requirements would be economy and optimum use of materials available from required excavation as backfill.

(2) The specifications will contain provisions for removing, segregating, and stockpiling or disposing of material from the excavation and will refer to the plans for locations of the stockpiles. The subsoil conditions and engineering characteristics requirements may state that the specifications must be quite definite concerning segregation and stockpiling procedures so that the excavated materials can be used most advantageously in the backfill. The specification may require that water be added to the material or the material be aerated as it is stockpiled to approximate optimum water content, that the stockpile be shaped to drain and be sealed from accumulation of excess water, and that the end dumping of material on the stockpile be prohibited to prevent segregation of material size or type along the length of the stockpile.

(3) An alternative to this latter action would be to specify the various classes of backfill required and leave the procedure for stockpiling the materials by type to the discretion of the contractor. In this case, the contractor should be required to submit a detailed plan for excavating and stockpiling the material. The plan should indicate the location of stockpiles for various classes of backfill so that the material can be tested for compliance with the specifications. The contractor may elect to obtain backfill material from borrow or commercial sources rather than to separate and process excavated materials. Then the specifications should require that stockpiles of the various classes of needed backfill be established at the construction site in sufficient quantity and far enough in advance of their use to allow for the necessary testing for approval unless conditions are such that approval of the supplier's stockpile or borrow source can be given.

6-3. Foundation preparation. The provisions for preparation for structures will generally not be grouped together in the specifications but will appear throughout the earthwork section of the specifications under paragraphs on excavation, protection of foundation materials, backfill construction, and concrete placement. When a structure is to be founded on rock, the specifications will require that the rock be firm, unshattered by blasting operations, and not deteriorated from exposure to the weather. The contractor will be required to remove shattered or weathered rock and to fill the space with concrete.

a. Specifications for structures founded on soil require the removal of all loose material and all unsuitable material, such as organic clay or silt, below the foundation grade. When doubt exists as to the suitability of the foundation materials, a soils engineer should inspect the area and his recommendations should be followed. When removal of rock material below the planned foundation level is required, the overexcavation will usually require filling with concrete. The specifications also require dewatering to the extent that no backfill or structural foundation is placed in the wet.

b. Specifications for preparation of the soil foundation to receive backfill require removing all debris and foreign matter, making the area generally level, and scarifying, moistening, and compacting the foundation to a specified depth, generally 12 inches. Specific provisions may or may not be given with respect to leveling procedures.

6-4. Backfill operations. The specifications define the type or types of material to be used for backfill construction and provide specific instructions as to where these materials will be used in the backfill, The percentage of CE 55 maximum dry density to be obtained, determined by a designated standard laboratory compaction procedure, will be specified for the various zones of backfill. The maximum loose-lift thickness for placement will also be specified. Because of the shape of the compaction curve (see discussion of compaction characteristics in Section B-1, app. B), the degree of compaction specified can be achieved only within a certain range of water contents for a particular compaction effort. Though not generally specified in military construction, the range of water contents is an important factor affecting compaction.

a. The specifications sometimes stipulate the characteristics and general type of compaction equipment to be used for each of the various types of backfill. Sheepsfoot or rubber-tired rollers, rammer or impact compactors, or other suitable equipment are specified for fine-grained, plastic materials. Noncohesive, free-draining materials are specified to be compacted by saturating the material and operating crawler-type tractor, surface or internal vibrators, vibratory compactors, or other similar suitable equipment. The specifications generally will prohibit the use of rock or rock-soil mixtures as backfill in this type of construction. However, when the use of backfill containing rock is permitted, the maximum size of the rock is given in the specifications along with maximum lift thickness, loading, hauling, dumping, and spreading procedures, type of compaction equipment, and method of equipment operation. The specifications should prohibit the use of rock or rock-soil mixtures as backfill in areas where heavy equipment cannot operate. Rock-soil mixtures having greater than 8 to 10 percent binder should be prohibited in all areas. In the case of backfill containing rock, the density is not generally specified. Obtaining adequate density is usually achieved by specifying the compaction procedures. The specifications may require that these procedures be developed in field test sections.

b. Specifications may also require specific equipment and procedures to ensure adequate bedding for round-bottom structures such as tunnels, culverts, conduits, and tanks. Procedures normally specified for placement of bedding for these types of structures are discussed in paragraph 5-1c (2).

c. The specifications will state when backfill may be placed against permanent concrete construction with respect to the time after completion; this time period is usually from 7 to 14 days. To provide adequate protection of the structures during backfill construction, the specifications require that the backfill be built up symmetrically on all sides and that the area of operation of heavy equipment adjacent to a structure be limited. Also, the minimum thickness of compacted materials to be placed over the structures by small compaction equipment, such as vibratory plate or rammer type, will be specified before heavy equipment is allowed to operate over the structure. The specifications require that the surface of the backfill be sloped to drain at all times when necessary to prevent ponding of water on the fill. The specifications also provide for groundwater control, so that all compacted backfill will be constructed in the dry. Where select, free-draining, cohesionless soils of high permeability are required in areas where compaction is critical, the specifications list gradation requirements. Gradation requirements are also specified for materials used for drains and filters.

d. Unusually severe specification requirements may be necessary for backfill operations in confined areas. The requirements may include strict backfill material-type limitation, placement procedures, and compaction equipment.

e. It is not the policy of the Government to inform the contractor of ways to accomplish the necessary protection from freezing temperatures. However, to ensure that adequate protection is provided, it may be necessary to specify that the contractor submit detailed plans for approval for such protection.

CHAPTER 7

CONSTRUCTION CONTROL

7-l. General. The heterogeneous nature of soil makes it the most variable construction material with which engineers are required to work. Research in soil mechanics and experience gained recently in constructing large earth embankments have provided additional knowledge toward understanding and predicting the behavior of a soil as a construction material. However, only with careful control can engineers ensure that backfill construction will satisfactorily fulfill the intended functions. Both the contractor and the Government share dual responsibility in achieving a satisfactory product. The contractor is responsible for inspection and tests through his quality control system. The Government's responsibility is assuring that the contractor's quality control system is achieving the desired results through its quality acceptance system.

a. *Contractor quality control.* The contractor is responsible for all of the activities that are necessary to ensure that the finished work complies with the plans and specifications to include quality control requirements, supervision, inspection, and testing. The construction contract special provisions explain the quality control system that the contractor must establish; the technical provisions specify the construction requirements with the tests, inspections, and submittals that the contractor must follow to produce acceptable work.

(1) Prior to construction, the contractor must submit for approval by the Contracting Officer his plan for controlling construction quality. The plan must contain all of the elements outlined in the special provisions and demonstrate a capability for controlling all of the construction operations specified in the technical provisions. The plan must include the personnel (whether contractor's personnel or outside private firm) and procedures the contractor intends to use for controlling quality, instructions and authority he is giving his personnel, and the report form he will use. The plan should be coordinated with his project construction schedule.

(2) During construction, the contractor is responsible for exercising day by day construction quality control in consonance with his accepted control plan. He must maintain current records of his quality control operations. Reports of his operations must be submitted at specified intervals and be in sufficient detail to identify each specific test.

(3) The prime contractor is responsible for the quality control of all work including any work by sub contractors.

b. *Corps acceptance control.* In contrast to the contractor's quality control, the Government is responsible for quality assurance, which includes: the checks, inspections, and tests of the products that comprise the construction; the processes used in the work; and the finished work for the purpose of determining whether the contractor's quality control is effective and he is meeting the requirements of the contract. These activities are to assure that defective work or materials are not incorporated in the construction.

c. *Coordination between Government and contractor.* The contractor's quality control does not relieve the Contracting Officer from his responsibility for safeguarding the Government's interest. The quality assurance inspections and tests made by the Government may be carried out at the same time and adjacent to the contractor's quality control operations. Quality control and quality assurance supplement one another and assist in avoidance of construction deficiencies or in early detection of such deficiencies when they can be easily corrected without requiring later costly tear out and rebuild. The remainder of this chapter discusses the Corps quality assurance activities.

7-2. Corps acceptance control organization.

a. *General.* Difficulties in construction of a compacted backfill can be attributed at least in part to inexperience of the control personnel in this phase of construction work or lack of emphasis as to the importance of proper procedure and control. Since it is essential that policies with regard to control be established prior to the initiation of construction, thorough knowledge of the capabilities of the control organization and of the intent of the plans and specifications is required. Control is achieved by a review of construction plans and specifications, visual inspection of construction operations and procedures, and physical testing. A well-organized, experienced inspection force can mean the difference between a good job and a poor one. A good field inspection organization must be staffed and organized so that inspection personnel and laboratory technicians are on the job when and where they are needed. Thus the organization must have knowledge of the construction at all times.

b. Inspection personnel training program. Prior to construction, the training, guidance, and support required to ensure that the inspection force is fully competent should be determined. If experience is lacking, training and supervision become more important and necessary.

(1) The training program for earthwork inspection personnel should consist of both classroom and field instruction. During the classroom sessions, the specifications should be studied, discussed, and interpreted as to the intent of the designer. The critical areas of compaction should be pointed out as well as the location of zoned and transitional areas. The inspection personnel should be instructed on the various zones of backfill, types of backfill, density requirements, and classification and compaction characteristics for each class of backfill. Inspection personnel should also be instructed as to approved sources of borrow for each type of backfill and borrow pit operations, such as loading procedures to provide uniform materials and prewetting to provide uniform moisture. The various types of backfill should be studied, so inspection personnel can recognize and readily identify these materials. Jar samples may be furnished for later reference and comparison; preferably these should be samples of the particular soils on which lab oratory compaction tests were performed in design studies. Instructions should be given as to water content control, lift thickness, and most suitable compaction equipment for each type of backfill. Inspection personnel should be capable of recommending alternate procedures to achieve the desired results when the contractor's procedure is unsuccessful.

(2) Inspection personnel should be made aware of the importance of their work by explaining the engineering features of the design on which the construction requirements are based. Every opportunity should be taken to assemble the inspection force for discussion of construction problems and procedures so that all can gain knowledge from the experience of others. Inspection personnel should be kept informed of all decisions and agreements pertinent to their work that are made at higher levels of administration. They should be advised of the limits of their authority and contact with contractor personnel.

(3) Field training of inspection personnel should include observation of their control techniques and additional instruction on elements of fieldwork requiring correction. Inspection personnel should be instructed in the telltale signs that give visual indications whether sufficient compaction is being applied and proper water content is being maintained (see para 7-5b *(4)* and EM 1110-2-1911 for discussion of telltale signs). They should develop the ability to determine from visual observations (based on correlations with tests on the project) that satisfactory compaction is being obtained so that considerable emphasis can be placed on such methods as a control procedure rather than relying on field tests alone. Inspection personnel should be capable of selecting locations at which field density and moisture determinations should be made. To meet this requirement they must be present almost continuously during compaction operations to observe and note areas where tests appear to be needed. Laboratory technicians should be made available to perform tests so that the inspection personnel will be free to observe the placement and compaction process on another portion of the backfill. Inspection personnel should be able to use expedient quick-check field apparatus such as the Proctor and hand-cone penetrometers (sec. B-3, app. B) to make a rapid check of the field water content to supplement acceptance testing and to serve as a guide in determining areas that should be tested. Inspection personnel should also be well versed in normal testing procedures so they can properly supervise testing or explain the procedure in case they are questioned by contractor personnel.

(4) It is necessary and important that inspection personnel ascertain their authority and responsibility at an early stage in the construction. Their policy should be one of firmness coupled with practicality. The quality of the work should not be compromised; however, unreasonable requirements and restrictions should not be placed on the contractor in enforcing the specifications. If the inspection personnel know their job and are fair and cooperative in dealing with the contractor, they will gain his or her respect and cooperation and be able to efficiently carry out their responsibilities.

b. Field laboratory facilities. The field laboratory is used for routine testing of construction materials (such as gradation, water content, compaction, and Atterberg limits tests) and for determining the adequacy of field compaction. The data obtained from tests performed by inspection personnel serve as a basis for determining and ensuring compliance with the specifications, for obtaining the maximum benefit from the materials being used, and for providing a complete record of the materials placed in every part of the project. The size and type of laboratory required are dependent on the magnitude of the job and the type of structures being built. Where excavation and backfill construction are extensive and widespread, the establishment of a centrally located field laboratory is generally beneficial. This laboratory in addition to having equipment for on-the-job control will provide a nucleus of experienced soils engineers or engineering technicians for general supervision and training of inspection personnel. Field control laboratories on the sites may be established as necessary during the excavation and backfill phases of the construction. They may be set up in an enclosed space allocated by the project officer or in mobile testing laboratories, such as pickup trucks with a camper and equipped with the necessary testing equipment for performance of field density tests, water content tests, and gradation tests. Another possibility is the use of large portable boxes in which equipment is stored. When special problems arise and the required testing equipment is not available at the site laboratory, the testing should be performed at the central laboratory.

7-3. Excavation control techniques. Control to obtain a satisfactory excavation is exercised by enforcement of approved plans, visual observations, a thorough knowledge of the contractor's plan of operation and construction schedule, the dimensions and engineering features of the structure(s) to be placed in the excavation, and vertical and horizontal control measurements to ensure that the proper line and grade requirements are met.

7-4. Foundation preparation control techniques. The main control technique for ensuring proper foundation preparation is visual inspection. Prior to backfill placement, all uncompacted fill should be removed from those portions of the excavation to be backfilled. The items included are road fills, loose material that has fallen into overexcavated areas adjacent to foundations, and construction ramps other than those required for access to the excavation. Identification of such items will be easier if the inspection personnel have charted the items on the plans as they *were* created, since they are not always easily discernible by visual inspection. It is desirable to control earth backfill placed in foundation leveling operations by water content and density tests. Care should be exercised to ensure that all subdrains required in the foundation are protected by filters and transitional zones that are adequate to prevent infiltration of fines from the surrounding backfill that might otherwise clog the drains and undermine structures.

7-5. Backfill quality acceptance control. The necessary authority to assure that compacted backfill is in compliance with the specifications is given in the specifications. The control consists of inspecting and testing materials to be used, checking the amount and uniformity of soil water content, maintaining the proper thickness of the lifts being placed, and determining the dry unit weight being obtained by the compaction process. While control consists of all of these things, good inspection involves much more.

a. Inspection activities. One of the best inducements to proper placement and compaction of backfill is the presence of the inspection personnel when backfill is being placed. However, to be of value the inspector must know his job. He should be familiar with all aspects of backfill operation, such as selection and availability of materials, processing, hauling, compaction, and inspection procedures. Some of the most common deficiencies in inspection personnel activities are as follows:

(1) Failing to enforce specification requirements for preparation of the area for backfill. Often temporary fills, the working platform, debris, and other undesirable materials are left in the excavation causing weak areas and resulting in greater consolidation in the backfill.

(2) Failing to be cognizant of detailed site-adapted plans for stockpiling and placing backfill at specific locations. Without knowledge of these plans, inspection personnel are sometimes forced to make engineering decisions beyond their capability, such as on-the-site approval of a new material or mixture of materials, and stockpile locations.

(3) Allowing processing of backfill material and adjustment of water content on the fill that should have been accomplished prior to placement. The results are the segregation of grain sizes and the nonuniform distribution of water content. All major processing, including crushing, raking, mixing, and adjusting of water content, must be done in the stockpile or borrow areas.

(4) Allowing lift thickness that is inconsistent with equipment capabilities and thicker than that allowed by specifications. Field density determinations will not necessarily detect this inconsistency.

(5) Allowing construction of backfill slopes that are too steep to obtain the full effect of compaction equipment.

(6) Failing to require that the fill be built up uniformly in a well-defined pattern. Since the contractor's next move cannot be predicted, the inspection personnel cannot adequately plan their operations, and it is difficult to determine which areas of backfill have been tested and approved when the backfill is built up in an unorganized manner.

(7) Allowing segregation of coarse-grained, noncohesive materials. This condition is caused by improper hauling, dumping, and spreading techniques.

(8) Allowing the use of compaction equipment not suited to material being compacted.

(9) Failing to perform sufficient field density testing in critical areas.

(10) Allowing material that is too wet or too dry to be compacted.

(11) Failing to require that intermediate backfill surfaces be shaped to drain during backfilling at other locations.

b. Inspection requirements. To properly control and inspect backfill operations, the inspection personnel must keep informed of the construction schedule at all times and be at the site where backfill is being placed.

The inspection personnel must be thoroughly familiar with *every* aspect of the earthwork section of the specifications and know boundary locations for the various zones of material. They should be able to readily identify the various classes of backfill and know their compaction characteristics and requirements. Good inspection personnel will also know the compaction capabilities of various types of equipment and the materials that each type is best suited to compact.

(1) To maintain adequate control of compaction operations, a staff of earthwork inspectors and laboratory personnel commensurate with the importance of the work and size of the operation is essential. There should be at least one inspector at the fill when backfill is being placed. His sole duty should be inspection of earthwork. Although he should be familiar with the testing procedures and capable of directing testing operations and selecting locations for testing, he should not be required to perform the tests. Laboratory technicians should be available for this purpose. A discussion of the methods and procedures for field density testing of the compacted fill is contained in section B-3, appendix B.

(2) The specifications should require that necessary processing of backfill materials be performed in the stockpile or borrow pit. Processing includes raking or crushing to remove oversize material, mixing to provide uniformity, and watering or aerating to attain a water content approximating optimum for compaction. An earthwork inspector is required at the stockpile or borrow pit to enforce these provisions. In addition, this inspector has the duties of classifying the materials, determining their suitability, and directing the zone of backfill in which they are to be placed. He is charged with the responsibility of seeing that the contractor uses the materials available for backfill in the most advantageous manner. Generally, the stockpile or borrow pit inspector relies upon visual inspection and experience to exercise control over these operations. Occasionally, he may require that appropriate tests be performed to confirm his judgment.

(3) The duties of the backfill inspector consist of checking the material for suitability as it is placed on the fill and spread, ensuring that any oversize material, roots, or trash found in the material is removed, checking the thickness of the lift prior to compaction, checking for uniformity and amount of water content, observing compaction operations, and directing or monitoring testing of the compacted material for compliance with density and water content requirements.

(4) There are many techniques and rule-of-thumb procedures that the earthwork inspector can and must resort to for assistance in his work. A few of them are discussed below; others can be ascertained by inspectors meeting together to discuss problems and corrective action.

(a) The thickness of loose lifts can be checked easily by probing with a calibrated rod just prior to compaction. Compaction of lifts too thick for the equipment will not normally be detected by performing density tests on the lift, since adequate compaction may be indicated by a test made in the upper portion of the lift and the lower portion may still have too low a density. It is therefore a requisite that lift thickness be controlled on a loos&thickness basis prior to compaction

(b) Checks for proper bond between layers can be made by digging through a lift after compaction and using a shovel to check this bond. If the soil can be separated easily along the plane between lifts, sufficient bond is not being provided. Backfill materials should not be placed on dried or smooth surfaces, as bond will be difficult to obtain.

(c) Inspection personnel should be thoroughly aware of areas where compaction is critical. These areas are the confined spaces around and adjacent to structures that are not accessible to the rolling and spreading equipment. Although the volume of backfill is usually rather small in these areas, a much higher frequency of check testing for density is required as well as a careful check of the quality and water content of the materials to be placed.

c. Compaction control tests. Compaction tests will have been performed on representative specimens obtained from exploratory sampling prior to construction. The selection of suitable backfill material are in fact generally made based on these and other tests. At least during the early phases of the backfill operation, density requirements are based on these and in some cases additional preconstruction compaction tests. Conditions may develop that require compaction tests during backfill operations to establish new density requirements. Generally, these changes are the results of backfill material deviations. The need for additional control tests may be ascertained from visual observation and changes in compaction characteristics during field compaction. For most backfill materials, quality acceptance compaction control tests must be performed according to the CE 55 test procedure specified in MIL-STD-621, the equivalent procedure in ASTM D 1557, or the two-point test procedure (app B). For some cohesionless soils where higher maximum dry densities can be obtained using the vibratory (relative density) compaction procedure, the specifications may require the vibratory test procedures as specified in EM 1110-2-1906 or ASTM D 2049. Field compaction control and rapid compaction check tests that are used to supplement the Corps acceptance control tests are discussed in appendix B.

d. Field moisture-density control techniques. Moisture-density control is the most important phase of backfill operations. The success of ensuring required backfill density often determines the functional service of the imbedded structure. Good control involves many techniques. An experienced inspector will not rely on any one technique but from experience will base his control on a combination of techniques. Moisture-density control techniques may be grouped into three categories: rule-of-thumb techniques, and indirect and direct moisture density measurements.

(1) *Rule-of-thumb methods.* Rule-of-thumb techniques are derived from experience and are based on visual observations and feel of the material. A rule-of-thumb for judging if the water content of a fine-grained, plastic material is near the optimum water content consists of rolling the material between the hands until it forms a thread approximately 1/8 inch in diameter. If the material at this stage tends to crack or crumble, it is in the proper water content range for compaction. It will be recognized that this method is similar to the method of determining the plastic limit of a soil. The methods are similar because the optimum water content for compaction of a cohesive soil roughly approximates the plastic limit of the soil.

(a) Another good indication of whether the proper water content has been obtained can be determined by observing the compacting equipment. When a sheepsfoot roller is being used and the soil sticks to the roller to any great extent, the material is being rolled too wet for the equipment being used; at optimum water content it may be expected that a few clods will be picked up by the roller but a general sticking will not occur. If the compacted fill does not definitely spring (noticeable to visual observation) under hauling and compaction equipment, it is probable that several lifts of fill have been placed too dry. The roller should roll evenly over the surface of the backfill if water content is uniform throughout the lift and should not ride higher on some portions of the backfill than on others. If on the first pass of a rubber-tired roller the tires sink to a depth equal to or greater than one-half the tire width, if after several passes the soil is rutting excessively, or if at any time during rolling the weaving or undulating (as opposed to normal "springing" of the surface) of the material is taking place ahead of the roller, either the tire pressure is too high or the water content of the material is too high. On the other hand, if the roller tracks only very slightly or not at all and leaves the surface hard and stiff after several passes, the soil is probably too dry. For most soils having proper water contents, the roller will track evenly on the first pass and the wheels will embed 3 to 4 inches. Some penetration should be made into soil at its proper water content, though the penetration will decrease as the number of passes increases. After several passes of a sheepsfoot roller, the roller should start walking out if adequate and efficient compaction is being obtained. Walking out means the roller begins bearing on the soil through its feet only-the drum is riding a few inches above the soil surface. If the roller walks out after only a few passes, the soil is probably too dry; if it does not walk out but continues churning up the material after the desired number of passes, the soil is too wet or the foot contact pressure is too high.

(b) A trained inspector will spend some time in the field laboratory, performing several compaction tests on each type of backfill material to become familiar with the differences in looks, feel, and behavior and learning to recognize when they are too dry or too wet, as well as when they are at optimum water content.

(2) *Indirect methods.* Indirect methods of determining the density and water content involve measurement of the characteristic of the material that has been previously correlated to the maximum density and optimum water content. These methods of measuring in-place density and water content can usually effect a more detailed control of a job than can be accomplished by direct methods alone because they can provide quicker determinations. However, no indirect method should ever be used without first checking and calibrating it with results obtained from direct methods, and periodic checks by direct methods should be made during construction. Indirect methods include the use of the nuclear moisture-density meter, the Proctor penetrometer (often referred to as the "Proctor needle"), the hand cone penetrometer, and in the hands of an experienced inspector even a shovel.

(a) The nuclear moisture-density method conducted in accordance with ASTM D 2922 (for density determination) and ASTM D 3017 (for water content determination) is the only indirect control method used for the Corps quality acceptance control. The method provides a relatively rapid means for determining both moisture content and density. Of the three methods presented in ASTM D 2922, Method B - Direct Transmission is the best suited for a compacted lift thickness exceeding approximately 4 inches. The nuclear moisture-density method is discussed in more detail in section B- 3, appendix B.

(b) Penetrometers, such as the Proctor and hand cone penetrometers, are useful under certain conditions for approximating density. However, both methods require careful calibration using soils of known density and water content and considerable operating experience. Even then, the results may be questionable because nonuniform water content (in fine-grained material) *or* a small piece of gravel can affect the penetration resistance. Penetrometers, therefore, are not recommended for general use in compaction control; however, they can be a very useful tool in supplementing the inspector's visual observations and providing a general guide for detecting areas of doubtful compac-

tion. The procedure using the Proctor penetrometer for determining the relation between wet density, penetration resistance, and water content is described in ASTM D 1558 and in section B-3, appendix B. The hand cone penetrometer procedure also is discussed in section B-3.

(c) Many inspectors in the past have had good success in estimating density by simply observing the resistance of the compacted soil to penetration by a spade. This method requires considerable experience and is useful only in detecting areas that might require further density tests.

(3) *Direct methods.* Direct field density determination consists of volume and weight measurements to determine the wet density of in-place backfill and water content measurements to determine in-place water contents and dry densities. The three methods used for the Corps quality acceptance density determination are: (a) the sand-cone method according to MIL-STD-621 (Method 106) and ASTM D 1556; (b) the rubber-balloon method according to ASTM D 2167; and for soft, fine-grained cohesive soils, the drive-cylinder method according to MIL-STD-621 (Method 102) and ASTM D 2937. In addition to the approved methods, a method sometimes employed to measure densities of coarse-grained cohesionless material consists of the large-scale, water-displacement method. The large-scale, water-displacement method is discussed in EM 1110-2-1911. The sand cone method is considered to be the most reliable method and is recommended as the proof or calibration test for calibrating other methods such as the nuclear density method. The direct field density methods are discussed in section B-3, appendix B.

e. Water content by microwave oven. The biggest problem associated with both field compaction tests and in-place density and water content control tests is the length of time required to determine water content. Conventional ovendrying methods require from 15 to 16 hours for most fine-grained cohesive soils. In some cases, such as confined zones, the contractor may have placed and compacted several layers of backfill over the layer for which density tests were made before quality acceptance test data are available. Even though the contractor places successive layers at his own risk, a rapid turn around between testing and test results could prevent costly-tear out and recompact procedures. Drying specimens in microwave ovens offers a practical means for rapid determination of water content for most backfill materials if properly conducted. Times required for drying in a microwave oven are primarily governed by the mass of water present in the specimen and the power-load output of the oven. Therefore, drying time must be calibrated with respect to water content and oven output. Also, it may not be possible to successfully dry certain soils containing gypsum or highly metallic soils such as iron ore, aluminum rich soils, and bauxite. Details of the microwave-oven method used for rapid determination of soil water content is given in section B-3, appendix B.

f. Frequency and *location of quality acceptance density tests.* Acceptance control testing should be more frequent at the start of backfill placement. After compaction effort requirements have been firmly established and inspection personnel have become familiar with materials behavior and acceptable compaction procedures, the amount of testing can be reduced. Many factors influence the frequency and location of tests. The frequency will be dependent on the type of material, adequacy of the compaction procedures, and how critical the backfill being compacted is in relation to the performance of the structure.

(1) A systematic testing program should be established at the beginning of the job. Acceptance control tests laid out in a predetermined manner are usually designated as routine control tests and are performed either at designated locations or at random representative locations, no matter how smoothly the compaction operations are being carried out. A routine acceptance control test should be conducted for at least every 200 cubic yards of compacted backfill material in critical areas where settlement of backfill may lead to structural distress and for at least every 500 cubic yards in open areas not adjacent to structures.

(2) In addition to routine acceptance control tests, tests should be made in the following areas: where the inspector has reason to doubt the adequacy of the compaction; where the contractor is concentrating fill operations over relatively small areas; where small compaction equipment is being used such as in confined areas; and where field instrumentation is installed, mainly around riser pipes.

g. Errors in field density measurements. Density and water content measurements determined by any of the methods discussed above are subject to three possible sources of errors. The three categories of possible error sources are human errors, errors associated with equipment and method, and errors attributed to material property behavior.

(1) Human error includes such factors as improper equipment readings and following improper test procedures. Human errors are not quantitative. However, errors of this type may be minimized by utilizing competent testing personnel familiar with testing procedures.

(2) There are two types of possible errors related to test equipment. One type of error relates to the sensitivity of the equipment with respect to its capability to accurately measure the true density or water content. Sensitivity errors are quantitative only in the sense that limiting ranges of possible error can be es-

tablished. An example of sensitivity error would be the nuclear density device that is capable of determining densities only to within 3 to 5 pounds per cubic foot of true density. The second type of error relates to constant deviations between measured and true density. Constant deviation errors can be corrected by calibrating test equipment against known densities.

(3) Material property errors are primarily limited to density determinations using either the sand-cone or the rubber-balloon method in sands. When a soil is physically sampled during the process of conducting an in-place density measurement using these two methods, a shearing action of the soil is unavoidable. Cohesionless soils are sensitive to volume change during shear, dense sands tend to expand and increase in volume, and loose sands tend to contract and decrease in volume. Errors of this nature cannot be quantified or detected in the field. However, such errors can be as high as 6 percent for sand using the rubber-balloon method for volume measurements.

h. Acceptance or rejection. The inspection personnel have the responsibility to accept or reject the backfill or any part thereof based on the quality acceptance control tests. On the surface, this task seems straightforward. If a segment of the backfill tested at several locations for acceptance passes or fails to pass minimum requirements by a wide margin, then it is generally safe to assume that the backfill within that segment either has or has not been adequately compacted and the acceptance or rejection of that segment can be made based on the test results. On the other hand, if the tests indicated insufficient compaction, the size of the affected area may be questionable; it is possible that the test(s) represents only a small area and the lift being tested may be sufficiently compacted elsewhere. In view of the possible errors associated with control tests, tests that indicate marginal passage or failure should be treated with caution. The borderline case requires a close look at several factors: how the result compares with all previous results on the job, how much compaction effort was used and did it differ from previous efforts, how does this particular material compare with previously compacted materials, the importance of the lift location in relation to the entire structure, and the importance of obtaining the correct density or water content from the designer's standpoint. When all factors have been considered, a decision is made as to which corrective measures are required. What makes such decisions so difficult is that they must be made immediately; time will not permit the problem to be pondered. Discussion with design engineers prior to beginning compaction operations may help in the evaluation of many of these factors.

(1) On jobs requiring large volumes of backfill, it may be advantageous to base the decision to accept or reject on statistical methods. Statistical methods require separate analysis for each backfill material type and compaction effort, complete random selection of test locations, and a large number of control tests as compared with the conventional decision method. In addition, statistical methods include water content control, which is not normally included in military specifications.

(2) The theory and details concerning the application of statistical methods for compaction control are well developed. Figure 7-1 shows a sequential inspection plan example of how the end results of a statistical analysis might be used for the purpose of acceptance or rejection. In this example, it was established by statistical analysis that adequate densities could probably be obtained with reasonable confidence by a given compaction effort for desired water contents ranging from 3 percentage points below to 1 percentage point above optimum. It was also established that a density corresponding to 95 percent of CE 55 maximum dry density was the minimum acceptable density based on required engineering performance of the backfill. The sequential inspection plan consists of examining, in sequence, single tests that are obtained at random from a segment of the backfill being considered for acceptance or rejection and, for each test, making one of three possible decisions: the segment is acceptable; the segment is unacceptable; and the evidence is not sufficient for either decision without too great a risk of error as indicated by the retest block in figure 7-1(a). The reject areas in figure 7-1 indicate conditions that cannot be corrected by additional rolling. The material must be replaced in thinner lifts and be within the desired water content range before adequate compaction can be achieved with the compaction equipment being used. If the retest decision is reached, an additional test is made at a second random location, and the same three decisions are reconsidered in light of this additional information. If the second test falls below the accept blocks, the segment of backfill representative of that test should be rejected; or if compaction procedures that have produced acceptable tests in the past have not been altered, then the compaction characteristics of that part of the backfill should be reevaluated.

(3) The primary advantage of statistical methods is that they offer a means of systematically evaluating acceptance or rejection decisions rather than leaving such decisions entirely to the judgment of the inspection personnel. However, if experienced and well trained inspection personnel are available, this approach may not be necessary.

i. Construction reports. A record should be maintained of construction operations. It is valuable in the event repairs or modifications of the structure are required at a later time. A record is necessary in the event claims are made either by the contractor or the

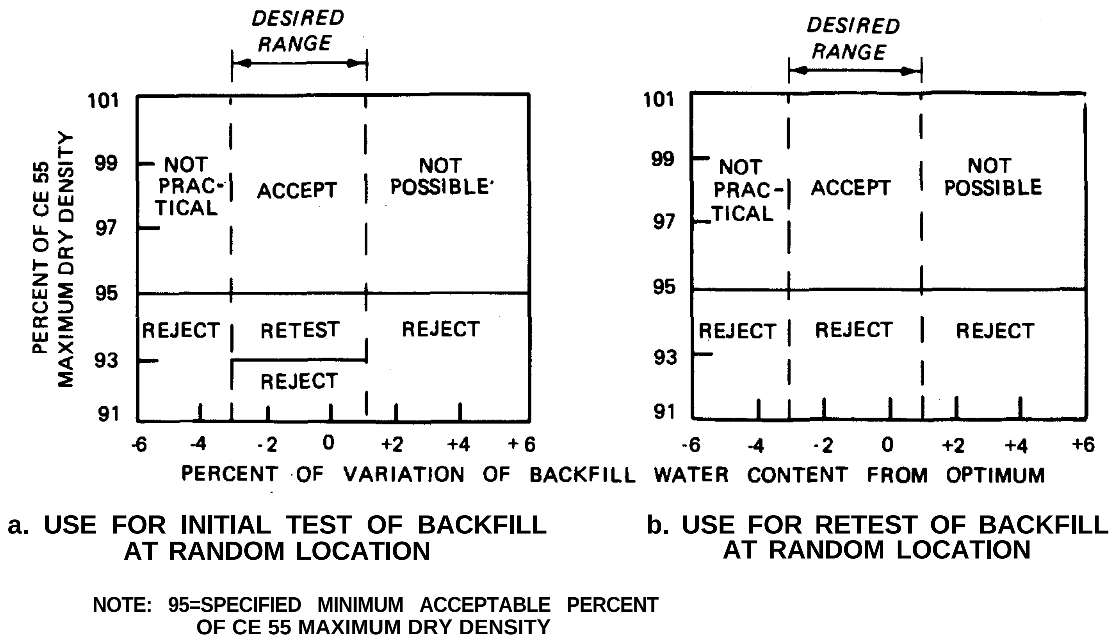

Figure 7-1. Acceptance Rejection Scheme for a Backfill Area.

Contracting Officer that work required or performed was not in accordance with the contract. Recorded data are also beneficial in improving knowledge and practices for future work. The basic documents of the construction record are the plans and specifications, modifications adopted that were considered to come within the terms of the contract, amendments to the contract such as extra work orders or orders for change, results of tests, and measurements of work performed. The amount of reporting required varies according to the importance and magnitude of the earthwork construction phase of the project and the degree of available engineering supervision. The forms to be used should be carefully planned in advance, and the inspection personnel should be apprised of the importance of their reports and the need for thorough reporting. Records should be made on every test performed in the laboratory and in the field. All information necessary to clearly define the locations at which field tests are made should be presented. In the daily reports, inspection personnel should include information concerning progress, adequacy of the work performed, and retesting of areas requiring additional work to meet specifications. These daily reports could be of vital importance in subsequent actions. It is good practice for the inspection personnel to keep a daily diary in which are recorded the work area, work accomplished, test results, weather conditions, pertinent conversations with the contractor, and instructions received and given.

FUNDAMENTALS OF COMPACTION, FIELD COMPACTION TEST METHODS, AND FIELD MOISTURE-DENSITY TEST METHODS

Section B-1. FUNDAMENTALS OF COMPACTION

B-1. Factors influencing compaction. Soil compaction is the act of increasing the density (unit weight) of the soil by manipulation by pressing, ramming, or vibrating the soil particles into a closer state of contact. The most important factors in soil compaction are type of soil, water content, compaction effort, and lift thickness. It is the purpose of field inspection to ensure that the proper water content, lift thickness, and compaction effort are used for each soil type so that the desired degree of compaction is obtained. When the water content, lift thickness, or compaction effort being used does not produce the desired degree of compaction, changes may be necessary. The determination of the necessary changes of these factors to produce the desired degree of compaction requires knowledge of the principles governing the compaction of soils. Therefore, it is important that inspection personnel have a general understanding of the fundamentals of compaction.

a. General. It has been established through research and construction experience that there is a maximum density to which a given soil can be compacted using a particular compaction effect, For each soil and a given compaction effort, there is a unique water content, which is called the optimum water content, that produces the maximum density. The purpose of the lab oratory compaction test is to determine the variation in density of a given soil at different water contents when compacted at a particular effort or efforts. Normally, the soil to be used is compacted in the laboratory over a range of water contents using the impact-compaction procedures given in MIL-STD-621A and ASTM D 1557. The compaction effort used is selected on the basis of the requirements of the structure. In foundation or backfill design for most major structures, the CE 55 (also termed modified) compaction effort that produces approximately 56,000 foot-pounds per cubic foot of compacted soil should be used.

(1) For some cohesionless soils, a greater maximum density can be obtained using vibratory-type compaction procedures given in EM 1110-2-1906 and ASTM D 2049 than can be obtained using MIL-STD-621A or ASTM D 1557 impact-compaction procedure. Thus, there may be cases where the vibratory compaction method may be more appropriate in determining the maximum density. The compaction effort used for design purposes should be the basis for construction control.

(2) A compaction curve is developed in the impact-compaction test by plotting densities (dry unit weights) as ordinates and the corresponding water contents (as percent of dry soil weight) as abscissas. For most soils the curve produced is generally parabolic in form. Figure B-1 shows a compaction curve. The water content corresponding to the peak of the curve is the optimum water content. The dry unit weight of the soil at the optimum water content is the maximum dry density. The zero air voids curve represents the relation between water content and dry density for 100 percent saturation of the particular material tested. Thus, it shows the dry density for a given water content based on the condition that all the air is forced out of the voids by the compaction process.

b. Influence of soil type. Compaction characteristics vary considerably with the type of soil. Figure B-2 shows four compaction curves representing the water content-density relation for four general soil types for standard compaction. The maximum dry density for a uniform sand occurs at about zero water content, although density approaching maximum can be obtained when the sand is saturated. A very sharp peaked curve of dry density versus water content is usually obtained for a silt, and water content is critical to achieving maximum density. A small change in water content (as small as 0.5 percentage point) above or below optimum causes a significant decrease in the density (as much as 2 to 4 pounds per cubic foot) for a given compaction effort. The compaction curve for a lean clay is not as sharp as that for the silt, and water content control is not as critical. Optimum water contents for silts and lean clays generally range between 15 and 20 percent. The compaction curve for fat clays is rather flat and water content is not particularly critical to obtaining maximum density; a 2 to 3 percentage point change in water content from optimum for fat clays causes only a *small* decrease (1 pound per cubic foot *or* less) in density. The maximum dry density, as obtained in laboratory compaction tests using MIL-STD-621A and

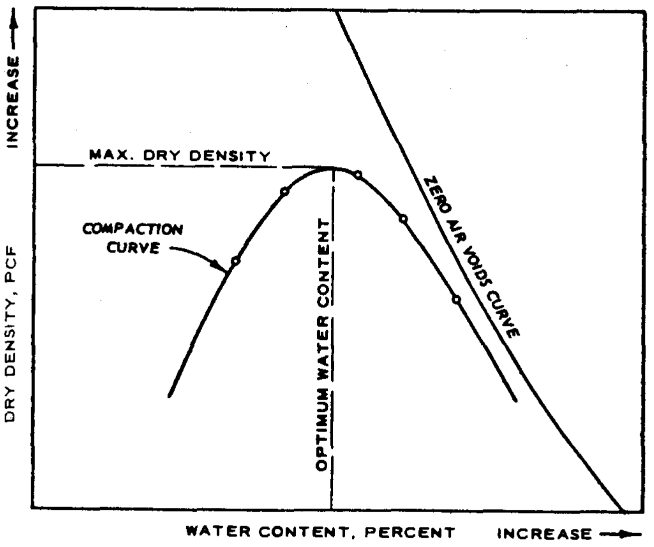

Figure B-1. Compaction curve.

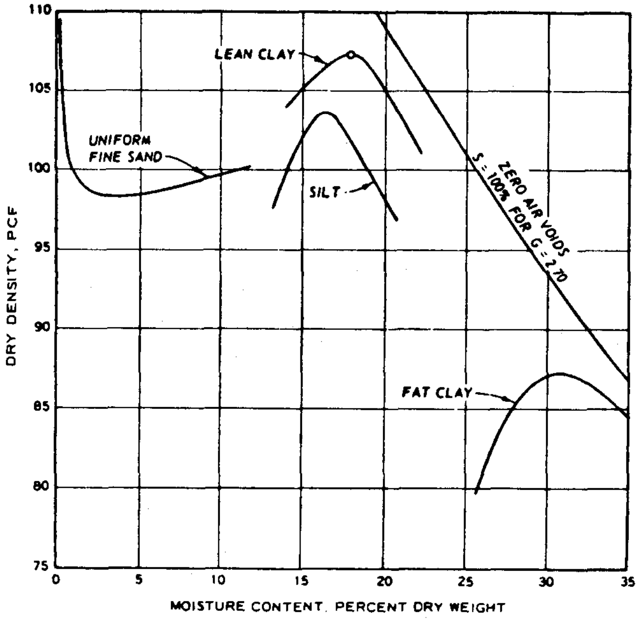

Figure B-2. Typical compaction test curves.

ASTM D 1557 or modified compaction effort, depends on the soil type and varies generally from about 125 to 140 pounds per cubic foot for well-graded, sand-gravel mixtures to about 90 to 115 pounds per cubic foot for fat clays. The optimum water content generally ranges from zero for the sand-gravel mixtures to about 30 percent for the fat clays.

c. Influence of water content. For a given fine-grained soil and a given compaction effort, the water content determines the state at which maximum dry density occurs. At low water contents when the soil is stiff and hard to compress, low, dry densities and high values of air content result. As the water content is increased, higher dry densities and lower air content values are obtained. Increased densities result with an increase in water content up to optimum water content. Beyond this point, the water in the voids becomes excessive, and pore pressures develop under the application of the compaction effort to resist a closer packing; lower dry densities are the result.

d. Influence of compaction effort. For most soils, increasing the energy applied (compaction effort) per unit volume of soil results in an increase in the maximum density (unit weight). This greater density occurs generally at a lower water content. This phenomenon is evident in both field and laboratory compactions. Thus, for each compaction effort, there is a unique optimum water content and maximum dry density for a given soil. Figure B-3 shows the effect of variation in compaction effort on the maximum dry density and optimum water content for a lean clay (CL). Where values of maximum dry density and optimum water content are specified, they should be referenced to the compaction effort used.

e. Influence of lift thickness. Compaction effort applied to a soil surface dissipates with depth. Therefore, it is important that the lift thickness to be compacted be commensurate with the type of soil and the compaction effort. With proper consideration and control over factors influencing compaction, most soils can be com-

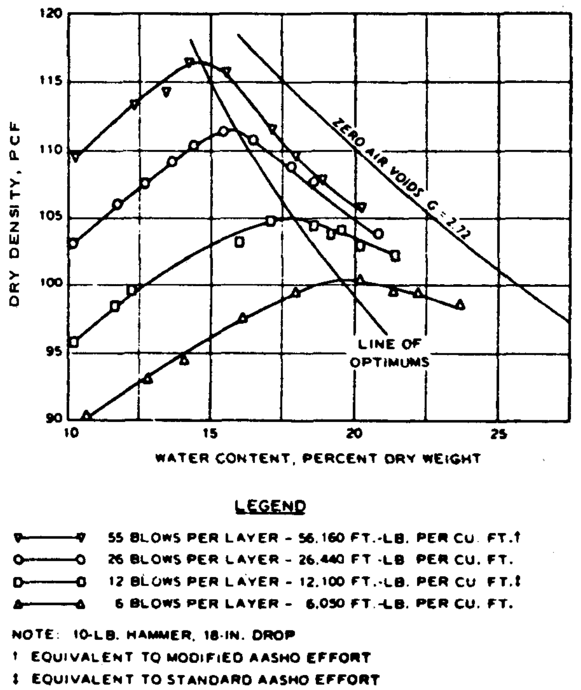

Figure B-3. Molding water content versus density-lean clay (laboratory impact compaction).

pacted to provide a stable backfill, with the exception of certain bouldery soils and soils containing significant amounts of soluble, soft, or organic materials.

B-2. Mechanics of compaction. The influence of the water content on compaction is markedly different on coarse-grained, cohesionless soils and fine-grained, cohesive soils. As a result, the mechanics or manipulation of soil grains in the two types of soil during the compaction process are different. The mechanics of compaction for the two soil types are discussed in subsequent paragraphs.

a. Compaction of coarse-grained soils. Compaction of coarse-grained soils that contain little or no fines and thus exhibit no plasticity (termed cohesionless soils) is achieved by causing the individual particles to move into a closer, more compact arrangement, with smaller particles filling in voids between larger particles. The compaction energy overcomes friction at contact points between particles as they move past one another into closer packing.

(1) A loose volume of coarse-grained soil, such as gravel or sand, contains spaces or "voids" between individual particles that are filled with air and/or water. The density that can be obtained in such a soil under a given amount of compaction effort depends on the gradation and shapes of the particles and on the water content. For a well-graded gravel or sand, the range of particle sizes is sufficient to allow a fairly compact arrangement of particles, with smaller particles filling in the voids between larger particles. For poorly graded soil, either of uniform gradation or skip-graded (lacking a specific range of particle sizes), the distribution of particle sizes limits the density that can be obtained. Segregation of similar size particles in a skip-graded material tends to occur and prevents the voids from being greatly reduced. In a uniform soil, point-to-point contact occurs at very low compaction effort and low density results; further increase in density can only be accomplished by crushing the grains. Therefore, a well-graded, coarse-grained material can generally be compacted to a greater density under a given compaction effort than a poorly graded, coarse-grained soil. The increase in maximum density with increase in compaction effort will be greater for a well-graded soil than that for a poorly graded soil.

(2) Rounded particle shapes facilitate movement and sliding of particles, while angular particle shapes restrict movement and sliding of grains in relation to one another. For either a well-graded, or a poorly graded, coarse-grained material, increase in angularily of grains requires a corresponding increase in compaction effort to obtain a given density. However, a higher density can usually be attained with angular soils because the particle shapes are more conducive to filling the voids.

(3) For coarse-grained soils containing only a small percentage (5 or less) of fine-grained particles, maximum density is more readily obtained when the soil is either dry or saturated. For water contents between these limits, the water in the soil forms menisci between the particle contacts, which tend to hold the soil particles together. This resistance to movement of particles into a more compact structure, termed apparent cohesion or "bulking," results in lower densities than those for either a dry or saturated cohesionless soil under the same compaction effort.

(4) It is to be noted that in the preceding paragraphs, the discussion has centered around the density in weight per unit volume of coarse-grained soils with different gradation characteristics. A more realistic parameter that is often used is the relative density of cohesionless coarse-grained soils. Relative density expresses the degree of compactness of a cohesionless soil with respect to the loosest and the densest conditions of the soil that can be attained by specified laboratory procedures. A soil in the loosest state would have a relative density of zero percent and in the densest state, a relative density of 100 percent. The dry unit weight of a cohesionless soil does not, by itself, reveal how loose or how dense the soil is due to the influence of particle shape and gradation on the density. Only when viewed against the possible range of variation, in terms of relative density, can the dry unit weight be related to the compaction effort used to place the soil in a backfill or indicate the volume-change tendency of the soil when subjected to foundation loads.

(5) Most coarse-grained soils can be compacted to a density such that detrimental additional consolidation will not take place under the prototype loading. This factor is the first important consideration. Another important consideration may be that the compacted soil be sufficiently pervious to provide good drainage. Proper consideration of these two basic factors will allow the use of most coarse-grained soils for backfill purposes.

b. Compaction of fine-grained soils. The mechanics by which fine-grained soils are compacted is quite complex because capillary pressures, hysteresis, pore air pressure, pore water pressure, permeability, surface phenomena, osmotic pressures, and the concepts of effective stress, shear strength, and compressibility are involved. Numerous theories have been developed in an attempt to explain the compaction mechanics. The current state-of-the-art theories involving effective stress give satisfactory explanations. The basic concepts of these theories are discussed below.

(1) Fine-grained soils are compacted in a partially saturated state; therefore, voids or pores contain both pore air and pore water between the soil particles. Ini-

tial compaction water contents below optimum result in initial high pore air pressures and pore water pressures, which reduce shear strength and allow soil particles to slide over one another displacing the pore air to form a more dense mass. This process continues as long as the trapped pore air pressure can escape but requires increasing amounts of compaction effort to achieve higher densities since the soil particles carry increasing amounts of the compaction energy. For a given compaction effort, enough water may eventually be added to the soil so that air channels become discontinuous, and the air is trapped. When the air voids become completely discontinuous, the air permeability of the soil drops to zero; no further densification is possible because at this condition transient pore air pressures can develop that resist the compaction effort. At zero permeability the soil has reached its so-called "optimum water content." Since zero permeability may also be established by closer packing of soil particles, it is evident that lower optimum water contents are possible at higher compaction efforts.

(2) The addition of water above optimum water content causes the voids to become completely filled with trapped pore air and pore water and thereby prevents the soil particles from moving into a more compact arrangement no matter what the compaction effort. Pore water pressure increases significantly with increasing water contents and causes increased reduction in shear strength. This fact is evident in the laboratory compaction mold when the compaction foot sinks deeper and deeper into the soil as water content increases past optimum. The same process occurs in the field when sheepsfoot rollers sink into the soil until the weight is carried by the drum or excessive rutting with rubber-tired rollers.

Section B-2. FIELD COMPACTION TEST METHODS

B-3. General. Laboratory test data obtained from laboratory-compacted specimens provide a basis for design, and it is assumed that the engineering characteristics that will be built into the field-compacted backfill will be approximately the same as those of the specimens. Experience has indicated that for most soils, laboratory densities, water contents, and strength characteristics can be satisfactorily reproduced in a field-compacted backfill.

B-4. Field compaction tests.

a. Compaction control tests. Compaction control of soils requires comparison of fill water content and dry density values obtained in field density tests with optimum water content and maximum dry density, or determination of relative density if more appropriate for the fill materials that are cohesionless. For fine-grained or coarse-grained soils with appreciable fines, field results are compared with results of CE 55 laboratory (modified effort) compaction tests performed according to procedures presented in MIL-STD-621A and ASTM D 1557. For free-draining cohesionless soils, relative density of the fill material is determined, if appropriate, using vibratory test procedures prescribed in EM 1110-2-1906 and ASTM D 2049.

b. Frequency compaction control tests. The performance of a standard laboratory compaction test on material from each field density test would give the most accurate relation of the in-place material to optimum water content and maximum density, but this test is not generally feasible to do because testing could not keep pace with the rate of fill placement. However, standard compaction tests should be performed during construction (1) when an insufficient number of the compaction curves were developed during the design phase, (2) when borrow material is obtained from a new source, and (3) when material similar to that being placed has not been tested previously. In any event, laboratory compaction tests should be performed periodically on each type of fill material (preferably 1 test for every 10 field density tests) to check the optimum water content and maximum dry density values being used for correlation with field density test results.

c. Quick field compaction tests. In addition to the standard compaction or relative density tests (para B-2a), at least four relatively quick compaction test methods can provide good approximations of maximum dry density comparable to the standard methods. The quick compaction methods include: one-point and two-point compaction methods; the Water and Power Resource Service (WPRS), formerly U.S. Bureau of Reclamation (USBR) rapid compaction control method; and for granular cohesionless material, compaction control by gradation. Since only the one-point and two-point methods are currently accepted by the Corps of Engineers for compaction control tests, only these two methods will be discussed in detail. The USBR and gradation methods are briefly summarized.

(1) *One-point compaction method.* In the one-point compaction method, material from the field density test is allowed to dry with thorough mixing to obtain a uniform water content on the dry side of estimated optimum, and then compacted using the same equipment and procedure used in the five-point standard compaction test. The water content and dry density of the compacted sample are then used to estimate its optimum water content and maximum dry density as illustrated in figure B-4. The line of optimums is

well defined in the figure, and the compaction curves are approximately parallel to each other; consequently, the one-point compaction method could be used with a relatively high degree of confidence. In figure B-5, however, the optimums do not define a line, but a broad band. Also, the compaction curves are not parallel to each other and in several instances cross on the dry side. To illustrate the error that could result from using the one-point method, consider the field density and water content shown by point B in figure B-5. Point B is close to three compaction curves. Consequently, the correct curve cannot be determined from the one point. The estimated maximum dry density and optimum water content could vary from about 92.8 pounds per cubic foot and 26 percent, respectively, to 95.0 pounds per cubic foot and 24 percent, respectively, depending on which curve was used. Therefore, the one-point method should be used only when the basic compaction curves define a relatively good line of optimums.

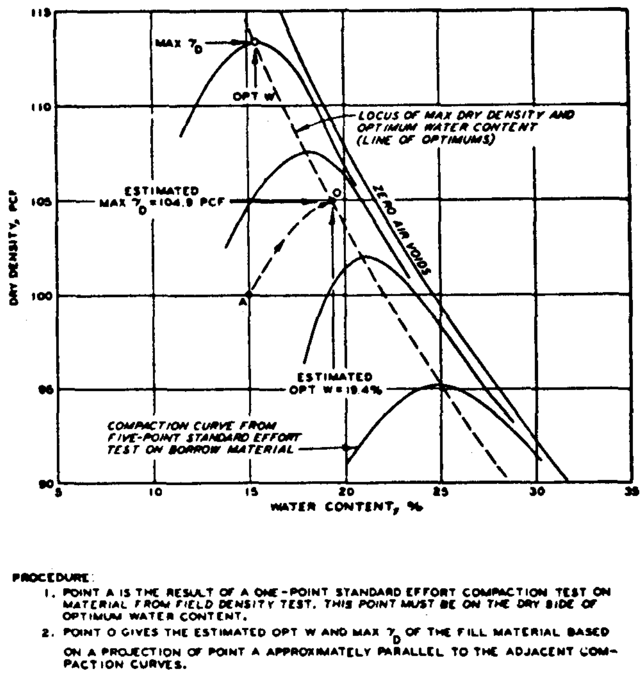

Figure B-4. Illustration of one-point compaction method.

(2) *Two-point compaction test results. In* the two-point test, one sample of material from the location of the field density test is compacted at the fill water content if thought to be at or on the dry side of optimum water content (otherwise, reduced by drying to this condition) using the same equipment and procedures used in the five-point compaction test. A second sample of material is allowed to dry back about 2 to 3 percentage points dry of the water content of the first sample, and then compacted in the same manner. After compaction, water contents of the two samples are determined by ovendrying or other more rapid means

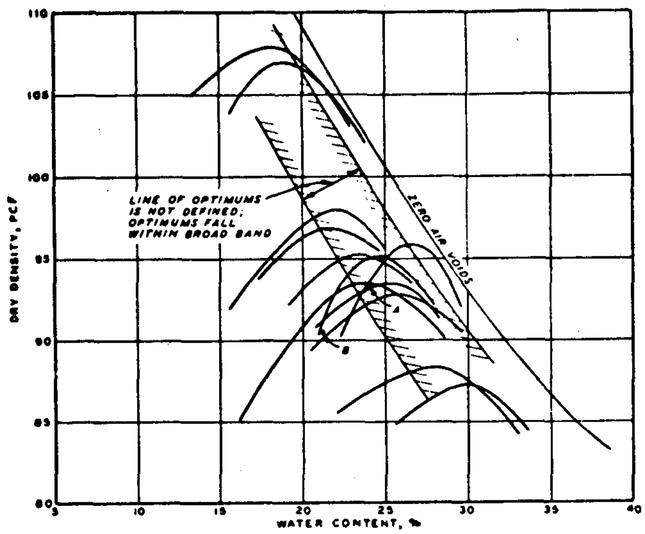

Figure B-5. Illustration of possible error using one- and two-point compaction methods.

(para B-8a), and dry densities are computed. The results are used to identify the appropriate compaction curve for the material test (fig. B-6). The data shown in figure B-6 warrant the use of the two-point compaction test since the five-point compaction curves are not parallel. Using point A only as in the one-point test method would result in appreciable error as the shape of the curve would not be defined. The estimated compaction curve can be more accurately defined by two compaction points as shown. Although the two-point method is more accurate than the one-point method, neither method would have acceptable accuracy when applied to the set of compaction curves shown in figure B-5.

(3) *Rapid one-point test for sands.* A rapid check test for compaction of uniform sands (SP to SM) with less than 10 percent fines (minus No. 200 sieve) is a modified one-point test. The ovendry sand is compacted in a 4-inch-diameter mold using CE 55 (modified) effort. Correlation with standard compaction tests is required to confirm the validity of test results for different sands used on each project.

(4) *USBR rapid compaction control method.* Details of this method are described in the USBR Earth Manual (app A), The test is applicable to fine-grained (100 percent minus No. 4 sieve) cohesive soils with liquid limits less than 50. The method, however, is applicable to soils containing oversize particles providing the proper corrections, as stated in EM 1110-2-1911, Appendix B, are applied. It is a faster method than the standard compaction test and is often more accurate than other methods. The method usually requires adding water to or drying back sampled fill material, and thorough mixing is needed to obtain uniform drying or

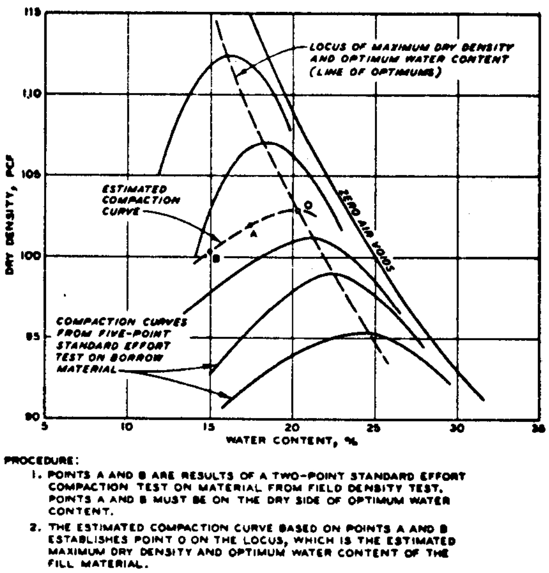

Figure B-6. Illustration of two-point compaction method

distribution of added water. Otherwise, the results may be erroneous, especially for highly plastic clays. In tough clays, it is likely to be inaccurate because of insufficient curing time for the specimens.

(5) *Grain-size gradation compaction control method.* This test method developed in 1938 is applicable to coarse, medium, and fine-grained sands. The method involves sieve analysis to establish grain-size gradation curves, whose shapes are then correlated with maximum dry density obtained from the standard five-point compaction tests or relative density tests. For a given compaction effort, the maximum dry density of cohesionless material (sand) is also a function of particle shape. Thus, the correlation between grain-size distribution and density would, by necessity, have to include consideration of particle shape. It is doubtful that this method would provide test results more rapidly than the one-point and two-point methods or the relative density method currently accepted by the Corps since samples must be dried for sieve analysis. Therefore, this method is not recommended for routine compaction control.

d. Possible errors. All tests involving mechanical devices and human judgment are subject to errors that could affect the results. In order to properly evaluate test results, the inspector must be familiar with the possible sources of such errors.

(1) *Five-point compaction tests.* The following errors can cause inaccurate results:

(a) Aggregations of air-dried soil not completely reduced to finer particles during processing.

(b) Water not thoroughly absorbed into dried material because of insufficient mixing and curing time.

(c) Material reused after compaction.

(d) Insufficient number of tests to define compaction curve accurately.

(e) Improper foundation for mold during compaction.

(f) Incorrect volume or weight of compaction mold.

(g) Incorrect rammer weight and height of fall.

(h) Excessive material extending into the extension collar at the end of compaction.

(i) Improper or insufficient distribution of blows over the soil surface.

(j) Tendency to press the head of the rammer against the specimen before letting the weight fall.

(k) Insufficient drying of sample for water content determination.

(2) *One-point and two-point compaction test.* The possible sources of errors for the one-point and two-point compaction test are essentially the same as those for the five-point method discussed in (1) above. In addition, appreciable inaccuracy in results may occur for both methods if attempts are made to extrapolate maximum density and optimum water contents from nonuniform families of compaction curves (fig. B-5).

B-5. Field compaction and test sections.

For most soils, laboratory densities, water contents, and strength characteristics can be satisfactorily reproduced in a field-compacted backfill. However, during the initial stage of construction frequent checks of density and water content should be made for comparison with design requirements and adjustments should be made in the field compaction procedure as necessary to ensure adequate compaction.

a. When a compacted backfill is constructed as foundation support for critical structures, or when other requirements, materials, and conditions are unusual, the specifications may provide for the construction of test sections. The test section is used to determine the best procedures for processing, placing, and compacting the materials that will produce compacted backfill having engineering properties compatible with design requirements. Therefore, construction of a test section may involve using different types and different weights of compaction equipment, using different lift thicknesses, using different amounts of compaction applications (different numbers of passes or coverages), processing materials differently with respect to water content control, and mixing to obtain improved gradation. A discussion on test sections for shale materials is presented in Appendix A of FHWA-RD-78-141 and illustrates a wide variation in test results, even for very carefully conducted field tests.

b. By exercising rigid control over the water content, processing, placement, and compaction procedures, by frequent density sampling, by keeping complete records of the procedures and tests, and then by studying and evaluating these records, a procedure to use on the job can be established. In addition to water content and density check tests, undisturbed samples should be obtained to determine that the shear and consolidation characteristics are consistent with design requirements. Once control for field conditions has been established, the backfill can proceed at a normal rate. The contractor should be required to adhere to the established processing, placement, and compaction procedures.

c. If provisions for construction of a test section are not contained in the specifications, the field engineers and inspection personnel should provide maximum guidance to the contractor to aid him in establishing adequate processing, placement, and compaction procedures. To meet this problem the contractor must be provided with suggested improvements of equipment type, if they have not been specified, and procedures during the initial stages of backfill operations. The establishment of the procedures and equipment type that will produce adequate compaction of the backfill material must be supported by a comprehensive program of control testing.

Section B-3. FIELD MOISTURE-DENSITY TEST METHODS

B-6. General. Field density measurements of the compacted backfill are essential to ensure that backfill meets the required design densities necessary for the proper functioning of the structure within that backfill. Although water content requirements are not generally specified in military specifications, the measurement and control of water content is important in obtaining required densities. The four density measurement test methods used for the Corps record and contract acceptance enforcement are listed below.

a. The sand-cone method as described in MIL-STD-621A (Method 106) and ASTM D 1556.

b. The rubber-balloon method as described in ASTM D 2167.

c. The nuclear moisture-density method as described in ASTM D 2922 (for density) and ASTM D 3017 (for water content).

d. The drive-cylinder method as described in MIL-STD-621A (Method 102) and ASTM D 2937 for soft, fine-grained cohesive soils. The water-displacement method described in EM 1110-2-1911, although not currently used for Corps contract enforcement, may be used for supplementary density testing for rocky materials. Rapid field methods of determining or approximating water content-density are also discussed in the following paragraphs.

B-7. Water content and density test methods. Field density can be determined by direct or indirect methods. In the direct methods, the weight of soil removed from a hole and the volume of the hole are determined and used to compute the density. In the indirect methods, a characteristic of the soil, such as radiation scattering or penetration resistance, is measured with an instrument such as a nuclear density meter or penetrometer, and then a previously determined relation between density and the characteristic measured is used to determine the density.

a. Direct methods. The sand-displacement method is considered to be the most reliable direct method and should be used as the standard test by which indirect test results are correlated with density. Other direct methods are the drive-cylinder method, rubber-balloon method, and water-displacement method.

(1) *Sand-cone method.* Procedures and equipment for the sand-cone method are described in MIL-STD-621A (Method 106) and ASTM D 1556. The procedure as described in the references involves preparation of the ground surface, measurement of an initial volume for the purpose of correcting for surface irregularities, and measurement of a second volume after a small hole is dug. The difference in the volumes is the volume of the hole. The sand used is a standard sand (Ottawa or other sands having rounded grains and a uniform gradation) that has been calibrated for weight versus volume occupied when falling from a standard, constant height. The weight of sand used is measured by weighing the sand density cylinder before and after each volume measurement, and the volume is determined from the weight versus volume calibration. The soil removed from the hole is weighed, the water content determined (MIL-STD-621A), and the dry weight computed. The wet density and dry density of the soil are computed by dividing the appropriate weights by the computed volume. The sand-cone method can be used to determine the in-place density of practically all soils except those containing large quantities of large gravel sizes.

(2) *Drive-cylinder method.* Procedures and equipment for the drive cylinder method are described in detail in MIL-STD-621A (Method 102) and ASTM D 2937. The procedure consists of driving a 3-inch-diameter by 3-inch-high sampling tube of known volume into the soil, excavating the sampling tube and soil, and trimming off the soil protruding from the ends of the tube. The weight and water content of the soil are measured and the dry weight is computed. The wet density and dry density of the soil are computed by dividing the appropriate weights by the computed volume. The drive-cylinder method is limited to moist, fine-grained cohesive soils.

(3) *Rubber-balloon method.* Procedures and equipment for the rubber-balloon method are described in ASTM D 2167. This method utilizes a rubber balloon attached to a glass or metal cylinder containing water and having a scale graduated in cubic feet. An annular device is seated on the prepared ground surface, and the balloon apparatus is placed and held down firmly on the ring. Then water is forced into the balloon under pressures of 2 to 3 pounds per square inch to obtain an initial volume measurement to correct for ground surface irregularities. The apparatus is removed, a small hole is dug, and the apparatus is replaced on the ring. Water is again pumped into the balloon and causes the balloon to conform to the boundary of the hole; then the volume is measured. This volume less the initial volume is the volume of the hole. The volumeter apparatus is simple and easy to operate, and the volume measurement can be made directly and in somewhat less time than that with the sand-cone volume apparatus. The results obtained are considered to be as accurate as those obtained from the sand-cone apparatus. Like the sand-cone method, the rubber-balloon method can be used to determine the in-place density of practically all soils except those containing large quantities of large gravel sizes.

(4) *Water-displacement method.* Where it is necessary to determine the in-place density for a large volume of soil, as in coarse-grained soils containing significant quantities of large gravel sizes, an approximate density can be obtained by excavating a large hole (several cubic feet) and determining the volume by lining the hole with thin plastic sheeting and measuring the quantity of water required to fill the hole. A relatively small sample representative of the material from the excavation is used for determining the water content. Using the wet and dry weights of the material excavated and the measured volume of the hole, the wet and dry densities of the soil can be determined. Although the procedure is not contained in a Military Standard, it is about the only means of determining an approximate density for soils with large sizes of gravel or rock.

b. Size and preparation of test hole. The size of the hole and the care used in preparing the test hole for the sand volume and balloon methods influence the accuracy of the volume measurement. The proper size of the hole is not well established; however, the larger the hole, the less significant small errors in measurement of volume become. The instructions in TM 5-824-2 indicate that a volume of at least 0.05 cubic foot should be used when testing materials with a maximum particle size of 1 inch and that larger volumes should be used for larger maximum particle sizes. ASTM D 1556 suggests certain relations between particle size and the test hole volume and weight of water content specimen. It also recommends increasing the size of the sample used for water content determination with increasing maximum particle size. The relations suggested by the American Society for Testing and Materials are shown in the following tabulation:

Maximum particle size, in.	Minimum test hole volume cu ft	Water content sample
0.187 (No. 4)	0.025	100
1/2	0.050	250
1	0.075	500
2	0.100	1,000

For significant quantities of larger particles the volumes above should be doubled. The accuracy of the test results is influenced by not only the care taken in preparing a test hole but also the degree of recovery of the excavated material. A hole with irregular surfaces will cause the volume measurement to be less accurate than a hole with smooth surfaces. Thus, the inside of the hole should be kept as free of pockets and sharp projections as possible. Digging a smooth test hole in cohesionless coarse-grained material is particularly difficult. In fine-grained soils without gravel particles, the hole may be bored with an auger, but hand tools will be required to smooth the walls and base of the hole and to recover loose material. For coarser-grained soils and soils containing a significant amount of gravel-size particles, hand tools will generally be required to excavate the hole to prevent disturbing the material in the walls and base of the test hole. Should it become necessary in digging a test hole in highly compacted material to loosen the material by using a chisel and hammer, care must be taken not to disturb the soil around the limits of the hole. All loose particles must be removed after the final depth has been reached, and all particles must be recovered. All soil should be placed in a waterproof container as the soil is taken from the hole. This measure will prevent loss of water before the soil can be weighed.

c. Indirect methods. The indirect methods include use of the nuclear moisture-density apparatus, Proctor penetrometer, and cone penetrometer. Both the Proctor penetrometer and cone penetrometer methods for determining the density require very careful calibration using soils of known density and water content, and considerable experience in operating the device; even so, the accuracy of these methods may be subject to question because of the great influence that nonuniformity of water content or a small piece of gravel can have on the penetration resistance. The Proctor penetrometer may also be used to approximate water content of fine-grained soils.

(1) *Nuclear moisture-density method.* Procedures and equipment for the nuclear moisture-density method are described in ASTM D 2922 (for density) and ASTM D 3017 (for water content). The three methods for determining in-place densities described in ASTM

D 2922 are Method A-Backscatter, Method B-Direct Transmission, and Method C-Air Gap. Of the three methods, Method B-Direct Transmission is recommended over Method A and Method C because it eliminates the effect of vertical density variations.

(a) Modern nuclear-moisture density equipment incorporates a radioactive source emitting neutrons and gamma rays and measuring elements (geiger tubes) or "scalers" into a single, self-contained unit. The determination of moisture by the nuclear method is dependent on the modifying of high energy or "fast" neutrons into low energy or "slow" neutrons (ASTM, STP No. 293). Any material containing hydrogen will moderate fast neutrons. Since hydrogen is present primarily in the molecules of free water, the degree of interaction between the fast neutrons and hydrogen atoms represents a measure of the water content of the soil, Density measurements are based on the scattering of gamma rays by the orbital electrons on the atoms comprising the soil. Since the scattering is a function of the electron density, which in turn is approximately proportional to the density of the soil, it is possible to correlate the backscatter of the gamma rays with the soil density.

(b) To obtain a water content or density measurement, the appropriate meter is set in place and the voltage setting is adjusted to the correct operating voltage. After the scaler is turned on, a short warmup period (not exceeding 1 minute) is allowed before the test count is started. Intimate contact at the interface between meter and soil is necessary for Method A-Backscatter because the scattering of the gamma rays for the density measurement is quite sensitive to *even* minute air gaps. The normal counting period is 1 minute, with one or two repeat counts taken as a check. Calibration curves for both moisture and density determinations, once the count rates have been established, are furnished by the manufacturers for each individual unit. In general, the calibration curve for moisture determination is more reliable than the curve for density determination. However, it is advisable to correlate both calibration curves on each type of soil with which the instrument is to be used. Such a correlation should be accomplished by using current standard methods for moisture and density determinations or by calibrating on blocks of material of known moisture and density. Examples of calibration for shale materials are given in Appendix A of FHWA-RD-78-141.

(c) For all nuclear-moisture density devices, separate standards are provided so that the count rate can be determined on each instrument at any time in the field. A standard count should be taken three or four times during a day's operation. Although adjustments can generally be made on the instruments so that the count will coincide with the standard count; even a slight adjustment is not usually justified. A more satisfactory procedure is to record the field measurement in terms of percent of this standard count rate, which should be within a reasonable percentage (± 5) of the given reference count. Use of the percent of standard count, rather than simply the counts per minute, is recommended for increased accuracy. Use of this procedure largely cancels out the effects of such variables as reduction in source strength, background count, and changes in sensitivity of the detector tubes.

(d) The calibration curve for the soil being tested is entered with the value of the density meter count rate (taking into consideration the variation from the standard count) to obtain the wet unit weight of the soil. Similarly, the moisture meter yields the weight of water per cubic foot of soil. The unit dry weight of the soil is simply the wet unit weight obtained by the density meter minus the weight of water obtained by the moisture meter. By dividing the water measurement by the dry density, the water content can be expressed in the more familiar terms of percentage of dry weight.

(e) Anyone working with nuclear meters must recognize that a possibility of exposure to radiation exists if the safety rules listed by the manufacturer are not followed. When proper procedures and safety rules are followed, the radiation hazard is negligible. For certain instruments, operating personnel must wear a body radiation film badge and carry a pocket dosimeter. These instruments must be ready weekly to ensure that the maximum permissible weekly dosage is less than 100 milliroentgen. Other safety rules deal with handling the devices and being aware of the built-in safety devices. The safety precautions mentioned above may vary or not be applicable for some of the newer devices being manufactured. Therefore, the manufacturer's literature should be carefully studied to determine appropriate safety requirements.

(f) It is possible, using nuclear-moisture density apparatus, for one inspector to conduct perhaps 30 water content and 30 density tests per 8-hour working day. The time required per test is only 20 or 25 percent of that required in direct sampling methods. A large number of tests with the nuclear meter correlated with a much smaller number of direct sampling determinations can be of great benefit in ensuring that adequate compaction of the backfill is being obtained. A simple statistical analysis of the data can be made, such as a plot of dry density versus number of tests (ASTM STP No. 293). The resulting bell-shaped curve is a very useful tool since each day's results can easily be added to the plot of previous test results. This procedure can provide an up-to-date picture of the fill densities being obtained and can show the effect of changes made in field compaction procedures.

(2) *Hand cone penetrometer.* The hand cone penetrometer offers a rapid means of checking density requirement of some compacted backfills. The process involves the correlation of penetration resistance with known in-place densities as determined by either the sand-cone or the rubber-balloon method.

(a) Cone penetration resistance is a measurement of soil bearing capacity. Since bearing capacity is dependent on shear strength and thus density, the hand cone penetrometer is an indirect measurement of density. Because shear strength is a function of any pore air and pore water pressures that may be generated by a shearing action of soils containing pore water, the method is applicable only to free-draining materials where pore pressures are dissipated as fast as they are generated. Penetration resistance can also be drastically influenced by the obstruction of gravel-size particles. Therefore, the method is applicable only to sands with 100 percent passing the U.S. Standard No. 4 sieve (4.76 mm) and no more than 15 percent passing the U.S. Standard No. 200 sieve (0.074 mm).

(b) A plot of hand-cone sounding resistance versus depth of sounding will result in an approximate linear relationship for homogenous materials of relatively constant density for depths of sounding ranging from approximately 2 inches to 20 inches depending on the geometry and size of the cone point and material type. Correlations may be made between known in-place densities and either the angle of inclination between sounding resistance and depth of penetration or the sounding resistance at a given depth. The range of known in-place density must be sufficient to establish a trend between sounding resistance and density. Correlations between density and sounding resistance at a given depth is the simplest correlation since the angle of inclination does not have to be computed. Figure B-7 shows a case example of a correlation between dry density and sounding resistance measured at 6 inches below the surface. Contract specification required a minimum acceptable dry density of 104.7 pounds per cubic foot (98 percent of the maximum dry density according to the compaction method described in ASTM D 1557). Figure B-7 also indicates that all soundings with resistances of 110 pounds or more corresponded to densities greater than 104.6 pounds per cubic foot. Therefore, no additional standard density checks are needed beyond the routine tests. When all soundings with resistance of 86 pounds and below correspond to densities below 104.6 pounds per cubic foot, it is evident that sufficient compaction has not been achieved and additional standard density checks are definitely needed for an acceptance or rejection decision. Sounding with resistances between 86 and 110 pounds may or may not need additional density checks depending on whether the inspector has reason to suspect adequate compaction has or has not been achieved.

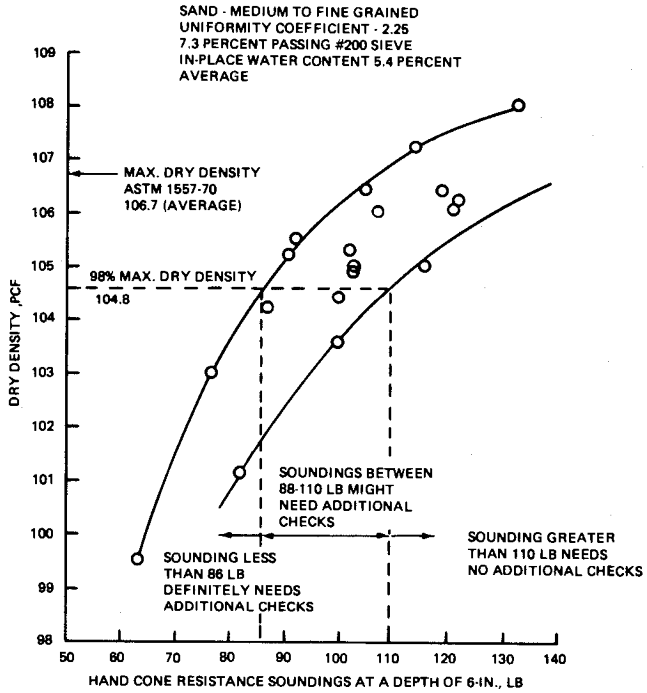

Figure B-7. Correlation between dry density and hand cone resistance at a depth of 6 inches below the surface.

(c) The correlation between sounding resistance and known in-place dry densities (fig. B-7) is made directly without knowing water content at each sounding location. Although sounding resistances are affected by water content for the dry, moist, and 1 to 2 percentage points above optimum state, the range of possible water content in the moist state does not significantly affect sounding resistance.

(d) The hand cone penetrometer is ideally suited for use in confined zones where sand is used as backfill and where rapid control aids are needed to determine if adequate compaction has been achieved. With a little practice, a hand-cone sounding can be -made in less than 1 minute.

d. Possible sources of errors. Since the decision to accept or reject a particular part of a backfill is primarily dependent upon the results of in-place density control tests, it is important for the inspector to be familiar with the possible sources of errors that might cause an inaccurate test result. Some of the more likely sources of errors for the sand-cone, rubber-balloon, and nuclear moisture-density methods are discussed below. All tests that are suspected to be in error must be repeated.

(1) *Sand-cone method.* The major sources of possible error are as follows:

(a) The sand-cone method relates the bulk density of a standard sand to the known weight of the

same sand occupying an in-place volume of sampled material. Changes in effective gradation between or within batches of sand may significantly affect the test results. This error can be minimized by frequent calibration of the sand's bulk density.

(b) Loose sand increases in density when subjected to vibrations. Care must be taken not to jar the sand container while calibrating bulk density in the laboratory or during in-place volume measurements in the field. A common error is to use the sand cone method for in-place volume measurements adjacent to the operation of heavy equipment. Heavy equipment can generate vibrations that densify the sand and result in erroneously high-volume measurements and low in-place densities.

(c) Appreciable time intervals between bulk density determination of the sand and its use in the field may result in change in the bulk density caused by a change in the moisture content of the sand.

(2) *Rubber-balloon method.* The major sources of possible error are as follows:

(a) New rubber-balloon volumeters should be calibrated against several known volumes of different sizes covering the volume range of in-place measurements.

(b) For stiff soils such as clay, it is possible to trap air between the sides of the sample hole and balloon. This error can be minimized by placing lengths of small-diameter string over the edge of the hole and down the inside wall slightly beyond the bottom center.

(c) The application of the 2- to 3-pounds-per-square-inch pressure to extend the balloon into existing irregularities in the hole will cause a noticeable upward force on the volumeter. Care must be taken to ensure that the volumeter remains in intimate contact with the base plate.

(d) The rubber balloon must be frequently checked for leaks.

(3) *Nuclear moisture-density method.* The major sources of possible error are as follows:

(a) The single consistent source of error is related to the accuracy of the system. The overall system accuracy in determining densities is statistical in nature and appears to vary with the equipment used, test conditions, materials tested, and operators. If proper procedures are followed, the standard deviations in terms of accuracy will vary on the order of 3 to 5 pounds per cubic foot for density tests and 0.5 to 1.0 pound of water per cubic foot of material for water content tests.

(b) Manufacturers furnish calibration curves for each piece of equipment. Due to the effects of differing chemical compositions, calibration curves may not be applicable to materials not represented in establishing the calibration curve. Apparent variations in calibration curves may also be induced by differences in the seating, background count, sample heterogeneity, and surface texture of the material being tested.

B-8. Rapid field water content control procedures. In many cases, particularly in confined zones, it is important to rapidly determine the dry density of a given part of the backfill in order to prevent the possibility of costly tear out and rebuild operations. The test procedures for determining dry densities using the sand-cone and rubber-balloon methods sometimes require extensive drying times (depend on material type up to 16 hours) to determine water content. Alternate techniques for rapidly determining water content are discussed below.

a. Microwave ovens. Microwave energy may be used to dry soil rapidly and thus enable quick determination of water content (ASTM STP No. 599). However, in drying soils with microwaves, the only control on the amount of energy absorbed by the soil is exposure time; consequently, if soils are left in the oven too long, severe overheating can occur. This overheating of the soil can cause bound water, a part of the soil structure, to be driven off and thus result in significant errors in water content measurements. In addition, continuous heating can result in excessive heat being generated; certain soils have been observed to fuse or explode and thereby create hazards to both equipment and personnel.

(1) Times required for drying in a microwave oven are primarily governed by the mass of water present and the power-load output of the oven, as expressed by

$$G_T = \frac{M_w[(0.2/w + 1)(100 - t_o) + 539](4.18896)}{P} \quad \text{(B-1)}$$

where

- T = time in the microwave oven, seconds
- M_w = mass of water present in the soil-water mixture, grams
- w = water content of the specimen
- t_o = initial temperature of the soil-water mass, degree Centigrade
- P = power output of the oven, watts

This governing equation indicates that in order to predict accurately the drying times required, an estimate of the specimen water content must be made and the oven power versus load relationship must be established by calibration.

(2) The limitation of having to estimate the initial water content of the specimen is not insurmountable. Test results indicate that slight overestimations of the actual water content, i.e., longer drying times, generally result in small differences between conventional oven and microwave oven water contents. Conversely, underestimations of water content result in more serious errors. If an accurate estimate of water content

cannot be made, experience has shown that close. visual observation often can be used to determine if soil overheating is occurring. An alternative approach is to incrementally dry a duplicate specimen until a constant weight is obtained, calculate the water content, and input this value into equation (B-1).

(3) The useful power output "P" is determined in the laboratory by subjecting a mass of distilled water to microwaves for a given time and then measuring the rise in temperature induced in the water. Power in watts is calculated from

$$P = \frac{M_w t}{T_c} 4.18896 \qquad \text{(B-2)}$$

where

M_w = mass of distilled water in the oven, grams

t = increase in temperature of the distilled water, degree Centigrade

T_c = time in the oven for calibration, seconds

A plot is then made of power output and oven load (mass of water in oven) in grams of water as shown in figure B-8.

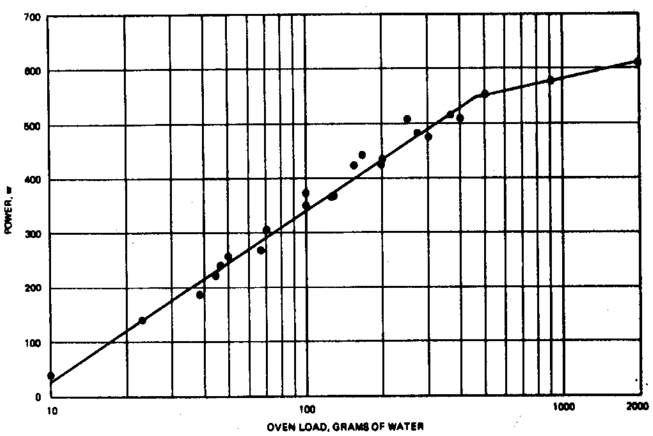

Figure B-8. Power Applied by the Oven to Dry Moist Soils.

(4) The water content estimate is used to calculate the mass of water in the specimen from

$$M_w = \frac{(W_{wet})(W)}{(1 + w)} \qquad \text{(B-3)}$$

where

M_w = mass of the water in the specimen, and equivalent to oven load in figure B-8, grams

W_{wet} = wet weight of the specimen, grams

By calculating M_w (oven load in fig. B-8) from equation (B-3) and finding a comparable value of power from a plot similar to figure B-8 for the particular oven used, the drying time may be calculated from equation (B-1).

(5) It may not be possible to successfully dry certain soils in the microwave oven. Gypsum may decompose and dehydrate under microwave excitation. Highly metallic soils (iron ore, aluminum rich soils, and bauxite) have a high affinity for microwave energy and overheat rapidly after all the free water has been vaporized. Hence, extreme care is required when drying these soils. For the same reason, metallic tare cans or aluminum plates are not permissible as specimen containers.

(6) Because microwaves are a type of radiation, normal safety precautions to avoid undue exposure should be observed.

b. Proctor penetrometer. The Proctor penetration resistance method in the hands of inspection personnel experienced in its use provides a rapid expedient check on whether the field water content is adequate for proper compaction. However, the method is suitable only for fine-grained soils because coarse sand or gravel may cause erroneously high resistance readings. The method consists of compacting by the procedure used for control of a representative sample of soil taken from the loose lift being placed. The compacted specimen is weighed, and the wet unit weight is determined. The penetration resistance of the compacted specimen in the mold is then measured with the soil penetrometer. The moisture content can then be estimated by comparing the penetration resistance of field compacted specimens with a relation previously established in the laboratory between wet unit weight, penetration resistance, and moisture content. The procedure requires about 10 minutes and is sufficiently accurate for most field purposes. The procedure to determine the relation between wet unit weight, penetration resistance, and moisture content is described in ASTM D 1558. The relation is generally developed in conjunction with the compaction test.

c. Other methods. Other methods for determining water content include drying by hot plate or open flame, drying by forced hot air and a rapid moisture test that uses calcium carbonate. In the hot plate method, a small tin pan and a hot plate, oil burner, or gas burner (something to furnish fast heat) are used. A sample of wet soil is weighed, dried by one of the above mentioned methods, and weighed again to determine how much water was in the sample. This method is fast, but care must be taken to ensure that the material is thoroughly dry. Also, if both organic matter and bound water are removed, higher water content determinations than those obtained by ovendrying sometimes result. In the forced hot air, a sample is placed in a commercially available apparatus containing an electric heater and blower. Hot air at 150 to 300 degrees Fahrenheit is blown over and around the sample for a preset time. A 110- or 230-volt source is required. Available sizes of apparatus can accommodate sample weights from 25 to 500 grams. Drying times are estimated to vary from 5 minutes for sand to as long as 30 minutes for fat clay. The rapid moisture test and limitations are described in STP 479.

FOREWORD

The Unified Facilities Criteria (UFC) system is prescribed by MIL-STD 3007 and provides planning, design, construction, sustainment, restoration, and modernization criteria, and applies to the Military Departments, the Defense Agencies, and the DoD Field Activities in accordance with USD (AT&L) Memorandum dated 29 May 2002. UFC will be used for all DoD projects and work for other customers where appropriate. All construction outside of the United States is also governed by Status of Forces Agreements (SOFA), Host Nation Funded Construction Agreements (HNFA), and in some instances, Bilateral Infrastructure Agreements (BIA). Therefore, the acquisition team must ensure compliance with the most stringent of the UFC, the SOFA, the HNFA, and the BIA, as applicable.

UFC are living documents and will be periodically reviewed, updated, and made available to users as part of the Services' responsibility for providing technical criteria for military construction. Headquarters, U.S. Army Corps of Engineers (HQUSACE), Naval Facilities Engineering Command (NAVFAC), and Air Force Civil Engineer Center (AFCEC) are responsible for administration of the UFC system. Defense agencies should contact the preparing service for document interpretation and improvements. Technical content of UFC is the responsibility of the cognizant DoD working group. Recommended changes with supporting rationale may be sent to the respective DoD working group by submitting a Criteria Change Request (CCR) via the Internet site listed below.

UFC are effective upon issuance and are distributed only in electronic media from the following source:

- Whole Building Design Guide web site http://www.wbdg.org/dod.

Refer to UFC 1-200-01, *DoD Building Code*, for implementation of new issuances on projects.

UNIFIED FACILITIES CRITERIA (UFC)
REVISION SUMMARY

Document: UFC 3-220-10, *Soil Mechanics*

Superseding: UFC 3-220-10N, *Soil Mechanics*

Description: "Soil Mechanics" or DM 7.1 (UFC 3-220-10N) has been a valuable legacy document in geotechnical engineering for 50 years. Revisions to the document occurred in 1982, 1986, and 2005; but for the most part; the document has remained substantially unchanged since the original publication in 1971. DM 7.1 has been on the bookshelf of many civil engineers, it has been used in many graduate and undergraduate soil mechanics classed attended by generations of geotechnical engineering students, and charts and correlations from the document have been cited in numerous textbooks and research papers. Currently, it can be found in electronic format at a variety of sites on the internet.

The lasting value of DM 7.1 is attributed to its success in distilling geotechnical engineering design procedures, particularly into graphical examples that are easy to follow and understand. The manual also contains correlations to estimate engineering properties of soil and rock that have become ubiquitous in engineering practice. Although the manual continues to be a part of everyday engineering, changes in the profession necessitate a substantial update of DM 7.1. The manual was initially written when the slide rule was the main calculation tool of engineers. Subsequent revisions predate the widespread use of personal computer software tools that are used by every practicing engineer. The manual also predates the global use of the internet as a means to gather pertinent information and to transfer data and documents. In addition, there have been many new methods of testing, exploration, and analysis that have been developed since the publication of the original manual.

This current revision was undertaken with an emphasis on retaining the elements that were responsible for the lasting value of DM 7.1. Graphical examples of engineering solutions, both old and new, are found throughout the chapters. A new chapter has been written that focuses on geotechnical engineering correlations. Details about computer solutions and numerical modeling tools have been added to the manual. Owing to the rapid changes that occur in geotechnical engineering software tools and internet addresses, the authors have tried to minimize the number of URLs and the names of specific software packages in the text. Appendix B contains a listing of software packages available at the time of publication (2021), along with vendor contact information, with the intention that this appendix can be updated periodically in the future. **1**\ The list is provided solely as a courtesy and has not been verified by the Tri-Services. The user is fully responsible for proper verification, validation, and applicability of the software. /**1**/

In accordance with MIL-STD-3007 and UFC 1-300-01, Criteria Format Standard, this UFC varies in format from traditional UFC format requirements. It was approved for variation in format as required in UFC 1-300-01.

TABLE OF CONTENTS

LIST OF FIGURES

LIST OF TABLES

INTRODUCTION

I-1 REISSUES AND CANCELS.

This UFC supersedes UFC 3-220-10N dated 8 June 2005.

I-2 PURPOSE AND SCOPE.

This UFC provides technical guidance on contemporary soil mechanics principles and the practice of geotechnical engineering used in planning, design, construction, evaluation and maintenance of Government facilities for the Department of Defense (DoD). Where other criteria, contractual, statutory or regulatory requirements are referenced, the more stringent requirement must be met.

I-3 APPLICABILITY.

This UFC follows the same applicability as UFC 1-200-01, paragraph 1-3, as it pertains to soil mechanics and the practice of geotechnical engineering.

I-4 GENERAL BUILDING REQUIREMENTS.

Comply with UFC 1-200-01, *DoD Building Code*. UFC 1-200-01 provides applicability of model building codes and government unique criteria for typical design disciplines and building systems, as well as for accessibility, antiterrorism, security, high performance and sustainability requirements, and safety. Use this UFC in addition to UFC 1-200-01 and the UFCs and government criteria referenced therein.

I-5 GLOSSARY.

APPENDIX C contains a list of symbols used in geotechnical engineering. APPENDIX D contains definitions of terms.

I-6 REFERENCES.

APPENDIX A contains a list of references used in this document.

This Page Intentionally Left Blank

CHAPTER 1 IDENTIFICATION AND CLASSIFICATION OF SOIL AND ROCK

1-1 INTRODUCTION.

1-1.1 Scope.

This chapter presents criteria for *soil* and *rock* identification and classification based on internationally accepted standards as well as information on their physical engineering properties. Common soils and rocks are discussed as well as special materials, such as expansive and collapsing soils, permafrost, limestone and related materials, coral and coral formations, quick clays, and other materials (i.e. man-made fills, chemically reactive and lateritic soils, calcareous sands, and submarine soils).

1-2 SOIL DEPOSITS.

1-2.1 Geologic Origin and Mode of Occurrence.

Soils are masses of solid particles along with the materials within the voids between the particles. The solid particles typically are a mixture of sediments or other accumulated, unconsolidated[1] material produced by the chemical and physical disintegration of rocks. Soils can contain organic materials. From a geologic standpoint, soils can be classified in terms of origin (e.g., transported, *pyroclastic*, *residual*, and *organic*), and mode of occurrence (e.g., *aeolian*, *alluvial*, *colluvial*, *glacial*, and *marine*). A geologic description can assist in correlating experiences between several sites, and in a general sense, can indicate the pattern of strata to be expected prior to making a field investigation (test borings, etc.).

Soils with similar origin and mode of occurrence are expected to have comparable, if not similar, engineering properties. For quantitative foundation analysis, a geological description is inadequate and a more specific classification and testing is required. A study of references on local geology should precede a major subsurface exploration program as this will help with planning the exploration and also with identifying possible challenges for the project. Also, information on known projects near the site should be obtained, if available, to give specific details about the soils and conditions that will likely be encountered. Table 1-1 describes the principal soil deposits grouped in terms of origin, and Table 1-2 describes the principal soil deposits by mode of occurrence.

[1] In this context, unconsolidated means that the particles have not lithified into rock. It does not imply a particular state of consolidation as described in Chapter 5.

Table 1-1 Principal Soil Deposits in Terms of Origin

Major Division	Principal Soil Deposits	Pertinent Engineering Characteristics
Organic: Accumulation of highly organic material formed in place by the growth and subsequent decay of plant life	*Peats*: Somewhat fibrous aggregate of decayed and decaying vegetation matter having a dark color and odor of decay	Very compressible; entirely unsuitable for supporting building foundations
	Mucks: Peat deposits which have advanced in stage of decomposition to such extent that the botanical character is no longer evident	
Pyroclastic: Material ejected from volcanoes and transported by gravity, wind and air	*Ejecta*: Loose deposits of volcanic ash, lapilli, bombs, etc.	Typically, shard-like particles of *silt* size with larger volcanic debris; weathering and redeposition produce high plasticity, compressible *clay*; unusual and difficult foundation conditions
	Pumice: Highly porous volcanic rock that is frequently associated with lava flows and mud flows, or may be mixed with nonvolcanic sediments	
Residual: Material formed by disintegration of underlying parent rock or partially indurated material	Residual sands and fragments of gravel-sized material formed by dissolution and leaching of cementing material, leaving behind the more resistant particles, commonly quartz	Generally favorable foundation conditions
	Residual clays formed by the decomposition of silicate rocks, disintegration of shales, and solution of carbonates in limestone; with few exceptions, becomes more compact, rockier and less weathered with increasing depth; at intermediate stage may reflect composition, structure and stratification of parent rock	Variable properties requiring detailed investigation; deposits present favorable foundation conditions except in humid and tropical climates, where depth and rate of weathering are very great
	Transported soils: See Table 1-2	

Table 1-2 Principal Soil Deposits by Mode of Occurrence

Major Division	Principal Soil Deposits	Pertinent Engineering Characteristics
Aeolian: Material transported and deposited by wind.	*Loess*: A calcareous unstratified deposit of silts or sandy or clayey silt traversed by a network of tubes formed by root fibers now decayed	Relatively uniform deposits characterized by ability to stand in vertical cuts; collapsible structure; deep weathering or saturation can modify characteristics
	Dune sands: Mounds, ridges, and hills of uniform fine sand characteristically exhibiting rounded grains	Very uniform grain size; may exist in relatively loose condition
Alluvial: Materials transported and deposited by running water.	*Floodplain:* Low-lying stream or river deposits that are subject to inundation by floodwaters	
	Point bar: Alternating deposits of arcuate ridges and swales (lows) formed on the inside or convex bank of mitigating river bends; ridge deposits consist primarily of silt and sand, swales are clay filled	Generally favorable foundation conditions; however, detailed investigations are necessary to locate discontinuities; flow slides may be a problem along riverbanks; soils are quite pervious
	Channel fill: Deposits laid down in abandoned meander loops isolated when rivers shorten their courses; composed primarily of clay; however, silty and sandy soils are found at the upstream and downstream ends	Fine-grained soils are usually compressible; portions may be very heterogeneous; silty soils generally present favorable foundation conditions
	Backswamp: The prolonged accumulation of floodwater sediments in flood basins bordering a river; materials are generally clays but tend to become siltier near riverbank	Relatively uniform in a horizontal direction; clays are usually subjected to seasonal volume changes
	Terrace: Relatively narrow, flat-surfaced, river-flanking remnants of floodplain deposits formed by entrenchment of rivers and associated processes	Usually drained and oxidized; generally favorable foundation conditions
	Estuarine: Mixed deposits of marine and alluvial origin laid down in widened channels at mouths of rivers and influenced by tide of body of water into which they are deposited	Generally fine grained and compressible; many local variations in soil conditions
	Lacustrine: Material deposited within lakes (other than those associated with glaciation) by waves, currents, and organo-chemical processes; deposits consist of unstratified organic clay or clay in central portions of the lake and typically grade to *stratified* silts and sands in peripheral zones	Usually very uniform in horizontal direction; fine-grained soils generally compressible
	Deltaic: Deposits formed at the mouths of rivers, which result in extension of the shoreline	Generally fine-grained and compressible; many local variations in soil condition
	Piedmont: Alluvial deposits at foot of hills or mountains; extensive plains or alluvial fans	Generally favorable foundation conditions

Table 1-2 (cont.) Principal Soil Deposits by Mode of Occurrence

Major Division	Principal Soil Deposits	Pertinent Engineering Characteristics
Colluvial: Material transported and deposited by gravity	*Talus*: Deposits created by gradual accumulation of unsorted rock fragments and debris at base of cliffs	Previous movement indicates possible future difficulties; generally unstable foundation conditions
	Hillwash: Fine colluvium consisting of clayey sand, sand silt, or clay	
	Landslide deposits: Considerable masses of soil or rock that have slipped down, more or less as units, from their former position on steep slopes	
Glacial: Material transported and deposited by glaciers, or by meltwater from the glacier.	*Glacial till*: An accumulation of debris, deposited beneath, at the side (lateral moraines), or at the lower limit of a glacier (terminal moraine); material lowered to ground surface in an irregular sheet by a melting glacier is known as a ground moraine.	Consists of material from *boulder* and *gravel* to clay; deposits are unstratified; present generally favorable foundation conditions but rapid changes in conditions are common.
	Glacio-fluvial deposits: Coarse and fine-grained material deposited by streams of meltwater from glaciers; material deposited on ground surface beyond terminal edge of a glacier is known as an outwash plain; gravel ridges known as kames and eskers; depressions known as kettles can be filled with peat	Many local variations; generally present favorable foundation conditions
	Glacio-lacustrine deposits: Material deposited within lakes by meltwater from glaciers; consisting of clay in central portions of lake and alternate layers of silty clay or silt and clay (varved clay) in peripheral zones	Very uniform in the horizontal direction
Marine: Material transported and deposited by ocean waves and currents in shores and offshore areas.	*Shore deposits*: Deposits of sands and/or gravels formed by the transporting, destructive, and sorting action of waves on the shoreline	Relatively uniform and of moderate to high density
	Marine clays: Organic and inorganic deposits of fine-grained material	Generally, very uniform, compressible and usually very sensitive to remolding

1-3 SOIL VISUAL DESCRIPTION, IDENTIFICATION, AND CLASSIFICATION.

Standardized procedures for visual description, identification, and formal classification of a soil specimen are presented in this section. These procedures follow the corresponding ASTM standard available for this purpose. Visual description entails describing the characteristics of the soil that can be perceived with the senses (e.g. vision, touch, and smell). The identification of the soil refers to knowing the soil type without having to use specialized equipment to do so. The visual description and identification of soils are normally done in the field and the procedures are based on ASTM D2488. The classification of the soils involves using specialized equipment and tests to classify the soil using a standard classification system.

1-3.1 Definitions.

The definitions used in this chapter agree with the Unified Soil Classification system presented in ASTM D2487.

Boulders: Rock particles will not pass a 12-inch square opening.

Clay: Soil particles passing a No. 200 (75-µm) sieve that exhibit plasticity (putty-like properties) within a range of water contents, and considerable strength when air dried. For classification of clayey soils, refer to Section 1-3.3.

Coarse-grained soils: Soils that contain 50% or more particles retained on a No. 200 (75 µm) sieve.

Cobbles: Rock particles that pass through a 12-inch square opening sieve but are retained on a 3-inch square opening sieve.

Fine-grained soils: Soils that contain 50% or more particles passing a No. 200 (75 µm) sieve.

Gravel: Soil particles that pass through a 3-inch square opening sieve but are retained on a No. 4 (4.75 mm) sieve. Gravels can be divided into: (1) coarse gravels, gravel particles that are retained on a ¾-inch square opening sieve, and (2) fine gravels, gravel particles that pass through a ¾-inch square opening sieve.

Sand: Soil particles that pass through a No. 4 (4.75 mm) sieve and are retained on a No. 200 (75 µm) sieve. Sands can be divided into: (1) coarse sands, sand particles that are retained on a No. 10 (2.00 mm) sieve, (2) medium sands, sand particles that pass through a No. 10 (2.00 mm) sieve and are retained on a No. 40 (425 µm) sieve, and (3) fine sands, sand particles that pass through a No. 40 (425 µm) sieve.

Silt: Nonplastic or very slightly plastic soil particles passing a No. 200 (75-μm) sieve that exhibit little or no strength when air dried. For classification of silty soils, refer to Section 1-3.3.

1-3.2 Visual Description and Identification (ASTM D2488).

Visual description of soil samples is commonly performed in the field during the drilling process and consists of a visual description of the soil accompanied by an identification of the type of soil. This should be done by an engineer or a qualified person and should include as much information as possible regarding the observed conditions of the soil *in situ*. The visual description of the soil, along with the drilling logs, can provide very useful qualitative information to the engineer if done correctly. One of the most widely used standards for this purpose is ASTM D2488, which uses visual examination and simple manual tests to describe and identify soils.

1-3.2.1 Visual Description.

The descriptors for soils consist of properties and qualitative information of the soil that can be perceived with our senses. This information can be very valuable to the engineer. Below are some guidelines on what should be observed based on ASTM D2488.

1-3.2.1.1 Descriptors for All Soils.

Color: Use the color or colors that best describes the sample. Color is an important property that can help in identifying organic soils. Within a given locality, it may also be useful in identifying materials of similar geologic origin. Layers or patches of different colors should also be noted. The color described should be that of a moist sample. If the color represents a dry condition, this should be stated in the report. A Munsell color chart is a useful tool to help describing the color.

HCl reaction: Diluted hydrochloric acid (HCl) (one part of HCl to three parts of distilled water) can be used to identify the presence of calcium carbonate. The HCl reaction should be described as: (1) none, for no visible reaction, (2) weak, for some reaction with bubbles forming slowly, or (3) strong, for violent reaction with bubbles forming immediately.

Moisture condition: The moisture condition of the soil should be described as follows: (1) dry, for soils with absence of moisture, dusty, or dry to the touch, (2) moist, for damp soils with no visible water, or (3) wet, for soils with visible free water.

Odor: The odor of the soils should be described if the soil is organic or has an unusual odor.

Others: Additional comments like the presence of roots or root holes, difficulty in drilling the hole, caving of the trench or hole, or the presence of mica should be included. In addition, a local or commercial name, or a geologic interpretation of the soil could be added to help identifying the soil.

1-3.2.1.2 Descriptors for Fine-Grained Soils.

Consistency: The consistency of intact fine-grained soils should be described as: (1) very soft, if the thumb will penetrate soil more than 1 inch (25 mm); (2) soft, if the thumb will penetrate soil about 1 inch (25 mm); (3) firm, if the thumb will indent soil about 1⁄4 inch (6 mm); (4) hard, if the thumb will not indent soil but readily indented with thumbnail; or (5) very hard, if the thumbnail will not indent soil.

Structure: The structure for intact soils should be described using the following terms:

1) *Stratified*: Use for soils with layers of different material or color of at least ¼ inch in thickness. The layer thickness should be noted.
2) *Laminated*: Use for soils with layers of different material or color of less than ¼ inch in thickness. The layer thickness should be noted.
3) *Fissured*: Use for soils that break along predetermined planes with little resistance.
4) *Slickensided*: Apply to fissured soils that show polished, glossy, or sometimes striated fracture planes.
5) *Blocky*: Describes soils that can be broken down into small angular lumps which are hard to break down further.
6) *Lensed*: Use for soils with inclusions of small pockets of different soils scattered through the mass of the clay. The lens thickness should be noted.
7) *Homogenous*: Use for soils with the same color and appearance throughout.

1-3.2.1.3 Descriptors for Coarse-Grained Soils.

Angularity: Describe the angularity of coarse-grained soils as: (1) angular, if the particles have sharp edges and relatively plane sides with unpolished surfaces, (2) subangular, if the particles are angular but with rounded edges, (3) subrounded, if particles have nearly plane sides but well-rounded corners and edges, or (4) rounded, if particles have smoothly curved sides and no edges. Figure 1-1 shows examples of these four terms.

Cementation: Describe the cementation of intact coarse-grained soils as: (1) weak, if the soil crumbles or breaks with handling or little pressure, (2) moderate, if the soil crumbles or breaks with considerable finger pressure, or (3) strong, if the soil will not crumble or break with finger pressure.

Figure 1-1 Typical Angularity of Bulky Grains (after Sowers 1979)

Hardness: Describe the hardness of coarse-grained soils as hard if the particles do not crack, fracture, or crumble when struck by a hammer, or state what happens to the particles when hit by a hammer.

Maximum particle size: Describe the maximum particle size. For sands, describe it as coarse, medium, or fine. For gravels, the maximum particle size is the smallest sieve opening that the particle will pass. For cobbles and boulders, the maximum particle size is the maximum dimension of the largest particle.

Range of particle size: Describe the range of particle sizes within each component. For example, about 15% of coarse gravel and about 45% of fine to coarse sand.

Shape: Describe the shape as: (1) flat, for particles with width/thickness > 3, (2) elongated, for particles with length/width > 3, or (3) flat and elongated, for particles that meet both criteria.

1-3.2.2 Identification.

The identification method presented in this section follows ASTM D2488. The identification should be performed on a sample that excludes cobbles and boulders. These large particles should be manually removed from disturbed samples and ignored for intact samples. The percentage of cobbles and boulders from the total samples should be estimated by volume and noted. Estimate the percentage, by dry mass, of gravel, sand and fines. The percentages should be estimated to the closest 5% and all the percentages should add to 100%. If one type of soil is encountered but the amount is less than 5% the term trace should be used to indicate its presence. A component described as trace should not be included in the 100%.

1-3.2.2.1 Identification of Fine-Grained Soils.

The identification of fine-grained soils is based upon the results of the dry strength, dilatancy, toughness, and plasticity tests.

Dry strength test: This test should be performed using a 0.5-inch diameter ball of soil. The ball needs to be air-dried or dried by artificial means at a temperature not exceeding 140°F. After drying, the ball is crushed between the fingers and the strength is classified as:

1) None, if the dry specimen crumbles into powder with the mere pressure of handling,
2) Low, if the dry specimen crumbles into powder with some finger pressure,
3) Medium, if the dry specimen breaks into pieces or crumbles with considerable finger pressure,
4) High, if the dry specimen cannot be broken with finger pressure but will break into pieces between thumb and a hard surface, or
5) Very high, if the dry specimen cannot be broken between the thumb and a hard surface.

Dilatancy: This test is performed using a 0.5-inch diameter ball molded to a soft but not sticky consistency. The ball is smoothed in the palm of one hand using the blade of a knife or a small spatula. The hand is then shaken horizontally and vigorously struck against the other hand several times. The reaction of water appearing on the surface should be noted. The soil is then squeezed by closing the hand or pinched between the fingers and the reaction of water is noted. The dilatancy is classified as:

1) None, if no visible change in the specimen was observed,
2) Slow, if water appears slowly on the surface of the specimen during shaking and does not disappear or disappear slowly upon squeezing, or
3) Rapid, if water appears quickly on the surface of the specimen during shaking and disappears quickly upon squeezing.

Toughness: This test is performed after the dilatancy test is completed and using the same specimen. The test specimen is rolled by hand on a smooth surface into a thread of about 1/8 inches in diameter. The sample is folded, mixed again, and rerolled until the threads break at a diameter of about 1/8 inches, which means the soil is near the plastic limit. The toughness of the soil is classified as:

1) Low, if only slight pressure is required to roll the thread near the plastic limit and the thread and the lump are weak and soft,
2) Medium, if medium pressure is required to roll the thread to near the plastic limit and the thread and the lump have medium stiffness, or
3) High, if considerable pressure is required to roll the thread to near the plastic limit and the thread and the lump have very high stiffness.

Plasticity: The plasticity of the soil is classified based on observations made during the toughness test as:

1) Nonplastic, if a 1/8-in-diameter thread cannot be rolled at any water content,
2) Low, if the thread can barely be rolled and the lump cannot be formed when drier than the plastic limit,

3) Medium, if the thread is easy to roll and not much time is required to reach the plastic limit, if it cannot be rolled after reaching the plastic limit, and the lump crumbles when drier than the plastic limit, or
4) High, if it takes considerable time rolling and kneading to reach the plastic limit, if the thread can be rerolled several times after reaching the plastic limit, and the lump can be formed without crumbling when drier than the plastic limit.

After these tests are performed, classify inorganic-fine-grained soils using the information in Table 1-2. If the soil contains enough organic matter, identify the soil as organic soil, OL/OH. Normally organic soils have a brown to black color and some organic odor. Normally organic soils will not have a high toughness or plasticity and the threads for the toughness test will be spongy.

Table 1-3 Classification of Fine-grained Soils

Soil Symbol	Dry Strength	Dilatancy	Toughness and Plasticity
ML	None to low	Slow to rapid	Low or thread cannot be formed
CL	Medium to high	None to slow	Medium
MH	Low to medium	None to slow	Low to medium
CH	High to very high	None	High

For fine-grained soils with an estimated percentage of sand, gravel or both the term “with sand” or “with gravel” depending on which one is more predominant should be added to the group name. If the percentage of sand and gravel is the same, use the term “with sand.” For fine-grained soils with an estimated percentage of sand, gravel or both above 30%, the words “sandy” or “gravelly” should be added to the group name depending on which one is more predominant. If the percentage of sand and gravel is the same, use the word “sandy.”

1-3.2.2.2 Identification of Coarse-Grained Soils.

For coarse-grained soils, the identification is only based on visual observations. Classify the soil as gravel or sand depending on which soil type is more predominant. The soil is considered a clean gravel or a clean sand if the percentage of particles that pass the #200 (75 μm) sieve is less than 5%. If the soil has a wide range of particle sizes and considerable amount of the intermediate particle sizes, the soil is considered to be a well-graded gravel or sand (GW or SW, respectively). If not, the soil is considered a poorly-graded gravel or sand (GP or SP, respectively).

For soils with 10% fines, a dual classification should be used. The first set of symbols consist of the clean gravel or sand symbols (GW, GP, SW, or SP) followed by the gravel or sand with fines symbols (GC, GM, SC, or SM). The group name should consist of the name of the first set of symbols followed by the words “with clay” or “with silt” to identify the fines.

If the soil has 15% or more fine-grained particles, the soil shall be identified as clayey gravel (GC) or clayey sand (SC), if the fines are clay as determined in the previous section, or silty gravel (GM) or silty sand (SM) if the fines are silty.

For gravels or sands with an estimated 15% or more of other coarse-grained particles, the words “with gravel” or “with sand” should be added. If the sample contains cobbles, boulders, or both the words “with cobbles,” “with boulders,” or “with cobbles and boulders” should be added to the group name.

1-3.2.3 Examples.

Below are a few examples of visual descriptions and identifications (ASTM D2488):

1) Poorly-Graded Gravel with Sand (GW): About 80% medium to coarse, hard, angular gravel; about 20% fine to coarse, hard, subangular sand; trace of fines; maximum size, 70 mm, gray, moist; no reaction with HCl.
2) Silty Sand with Gravel (SM): About 65% predominantly medium to fine sand; about 20% silty fines with low plasticity, low dry strength, low dilatancy, and low toughness, about 15% fine, hard, rounded gravel, a few gravel-size particles fractured with hammer blow; maximum size, 1.5 inch (38 mm); weak reaction with HCl.
3) Organic Soil (OL/OH): About 100% fines with low plasticity, slow dilatancy, low dry strength, and low toughness; wet, black, organic odor; strong reaction with HCl.
4) Well-Graded Gravel with Clay, Sand, Cobbles and Boulders (GW-GC): About 70% medium to coarse, hard, rounded to subangular gravel; about 20% fine, hard, rounded to subangular sand; about 10% clay low plasticity fines; moist, dark grey; no reaction with HCl; original field sample had about 5% (by volume) hard, rounded cobbles and a trace of hard, rounded boulders, with a maximum dimension of 18 inches (450 mm).

1-3.3 Unified Soil Classification System (ASTM D2487).

The unified soil classification system (USCS) is the most common classification system used for soils in the engineering community. This section is based on the USCS as presented in ASTM D2487. This classification system consists of three major soil divisions: coarse-grained soils, fine-grained soils, and highly organic soils, which are further subdivided into 15 soil groups. To use this soil classification system the grain-size distribution (ASTM D6913) of the minus 3-inch (75-mm) material, and the liquid limit and plasticity index (ASTM D4318) of the minus No. 40 (425-μm) sieve material should be known. The various groups used in this classification system have been divided to correlate in a general way with the engineering behavior of soils.

The grain-size distribution is needed for soils with 10% or more coarse-grained particles and it can be estimated for soils with less than 10% coarse-grained particles. The liquid limit and plasticity index are required for soils with 15% or more fines and the plasticity can be estimated for soils with 5% to less than 15% fines as described in Section 1-3.2.2.1. For soils with less than 5% fines, the plasticity is not needed.

1-3.3.1 Classification of Fine-Grained Soils.

Using the liquid limit and plasticity index, classify inorganic soils as lean clay (CL), fat clay (CH), silt (ML), elastic silt (MH), or silty clay (CL-ML) using Figure 1-2. For dark soils with organic odor, two liquid limit tests should be performed on the soil. One test is performed before drying, and a second test is completed after oven drying the soil at 110 ± 5°C. The soil is considered an organic silt or clay if the liquid limit of the oven-dried material is less than 75% of that of the material before oven drying. Classify the organic soil as organic silt or clay OL or OH depending on where the liquid limit and plasticity index of the non-oven-dried material plot in Figure 1-2.

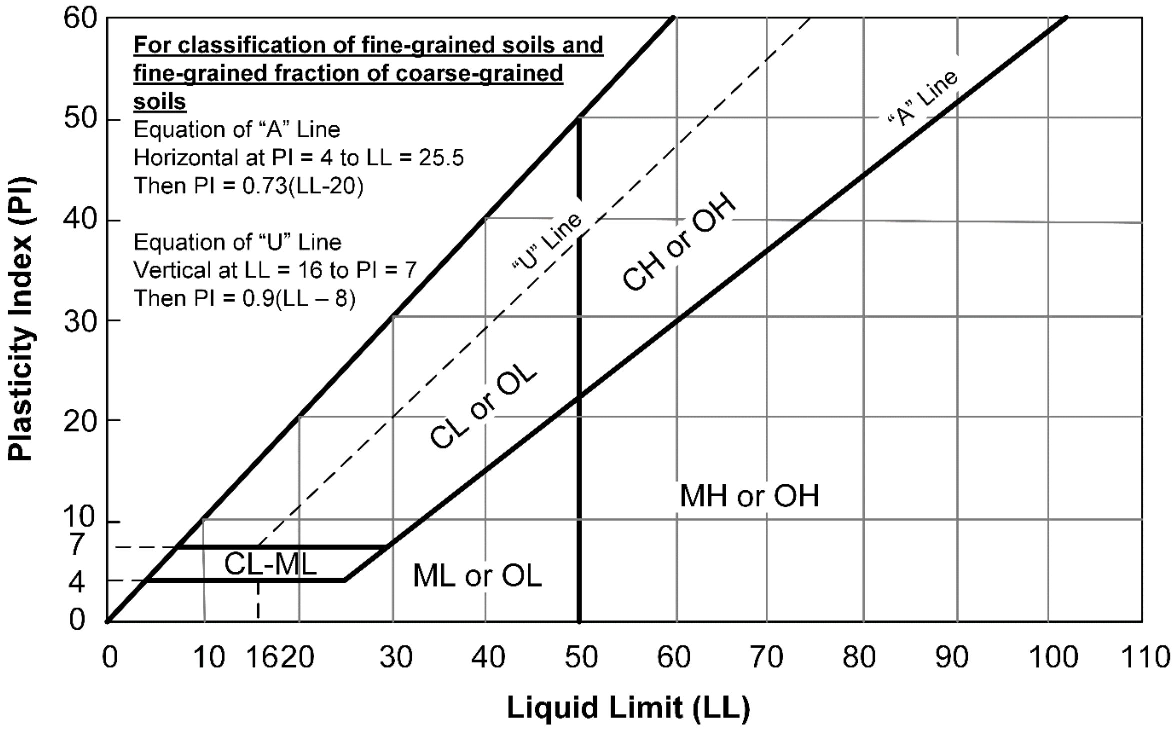

Figure 1-2 Plasticity Chart

If the fine-grained soil contains 30% or more retained in the No. 200 (75 μm) sieve the words "gravelly" or "sandy" should be added to the group name based on the type of particle that is predominant in the coarse-grained portion. For soils with equal percentage of sand and gravel, use “sandy.” If the coarse-grained portion is less than 30% but greater or equal than 15%, the words “with gravel” or “with sand” should be added to the group name depending whichever is predominant. For soils with equal percentage of sand and gravel, use “with sand.”

Some properties of fine-grained soils are usually related to the plasticity characteristics of the soil. Figure 1-3 describes how the liquid limit and plasticity index affect the compressibility, permeability, toughness at the plastic limit, and the dry strength of fine-grained soils.

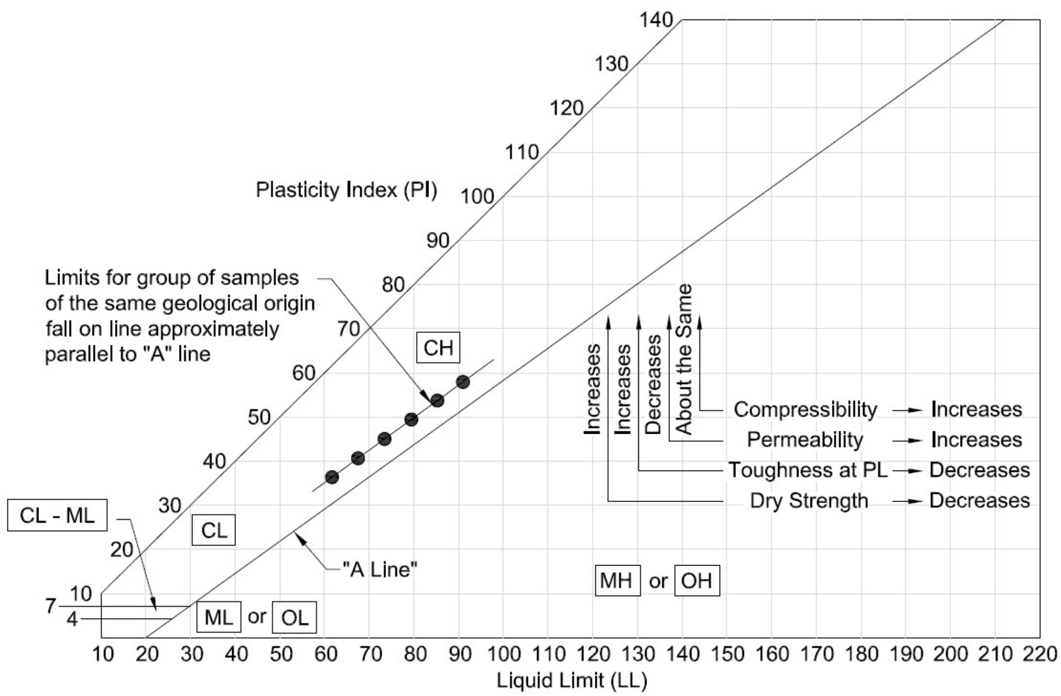

Figure 1-3 Soil Property Variation with Liquid Limit and Plasticity

1-3.3.2 Classification of Coarse-Grained Soils.

Coarse-grained soils that contain more than 50% of the coarse-grained fraction retained on the No. 4 (4.75-mm) sieve should be classified as gravel, and as sand otherwise. Using the information on the grain-size distribution curve, calculate the following to define whether the soil is well-graded or poorly-graded:

$$C_u = \frac{D_{60}}{D_{10}} \quad \textbf{(1-1)}$$

and

$$C_c = \frac{D_{30}^2}{D_{60} \times D_{10}} \quad \textbf{(1-2)}$$

where:
D_{60}, D_{30}, and D_{10} = particle-size diameters corresponding to 60%, 30%, and 10%, respectively, passing on the cumulative particle-size distribution curve,
C_u = coefficient of uniformity, and
C_c = coefficient of curvature.

Coarse-grained soils are classified as well-graded if C_u is greater than or equal to 4.0 for gravels or greater than 6.0 for sands, and C_c is at least 1.0 but not more than 3.0. Otherwise, the soil is poorly-graded.

Coarse-grained soils with less than 5% passing the No.200 (75-µm) sieve are considered *clean* and are classified as well-graded gravel (GW), well-graded sand (SW), poorly-graded gravel (GP), or poorly-graded sand (SP).

For coarse-grained soils with more than 12% fines, the classification of the fines needs to be determined using the plasticity chart presented in Figure 1-2. If insufficient fines are available to run plasticity tests, the classification of the fines shall be completed as described in Section 1-3.2.2.1. Classify the soil as silty gravel or sand (GM or SM, respectively) if the fines are silt or clayey gravel or sand (GC or SC, respectively) if the fines classify as clay. If the fines plot as silty clay (CL-ML) classify the soil as a silty, clayey gravel (GC-GM) or a silty, clayey sand (SC-SM).

Coarse-grained soils with a fine content between 5% and 12% require the use of a dual classification. The first group symbol corresponds to that for a gravel or sand having less than 5% fines (GW, GP, SW, or SP), and the second symbol correspond to a gravel or sand having more than 12% fines (GC, GM, SC, or SM). The group name is formed by the name of the first group symbol following the words “with clay” or “with silt” depending on the characteristics of the fines. If the fines plot as a silty clay, CL-ML, the second group symbol would be either GC or SC and the words “with silty clay” will be used in the name.

If the soil is mainly sand or gravel but contains 15% or more of the other coarse-grained constituent, the words “with gravel” or “with sand” shall be added to the group name. Soils with cobbles and boulders should have the words “with cobbles,” “with boulders,” or “with cobbles and boulders” added to the group name.

1-3.3.3 Examples.

Below are a few examples of visual descriptions and identifications accompanied by the proper USCS classification (ASTM D2487):

1) Well-Graded Gravel with Sand (GW): 71% fine to coarse, hard, angular gravel; 25% fine to coarse, hard, angular sand; 4% fines; C_c = 2.7, C_u = 12.4.
2) Silty Sand with Gravel (SM): 62% predominantly medium sand; 22% silty fines, LL = 32, PI = 6; 16% fine, hard, rounded gravel; no reaction with HCl.
3) Poorly-Graded Gravel with Silt, Sand, Cobbles and Boulders (GP-GM): 75% medium to coarse, hard, rounded to subangular gravel; 19% fine to medium, hard, rounded to subangular sand; 6% silty (estimated) fines; moist, brown; no reaction with HCl; original field sample had 7% hard, subrounded cobbles and 2% hard, subrounded boulders with a maximum dimension of 18 inches.

1-3.4 Soil Classification for Highways (AASHTO).

The American Association of State Highway and Transportation Officials (AASHTO) developed their soil classification system, which is mainly used for highway design and construction purposes. This system classifies the soils in 12 divisions based on the grain-size distribution, the liquid limit, and the plasticity index, using only the soil particles that pass through a 3-inch sieve. This section is based on the classification system as detailed in ASTM D3282.

An important distinction between this classification system and the USCS is the threshold used between the different types of soils. Coarse-grained or granular materials are considered to be any soil that has 35% or less passing a No. 200 (75 µm) sieve. Gravel is any material passing a 3-inch sieve and retained on a No. 10 (2.00 mm) sieve. Coarse sand is considered any soil that passes a No. 10 (2.00 mm) sieve and is retained on a No. 40 (0.425 mm) sieve. Fine sand is any material passing a No. 40 (0.425 mm) sieve and retained on a No. 200 (75 µm) sieve. Silts and clays are anything passing a No. 200 (75 µm) sieve, silts being materials with plasticity indices of 10 or less and clays being materials with plasticity indices above 10.

Soils are classified using Table 1-5 below from left to right. Highly organic soils (peat or muck) may be classified in Group A-8. Classification of organic soils is based on visual inspection and is not dependent on the percentage passing the 75-µm (No. 200) sieve, liquid limit, or plasticity index. Organic material is composed primarily of partially decayed organic matter, generally has a fibrous texture, a dark brown or black color, and an odor of decay. These organic materials are unsuitable for use in embankments and subgrades. They are highly compressible and have low strength.

The classification obtained with the table above might be modified by adding a group-index value that will be shown in parenthesis after the group symbol. The group index is calculated using the empirical equation shown below:

$$GI = (F - 35)[0.2 + 0.005(LL - 40)] + [0.01(F - 15)(PI - 10)] \quad \textbf{(1-3)}$$

where:

GI = group index,
F = percentage passing a No. 200 (75 μm) sieve (only considering the particles passing a 3-inch sieve),
LL = liquid limit of the soil, and
PI = plasticity index of the soil.

The group index should be reported as zero if calculated to be negative, if the soil is nonplastic, and when the liquid limit cannot be determined. For soils in the A-2-6 and A-2-7 subgroups, the group index should be calculated using the second part of the equation only (the part that contains the PI).

1-3.5 Other Classification Systems.

Different regions in the United States and countries around the world have their own soil classification systems. Below is a list containing the name of the country or region in the United States and the reference to the standard used. This list is not intended to be exhaustive but to show some examples. For the countries who are member of the European Union, all the local standards are superseded by the ISO standards which have the same numbers as European Norms (EN). Each country is allowed to further refine the ISO/EN standards by adding appendices as long as the appendices do not contradict the main standard. Each local standard will have the same number as the ISO standard but will have the country designation at the beginning (e.g. BS for British standards). When working on different projects in different parts of the United States or the world the engineer should investigate the standards and norms that are used in that particular area.

Table 1-4 Other Soil Classification Systems

Country / Region of USA / Agency	Reference / Name
Australia	AS 1726
Canada	Canadian System of Soil Classification
International Organization for Standardization (ISO)	ISO 14688
Occupational Safety and Health Administration (OSHA)	1926 Subpart P App A
New Orleans	USACE New Orleans District Internal Document
USDA	USDA Soil Taxonomy

Table 1-5 AASHTO Soil Classification System

Instructions: Work from left to right checking each column. The classification is the first one that matches all the criteria in the column.

General Classification	Coarse-grained (granular) Materials (35% or less passing No. 200 sieve)							Fine-grained (Silt-Clay) Materials (more than 35% passing No. 200 sieve)					Highly Organic
Group Classification	A-1		A-3	A-2				A-4	A-5	A-6	A-7[b]		A-8
	A-1-a	A-1-b		A-2-4	A-2-5	A-2-6	A-2-7				A-7-5	A-7-6	
Sieve analysis Percent passing:													
#10 (2 mm)	≤ 50												
#40 (0.4 mm)	≤ 30	≤ 50	≥ 51										
#200 (0.075 mm)	≤ 15	≤ 25	≤ 10	≤ 35	≤ 35	≤ 35	≤ 35	≥ 36	≥ 36	≥ 36	≥ 36	≥ 36	
Characteristics of fraction passing #40													
Liquid Limit				≤ 40	≥ 41	≤ 40	≥ 41	≤ 40	≥ 41	≤ 40	≥ 41	≥ 41	
Plasticity Index	≤ 6	≤ 6	NP[a]	≤ 10	≤ 10	≥ 11	≥ 11	≤ 10	≤ 10	≥ 11	≥ 11	≥ 11	
Usual types of significant constituent materials	Stone fragments; gravel and sand		Fine sand	Silty or clayey gravel and sand				Silty soils		Clayey soils			Peat or muck
General rating as subgrade	Excellent to good							Fair to poor					Unsuitable

Notes:

[a]NP indicates that the soil is "non-plastic." NP soils have $LL = PL$, $LL < PL$, or PL that cannot be determined.

[b]Use the following criteria to divide A-7: A-7-5 has $PI \leq (LL - 30)$ and A-7-6 has $PI > (LL - 30)$.

Group Index, GI

$$GI = (F-35)\left[0.2+0.005(LL-40)\right]+0.01(F-15)(PI-10)$$

Calculate the group index as:
where: F= %fines = P#200, LL = liquid limit, and PI = plasticity index.

If a negative value is calculated for GI, then report GI = 0.
Note: Use only the second term in the GI equation for A-2-6 and A-2-7 soils.

1-3.6 Common Soil and Rock Names.

In practice, some areas have specific names for different types of soils. Some of these names can be considered colloquialisms within the geotechnical engineering community. Below is a list with definitions of the most common soil names used in practice.

Adobe: Refers to sandy clays and silts of medium plasticity usually found in the semiarid regions of the southwestern United States. These soils were commonly used to make sun-dried bricks. The name is also applied to some high plasticity clays with high clay content and high swell and shrink potential usually found in the western part of the United States.

Baby poop: Refers to a very soft clay located just above limestone in karst. Frequently orange and formed by dissolution.

Back-packing: Refers to any material (commonly granular) that is used to fill the empty space between the lagging of a wall system and the rock surface.

Bank-run sand and gravel: Refers to the raw material excavated from a borrow pit, but not sorted or separated into specific grades.

Beachrock: See reefrock.

Bentonite: Refers to a high plasticity clay consisting of mostly montmorillonite, resulting from the weathering of volcanic ash mainly in the presence of water. It is normally hard when dry but swells considerably when wet. This clay is commonly used with water as drilling mud and as liner in landfills.

Black cotton soil: Refers to a black expansive soil commonly encountered in India. The name comes because this soil is common in areas where the main crop is cotton.

Blow sand: Term normally used for wind-driven or drifted sands.

Blue Marl: Name given to a bluish-green clay from the Miocene that can be found along the fall line from Richmond into Maryland. This soil is considered to be acidic, usually with a pH less than 4.0, which can affect water quality and prevent plant or aquatic life.

Bog: Refers to a wetland covered with peat with a high water table that accumulates dead plants, such as sphagnum. It is generally nutrient poor and acidic.

Boney ground: Ground containing significant amounts of large gravel, cobbles and boulders.

Boulder clay: Geological term used to designate clays formed from glacial drift that have not been subjected to the sorting action of water and therefore contains particles from boulders to clay sizes. Boulder clays are also called tills.

Breaker run: Crushed rock with large particles refers to large broken stone obtained as part of quarrying or mining activities.

Buckshot: Term applied to clays of the southern and southwestern United States that cracks into small, hard, relatively uniform-sized lumps on drying. The lumps are usually the size of buckshot and the soil is very sticky when wet.

Bull's liver: Name given to an inorganic silt or silty sand usually encountered in the New York City area. The name Bull's liver comes from its red color and jelly-like behavior when it is subjected to vibration.

Bull's Tallow or Bull Tallow clay: Refers to a tan or gray high plasticity clay typically found in relatively thin layers directly above partially weathered rock or rock in the Charlotte, NC area. This clay normally has high shrink and swelling potential.

Caliche: Refers to a sedimentary rock from arid and semiarid climate in which soil particles, such as gravel, sand, clay, and silt, are cemented and coated by carbonate (often calcium or magnesium carbonate). The level of cementation varies significantly within a deposit. The soil has light coloration often exhibits light colored concretions of various sizes depending on the level of development of the soil profile. The consistency of caliche varies from soft rock to firm soil.

Chip: Name given to crushed angular rock fragments smaller than a few centimeters.

Coffee grounds: Soil formed from freshwater marshes that has been dry for decades and has decomposed to the point that is black and inert with no plasticity. It is black and granular even when wet.

Colluvium: Loose soil deposited at the bottom of a slope.

Coquina: Soft, porous sedimentary rock, mainly limestone, composed largely of shells, coral, and fossils cemented together with particles averaging 0.079 inch (2 mm) or greater in size.

Desert varnish: Also called patina, rock varnish or rock rust. Consists of a thin, dark red to black mineral coating found on pebbles and rocks surfaces in arid regions.

Diatomaceous earth: Soft, siliceous sedimentary rock that usually crumbles into powder. When crumbled, the particles are silty and contain large amounts of diatoms, the siliceous skeletons of minute marine or freshwater organisms.

Dispersive clays: These clays contain a high percentage of dissolved sodium in the pore water. When these soils are exposed to water, the clay particles deflocculate (i.e., separate) making these soils very susceptible to erosion.

Fibric peat: Peat in which the original plant fibers are slightly decomposed and contain 67% or more of fibers.

Fill: Any man-made soil deposit. It can range from soils that are free of organic matter and that are carefully compacted to heterogeneous accumulations of rubbish and debris.

Fuller's earths: Soils having the ability to absorb fats or dyes. These soils have the capability to decolorize oil or other liquids without chemical treatment. They are usually high plasticity sedimentary clays.

Glacial till: See boulder clay.

Glassified sand: Term used to name the ground surface after a big forest fire.

Goonies: Name given to the cobbles found floating in a soil matrix.

Grove sand: See sugar sand.

Gumbo: Refers to a fine-grained, high plasticity clay of the Mississippi Valley according to Sowers (1979). It has a sticky, greasy feel and forms large shrinkage cracks on drying.

Gyp or gip soil: Refers to gypsum soil (or soil containing gypsum) or caliche soil.

Hardpan: Normally refers to a soil layers that has become hard as rock due to cementing minerals, does not become plastic when mixed with water and is relatively impervious. The name has also been applied to any hard or overconsolidated layer that is hard to excavate. Because of this ambiguity, Sower (1979) recommends that engineers should avoid this term because many lawsuits have centered about the meaning of it. The name implies a condition of the soil rather than a type of soil.

Humus: Refers to a brown or black material formed by the partial decomposition of vegetable or animal matter. It is the organic portion of soil.

Kaolin: Refers to a white or pink clay of low plasticity. It is composed largely of minerals of the kaolinite family.

Laterites: Refers to residual soils rich in iron formed in hot and humid climates (tropical regions). The cementing action of iron oxides and hydrated aluminum oxides makes dry laterites extremely hard. The high iron oxide content makes nearly all laterites to be rusty-red. These are usually developed after significant weathering of the parent rock.

Ledge: Name used for bedrock in Vermont, and sometimes in New Hampshire.

Loam: Refers to a low plasticity sandy silt or silty sand mixed with organic matter that is well suited to tilling. Mainly applies to the uppermost soil layer and should not be used to describe deep deposits of parent materials. Major soil type in the USDA system.

Marl: Refers to a calcium carbonate or lime-rich sedimentary rock. It is mainly composed of a mixture of sand, silt, or clay. Marls are often light to dark gray or greenish in color and sometimes contain colloidal organic matter.

Montmorillonite: A group of very fine clay minerals with extreme swelling and shrinking properties. Normally results from volcanic or hydrothermal activities. Bentonite is a form of montmorillonite.

Muskeg: Refers to peat found in North America. According to Sowers (1979) the bogs in which the peat forms are often termed muskegs.

Peat: Refers to a fibrous, partially decomposed and highly compressible organic soil. Peats are dark brown or black.

Pit-run sand and gravel: See bank run.

Pluff mud: Refers to an odoriferous and very soft mud usually encountered in South Carolina.

Recycled concrete aggregate (RCA): Recycled road or structural concrete. The concrete is usually processed and screened. The processing consists of crushing the concrete into smaller pieces. Any leftover steel is removed using a magnet. This type of material is very popular as a replacement for natural stone aggregates.

Recycled or reclaimed asphalt pavement (RAP): Term used to describe the removed asphalt layer. When properly processed, it consists of high-quality and well-graded aggregates coated by asphalt cement.

Recycled or reclaimed asphalt shingles (RAS): Recycled shingles that are used as aggregate for hot mix asphalt. Depending on the quality, this can reduce the cost of the new asphalt mix and the amount of fine aggregate used in the mix.

Recycled pavement material (RPM): Pulverized mixture of asphalt and base course material usually forming a broadly-graded material.

Reefrock: Cemented coralline deposits.

Riprap: Boulder-size material normally placed to strengthen structures against scour, wave action, and ice erosion.

Riverjack: Name usually given to alluvial cobbles and boulders.

Rock dirt combination (RDC): Local term used in the Harrisonburg, VA area to describe material from a quarry consisting of a mixture of overburden soil and rock.

Rock flour: Fine-grained soil with silt-sized particles formed by the grinding of bedrock by glaciers.

Shale: Refers to a fine-grained sedimentary rock made of silt and clay particles. This rock usually breaks along thin laminates and can slake when subjected to wet-dry cycles.

Shot rock: Refers to the material from a rock quarry that has not been sorted. It includes everything that can be picked up (from fine sand to small boulders) after a quarry blast. It is also a name given to riprap, although riprap is typically sorted and graded.

Slickensided clay: Name given to a clay that has experienced repeated or enough displacement along a fissure or a failure plane causing the surface to be smooth and shiny.

Stone: Gravel size-particles manufactured by crushing rock.

Sugar sand: Local name for a type of fine sandy soil found in New Jersey. In Kansas, the term refers to a type of granular calcite found in Ness and Hodgeman counties. In addition, the term may refer to a fine sand usually found in Florida that does not hold water or nutrients very well. It is normally windblown medium and/or fine sand, poorly-graded, nonplastic. It often contains nonplastic silt.

Till: See boulder clay.

Tire derived aggregate (TDA): Refers to a lightweight construction material obtained by shredding or chipping scrap tires. The particle size usually ranges from 0.5 inches to 12 inches. TDA has been used in a wide range of projects, including lightweight embankment fill, landslide repair or stabilization, landfills, retaining wall backfill, roads, vibration mitigation, among others.

Topsoil: Upper and outermost layer of soil that support plant life. Usually contains considerable organic matter.

Trap: Includes any dark-colored, fine-grained, non-granitic intrusive rock. The most common trap rock is basalt, but also includes peridotite, diabase, and gabbro.

Tuff: Refers to a soft porous rock made from consolidated volcanic ash.

Varved clays: Sedimentary deposits consisting of alternate thin layers of silt and clay. According to Sowers (1979), each pair of silt and clay layers is from 1/8 inch to 1/2 inch thick. These soils result from deposition in lakes during periods of alternately high and low water in the in flowing streams and are often formed in glacial lakes.

1-4 ROCK VISUAL DESCRIPTION, AND CLASSIFICATION.

1-4.1 Definitions.

Azimuth: Angle of a feature measured from North at 0° in a spherical coordinate system.

Bedding: Planes of dissimilar materials caused by deposition normally encountered in sedimentary rocks.

Dip: Angle that the surface of the rock forms with a horizontal plane.

Flow banding: Refers to the layering that is normally seen in rocks formed from magma.

Foliation: Refers to the laminated structure of the minerals in a rock created by the deformation.

Igneous rocks: Rocks formed from the cooling and solidification of magma.

Lamination: Sequence of fine layers in a small scale (usually less than one centimeter in thickness) normally observed in sedimentary rocks.

Metamorphic rocks: Rocks formed from the transformation by heat, pressure, or both of existing rocks. This transformation can alter the physical and chemical properties of the rock.

Rock: Natural solid mineral or aggregate of minerals which is normally classified by the way it was formed.

Rock mass: A large body containing rock in intact and weathered conditions accompanied by structural discontinuities like fault, joints, etc., which can be interbedded with soil material.

Sedimentary rocks: Rocks formed by the accumulation and cementation of smaller particles.

Strike: Is the line representing the intersection of the rock surface with a horizontal plane.

1-4.2 Visual Classification.

Rock samples and exposures can be visually classified by weathering, discontinuities, color and grain size, hardness, and geological origin.

1-4.2.1 Geological Name and Origin.

The first step in visually classifying a rock is to identify the type of rock (e.g., igneous, metamorphic, or sedimentary). Then, the geologic name and local name (if any) is identified based on characteristics, such as texture and mineralogy. Igneous rocks are normally classified by their mineralogical composition, texture, and color as can be seen in Table 1-6.

Metamorphic rocks are normally classified by their texture and structure, as can be seen in Table 1-7. Sedimentary rocks are normally classified by whether they are derived from clastic sediments or chemical precipitates/organisms, as can be seen in Table 1-8. Subordinate constituents in rock samples, such as seams or bands of other type of minerals, should also be identified (e.g., dolomitic limestone, calcareous sandstone, sandy limestone, mica schist).

Table 1-6 Simplified Rock Classification - Common Igneous Rocks

Color		Light		Intermediate	Dark	
Principal Mineral		Quartz and Feldspar Few other minerals	Feldspar	Feldspar and Hornblende	Augite and Feldspar	Augite, Hornblende, Olivine
Texture	Coarse, Irregular Crystalline	Pegmatite	Syenite Pegmatite	Diorite Pegmatite	Gabbro Pegmatite	
	Coarse and Medium Crystalline	Granite	Syenite	Diorite Dolerite	Gabbro Dolerite	Peridotite Dolerite
	Fine Crystalline	Aplite			Diabase	
	Aphanitic	Felsite			Basalt	
	Glassy	Volcanic Glass			Obsidian	
	Porous (Gas Openings)	Pumice		Scoria or vesicular basalt		
	Fragmental	Tuff (fine), Breccia (coarse), cinders (variable)				

Table 1-7 Simplified Rock Classification - Common Metamorphic Rocks

Texture	Structure		
	Foliated		Massive
Coarse Crystalline	Gneiss		Metaquartzite
Medium Crystalline	Schist	Sericite	Marble
		Mica	Quartzite
		Talc	Serpentine
		Chlorite	Soapstone
Fine to Microscopic	Phyllite		Hornfels
	Slate		Anthracite Coal

Table 1-8 Simplified Rock Classification – Common Sedimentary Rocks

Group	Grain Size	Composition		Name
Clastic	Mostly coarse grains	Rounded pebbles in medium-grained matrix		Conglomerate
		Angular coarse-grained fragments, often quite variable		Breccia
	More than 50% medium grains	Medium coarse grains	Less than 10% of other minerals	Siliceous sandstone
			Appreciable quantity of clay minerals	Argillaceous sandstone
			Appreciable quantity of calcite	Calcareous sandstone
			Over 25% feldspar	Arkose
			25%-50% feldspar and darker minerals	Graywacke
	More than 50% fine grains	Fine to very fine quartz grains with clay minerals		Siltstone (if laminated, Shale)
		Microscopic clay minerals	<10% other minerals	Shale
			Appreciable calcite	Calcareous Shale
			Appreciable carbon / carbonaceous material	Carbonaceous Shale
			Appreciable iron oxide cement	Ferruginous Shale
Organic	Variable	Calcite and fossils		Fossiliferous Limestone
	Medium to microscopic	Calcite and appreciable dolomite		Dolomite Limestone or Dolomite
	Variable	Carbonaceous material		Bituminous coal
Chemical	Microscopic	Calcite		Limestone
		Dolomite		Dolomite
		Quartz		Chert, Flint, etc.
		Iron compounds with Quartz		Iron Formation
		Halite		Rock Salt
		Gypsum		Rock Gypsum

1-4.2.2 Color and Grain Size.

Rock can be described with respect to basic colors on a rock color chart. The most common chart used for this purpose in the United States is the Munsell rock color chart which includes 115 color chips and works with both wet and dry specimens. Another commonly used system is the one published by the Geological Society of London (1977). This system is based on three descriptors as can be seen in Table 1-9.

Grain size for rock refers to the sizes of the small grains that comprise the rock. Because of the nature of some rocks, a 10X hand lens can be used, if necessary, to examine rock sample. Various grain-size criteria have been established, and no single criteria is standard or used most often. An example of grain-size descriptors for different types of rock are found in Table 1-10. Another criterion presented by FHWA (2017) is also included here in Table 1-11 which is similar to that presented by the Geological Society of London (1977).

Table 1-9 Rock Color Descriptors (Geological Society of London 1977)

1st Descriptor	2nd Descriptor	3rd Descriptor
Light Dark	Yellowish Buff Orangish Brownish Pinkish Purplish Orange Olive Greenish Greyish	White Yellow Buff Orange Brown Pink Red Blue Green Purple Olive Grey Black

Table 1-10 Grain-Size Descriptors for Rock

Igneous and Metamorphic		Sedimentary Rocks	
Description	**Grain Diameter**	**Description**	**Grain Diameter**
Coarse-grained	> 5 mm	Coarse-grained	> 2 mm
Medium-grained	1 to 5 mm	Medium-grained	0.06 to 2 mm
Fine-grained	< 1 mm	Fine-grained	0.002 to 0.06 mm
Aphantic	Too small to be perceived by eye	Very fine-grained	< 0.002 mm
Glassy	No grain form distinguishable		

Table 1-11 Criteria for Defining Rock Grain Size (after FHWA 2017)

Grain Size	Description	Criteria
< 0.003 in. (< 0.075 mm)	Very Fine-Grained	Cannot be distinguished by unaided eye. Few to no mineral grains are visible with a hand lens.
0.003 – 0.02 in. (0.075 – 0.425 mm)	Fine-Grained	Few crystal boundaries are visible; grains can be distinguished with difficulty by the unaided eye but can be somewhat distinguished by hand lens.
0.02 – 0.8 in. (0.425 – 2 mm)	Medium-Grained	Most crystal boundaries are visible; grains distinguishable by eye and with hand lens.
0.8 – 2 in. (2 – 4.75 mm)	Coarse-Grained	Crystal boundaries are visible; grains distinguishable with naked eye.
2 in. (> 4.75 mm)	Very Coarse-Grained	Crystal boundaries are clearly visible; grains are distinguishable with the naked eye.

1-4.2.3 Weathering.

Weathering is the mechanical or chemical deterioration of rock properties by the exposure to water, temperature changes, among other factors. Rock can be described as fresh, slightly weathered, etc. in accordance with Table 1-12 as indicated by the International Society of Rock Mechanics (ISRM). As the degree of weathering increases, usually the strength, stiffness, and quality of the rock decrease.

Table 1-12 Weathering Classification

Grade	Symbol	Weathering Grade[1]	Diagnostic Features
Fresh	F	I	No visible sign of decomposition or discoloration; rings under hammer impact
Slightly Weathered	WS	II	Slight discoloration inwards from open fractures, otherwise similar to F
Moderately Weathered	WM	III	Discoloration throughout; weaker minerals such as feldspar decomposed; strength somewhat less than fresh rock but cores cannot be broken by hand or scraped by knife; texture preserved
Highly Weathered	WH	IV	Most minerals somewhat decomposed; specimens can be broken by hand with effort or shaved with knife; core stones present in rock mass; texture becoming indistinct but fabric preserved
Completely Weathered	WC	V	Minerals decomposed to soil but fabric and structure preserved (saprolite); specimens easily crumbled or penetrated
Residual Soil	RS	V	Advanced state of decomposition resulting in plastic soils; rock fabric and structure completely destroyed; large volume change.

[1] After FHWA (2017).

1-4.2.4 Discontinuities.

The spacing of discontinuities in the rock can be described as close, wide, etc., in accordance with Table 1-13. The structural features of a rock mass can be described as thickly bedded or thinly bedded, in accordance with Table 1-13. Depending on project requirements, the form of joint should be identified as stepped, smooth, undulating, planar, etc. In addition, the dip (in degrees), surface condition (rough, smooth, slickensided), opening size (giving width), and filling (none, sand, clay, breccia, etc.) should also be recorded.

1-4.2.5 Hardness.

The hardness of rock can be estimated by field tests using a geologic hammer or knife and, in the laboratory, using the point load test in accordance with Table 1-14. The corresponding range of strength values for intact rock is also provided. A more recent grading system presented by the ISRM is presented in Table 1-15.

Table 1-13 Discontinuity Spacing

Type of Feature	Description	Spacing	Description for Joints, Faults, or Other Fractures
Macrostructural: Bedding, Foliation, or Flow Banding	Very thickly (bedded, foliated, or banded)	> 6 feet	Very widely (fractured or jointed)
	Thickly	2 to 6 feet	Widely
	Medium	8 to 24 inches	Medium
	Thinly	2.5 to 8 inches	Closely
	Very Thinly	0.75 to 2.5 inches	Very Closely
Microstructural: Lamination, Foliation, or Cleavage	Intensely (laminated, foliated, or cleavage)	0.25 to 0.75 inch	Extremely close
	Very Intensely	< 0.25 inch	

Table 1-14 Hardness Classification of Intact Rock (Hough 1969)

Class	Hardness	Field Test	Approximate compressive strength (kg/cm^2 or tsf)
I	Extremely hard	Many blows with geologic hammer required to break intact specimen	>2000
II	Very hard	Handheld specimen breaks with hammer end of pick under more than one blow	1000 - 2000
III	Hard	Cannot be scraped or peeled with knife, hand held specimen can be broken with a single moderate blow with pick	500 - 1000
IV	Soft	Can just be scraped or peeled with knife. Indentations of 1 mm to 3 mm show in specimen with moderate blow with pick	250 - 500
V	Very soft	Material crumbles under moderate blow with sharp end of pick and can be peeled with a knife, but is too hard to hand trim for triaxial test specimen	10 – 250

Table 1-15 Criteria and Descriptions for Relative Rock Strength (after FHWA 2017)

Grade	Description	Field Identification	Approximate Compressive Strength (kg/cm^2 or tsf)
R0	Extremely Weak Rock	Specimen can be indented by thumbnail	2.5 – 10.8
R1	Very Weak Rock	Specimen crumbles under sharp blow with point of geological hammer and can be peeled with a pocket knife	10.8 – 52.2
R2	Weak Rock	Shallow cuts or scrapes can be made in a specimen with a pocket knife; a firm blow with a geological hammer creates shallow indents	52.2 – 252
R3	Medium Strong Rock	Specimen cannot be scraped or cut with a pocket knife; specimen can be fractured with a single firm blow with a geological hammer point	252 – 522
R4	Strong Rock	Specimen requires more than one firm blow of the point of a geological hammer to fracture	522 – 1,044
R5	Very Strong Rock	Specimen requires many firm blows from the hammer end of a geological hammer to fracture	1,044 – 2,610
R6	Extremely Strong Rock	Specimen can only be chipped with firm blows from the hammer end of a geological hammer	> 2,610

1-4.3 Classification by Field and Laboratory Measurements.

1-4.3.1 Rock Quality Designation.

The Rock Quality Designation (RQD) is only for NX size core samples and is computed by summing the lengths of all pieces of core equal to or longer than 4 inches and dividing by the total length of the coring run. The resultant is multiplied by 100 to get RQD in percent. It is necessary to distinguish between natural fractures and those caused by the drilling or recovery operations. The fresh, irregular breaks should be ignored and the pieces counted as intact lengths. Depending on the engineering requirements of the project, breaks induced along highly anisotropic planes, such as foliation or bedding, may be counted as natural fractures. A qualitative relationship between RQD, velocity index, and rock mass quality is presented in Table 1-16. The velocity index is defined as the square of the ratio of the *in situ* to laboratory or intact compressional wave velocities.

Table 1-16 Engineering Classification for *In situ* Rock Quality (Merritt and Coon 1970)

RQD	Velocity Index	Rock Mass Quality
90-100	0.80-1.00	Excellent
75-90	0.60-0.80	Good
50-75	0.40-0.60	Fair
25-50	0.20-0.40	Poor
0-25	0.00-0.20	Very Poor

1-4.3.2 Classification by Strength.

The uniaxial compressive strength and modulus ratio can be used to classify rock using the results of ASTM D7012. The strength of intact sample can be used with Figure 1-4 to assign a classification as weak, strong, etc.

The point load strength can also be used to classify rock as indicated in Figure 1-4. Point load strength tests, described in ASTM D5731, are sometimes performed in the field for larger projects where rippability and rock strength are critical design factors. This simple field test can be performed on core samples and irregular rock specimens. The point load strength index, $I_{s(50)}$, is defined as:

$$I_{s(50)} = F \cdot \frac{P}{d^2} \quad \textbf{(1-4)}$$

$$F = \sqrt{\frac{D_e}{50}} \quad \textbf{(1-5)}$$

where:
F = size correction factor,
P = the applied force at failure,
d = the distance between the loaded points, and
D_e = equivalent core diameter.

This index is related to the direct tensile strength of the rock by a proportionality constant F depending on the size of sample. Useful relationships of point load tensile strength index to other parameters such as specific gravity, seismic velocity, elastic modulus, and compressive strength are readily available in the literature.

1-4.3.3 Classification by Durability.

Short-term weathering of rocks, particularly shales, and mudstones, can have a considerable effect on their engineering performance. The weatherability of these materials is extremely variable, and rocks that are likely to degrade on exposure should be further characterized by use of tests for durability under standard drying and wetting cycles. The slake durability test is a standardized procedure, described in ASTM D4644, used for this purpose. For example, if wetting and drying cycles reduces the grain size of shale, then rapid slaking and erosion in the field is probable when the rock is exposed. Another method used for this purpose is the jar slake test described by Santi (1998).

1-4.4 Rock Mass Classification Systems.

Various classification systems have been developed for classifying rock mass for engineering projects. Three of the main systems are described in this section. The reader is encouraged to check for the classification system used in the region of practice and that most applies to the project in question.

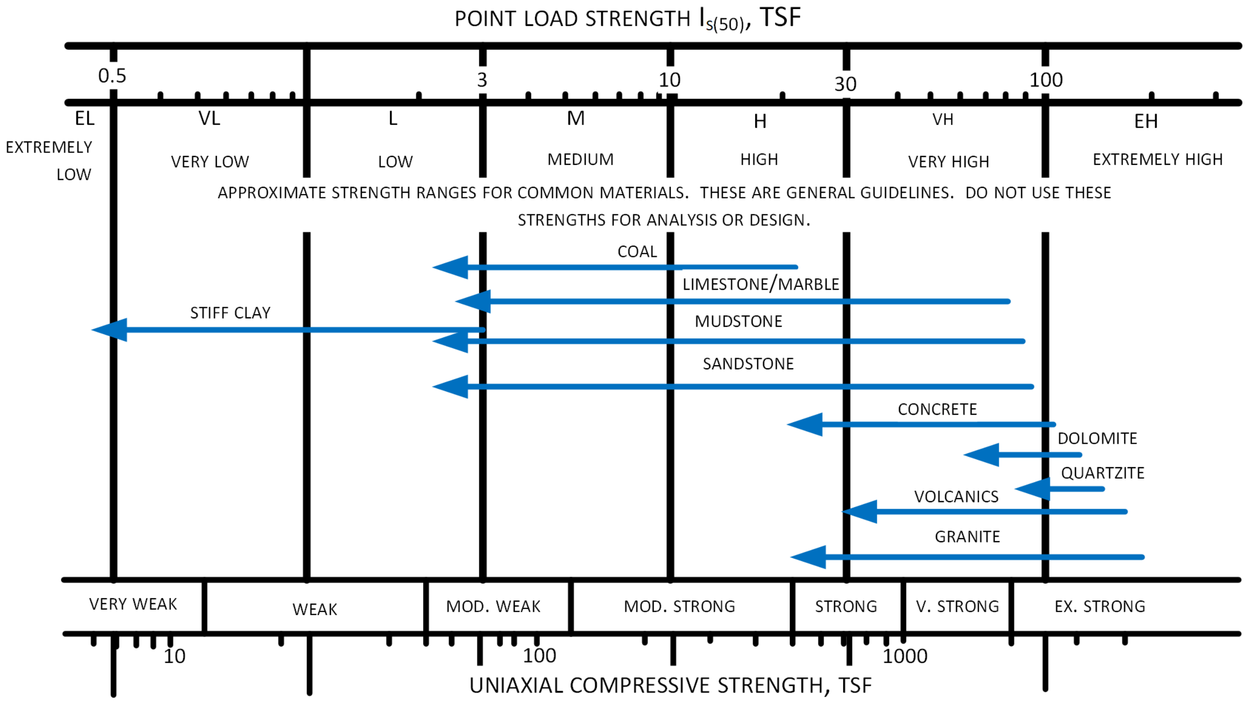

Figure 1-4 Rock Strength Characterization (after Broch and Franklin 1972)

The classification of the rock mass using some of these systems is useful to estimate physical and engineering properties using published values and charts. Also, some design methodologies rely on the classification of the rock mass.

1-4.4.1 *Q* System.

Barton et al. (1974) defines the value of *Q* in terms of *RQD*, the number of joint sets, the joint properties, and a stress reduction factor. Extensive tables are provided to guide the engineer in the selection of appropriate values. The roof pressure and support requirements for tunnels can be estimated from the value of *Q*, as well as some of the joint properties.

1-4.4.2 Rock Mass Rating System.

The rock mass rating system (*RMR*), also known as the Geomechanics classification, by Bieniawski (1973) classifies rock based on the uniaxial compressive strength, *RQD*, the spacing and properties of the joints, and groundwater conditions. While not solely intended for tunneling applications, the *RMR* can be related to stand-up time, unsupported active span length, and roof pressure.

1-4.4.3 Geological Strength Index.

The Geological Strength Index (*GSI*) has become a commonly used approach to describe rock mass quality in a qualitative manner (Marinos et al. 2007). Because it is closely linked to rock strength, *GSI* is most useful as a tool to help estimate rock properties for stability analysis. The *GSI* can be quantified as indicated in Figure 1-5; however, a range of values should always be used. Such values of *GSI* may be used as input for empirical equations for the shear strength of a rock mass.

The *GSI* is most useful for rock masses with many discontinuities that cannot be effectively modeled in direct fashion. According to Marinos et al. (2007), *GSI* should not be used for (1) rocks with clear discontinuities and well-defined dominant structure, (2) excavated faces in strong, hard rock with discontinuities spaced at similar dimensions to the tunnel or slope, or (3) low strength "young" rocks such as marls, claystones, siltstones, and weak sandstones. Marinos et al. (2007) developed a modified *GSI* system for heterogeneous rocks, such as layered shales and sandstones, as shown in Figure 1-6. The application of *GSI* to these rocks should account for their tendency to behave differently at depth compared to near the ground surface.

1-4.4.4 Other Classification Systems.

Some other classification systems have been proposed depending on the region, purpose, and needs. Some of these systems are summarized in Table 1-17.

Table 1-17 Other Rock Classification Systems

Rock Mass Classification System	**Main Uses**	**Reference**
Rock Structure Rating	Tunnel support and excavation and other ground support work in mining and construction	Skinner (1988)
Unified Rock Classification	Foundations, methods of excavation, slope stability, uses of earth materials, blasting characteristics of earth materials, and transmission of groundwater	Williamson and Kuhn (1988)
Rock Material Field Classification	Shallow excavation, particularly with regard to hydraulic erodibility in earth spillways, excavatability, construction quality of rock, fluid transmission, and rock-mass stability	NRCS (2002)
New Austrian Tunneling Method	Conventional (cyclical, such as drill and-blast) and continuous (tunnel-boring machine or TBM) tunneling; this is a tunneling procedure in which design is extended into the construction phase by continued monitoring of rock displacement; support requirements are revised to achieve stability	Lauffer (1997)
Coal Mine Roof Rating	bedded coal-measure rocks, in particular with regard to their structural competence as influenced by discontinuities in the rock mass	Molinda and Mark (1994)

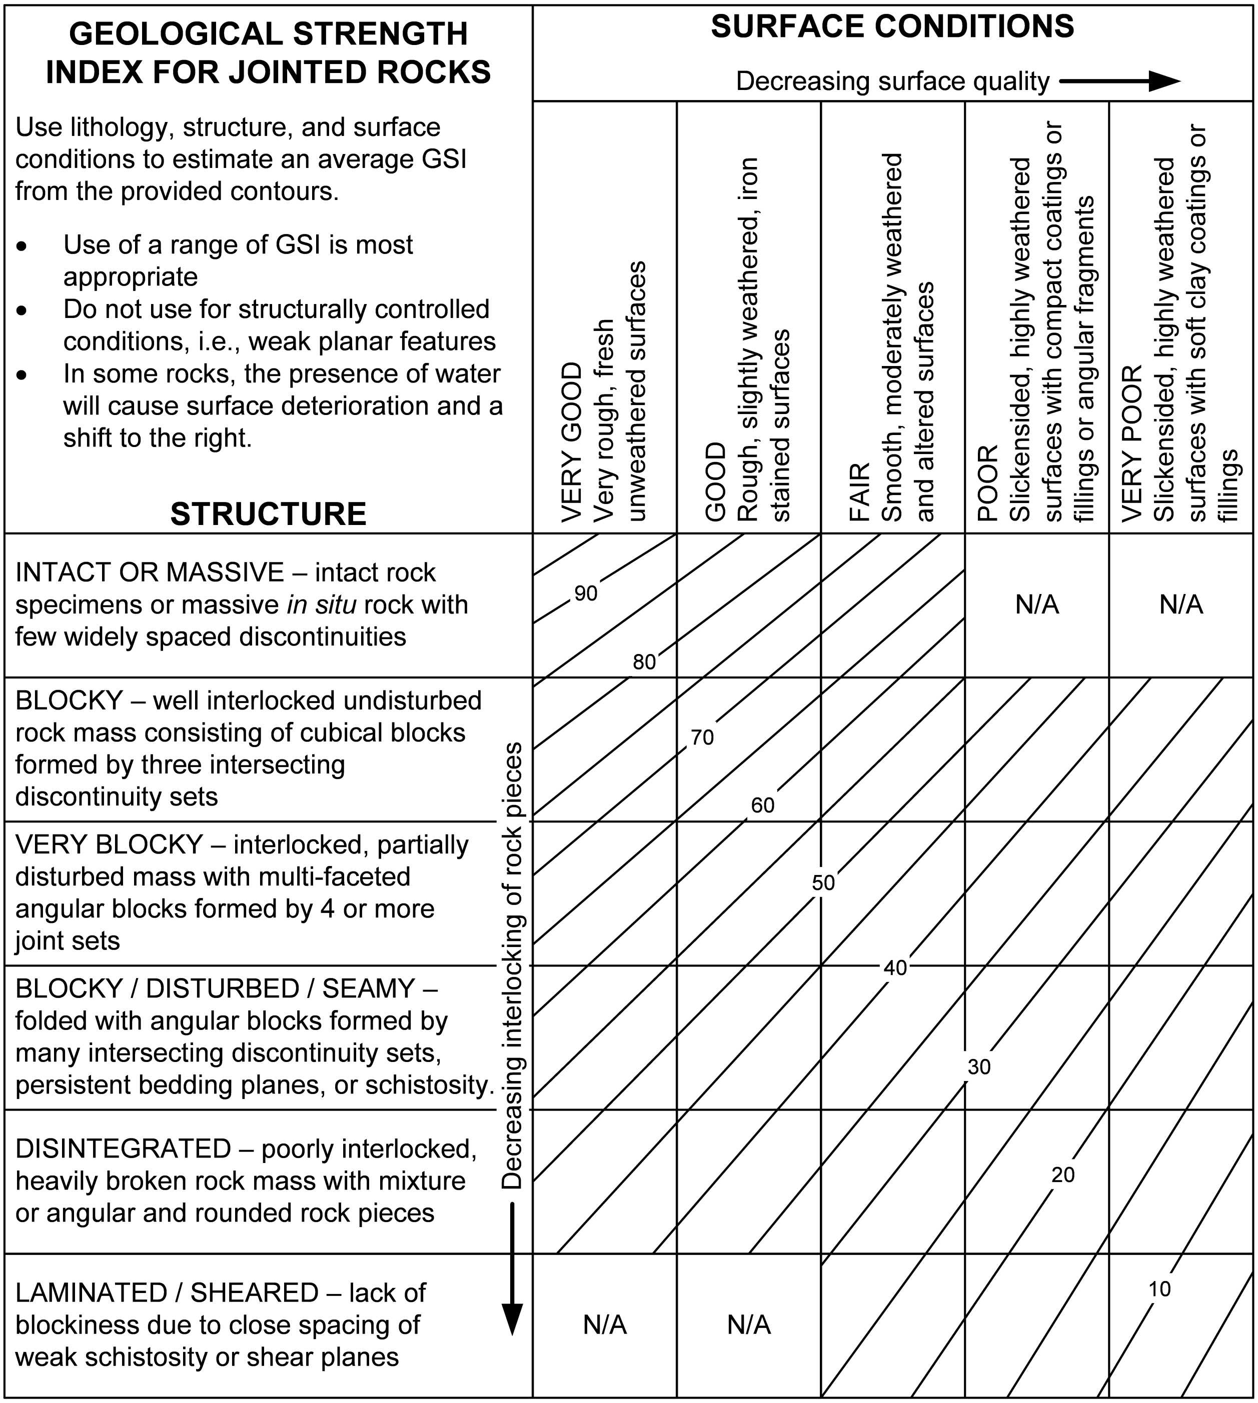

Figure 1-5 *GSI* Selection Chart for Jointed Rock (after Marinos et al. 2007)

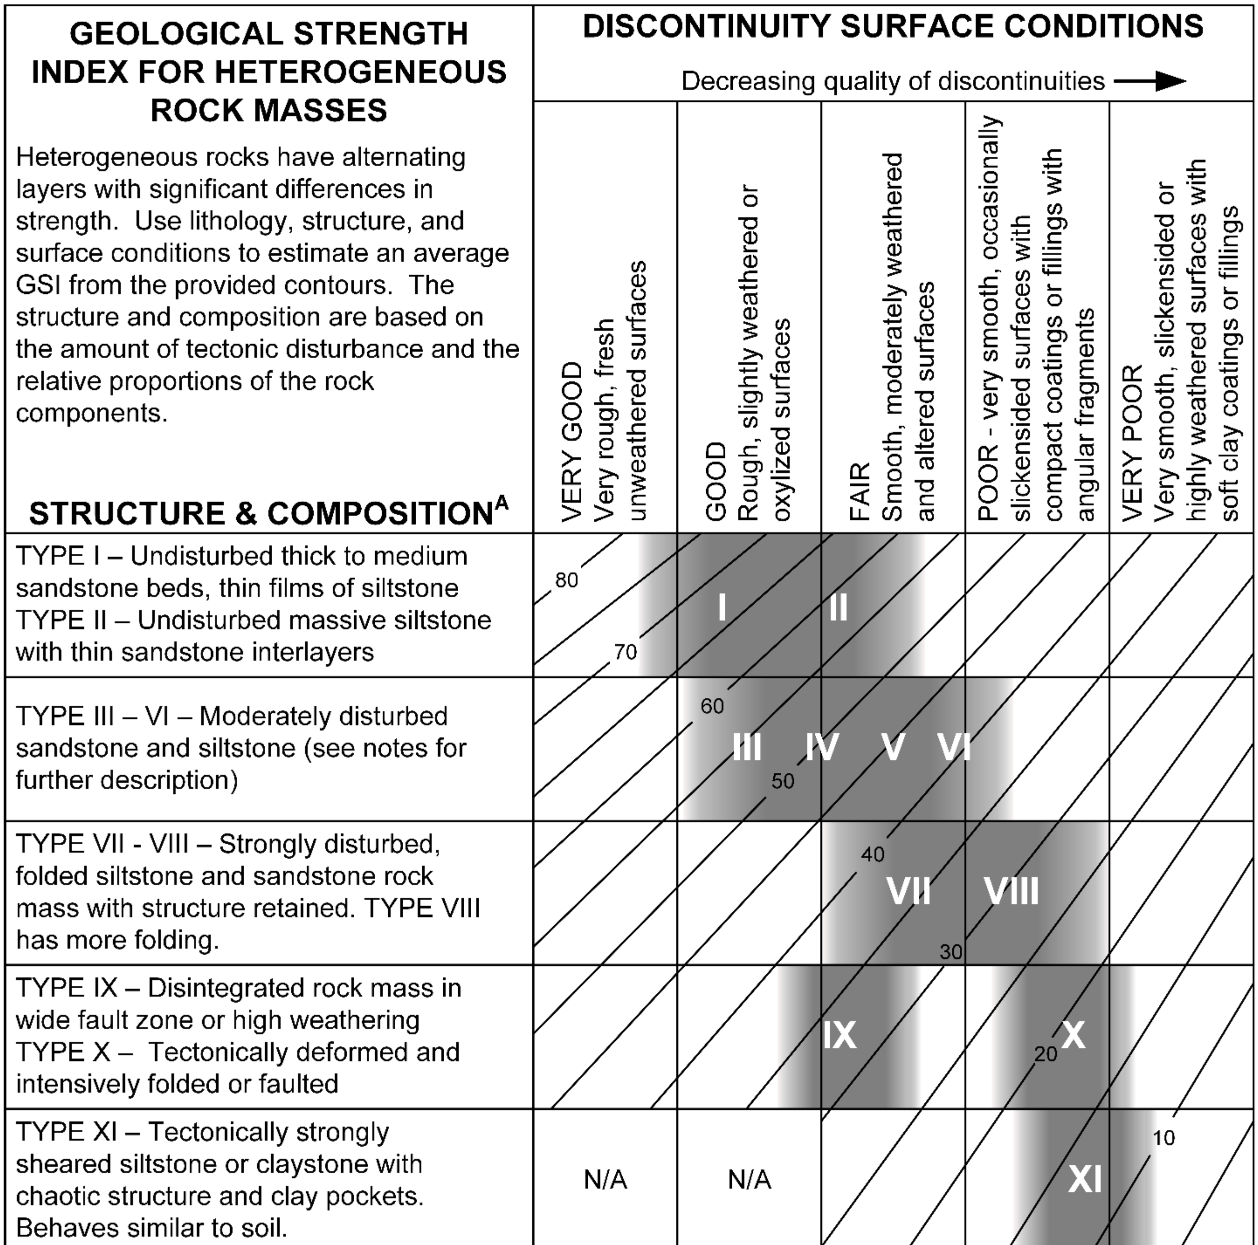

NOTES:
[A] See Marinos et al. (2007) for more details on distinguishing Type I to XI rocks
TYPE III – Sandstone with this films or interlayers of siltstone
TYPE IV – Sandstone and siltstone in similar amounts
TYPE V – Siltstone with sandstone interlayers
TYPE VI – Siltstone with sparse sandstone interlayers

Figure 1-6 *GSI* Selection Chart for Heterogeneous Rock (after Marinos et al. 2007)

1-5 SPECIAL MATERIALS.

1-5.1 Expansive Soils.

1-5.1.1 Characteristics.

Expansive soils are distinguished by their potential for excessive volume increase upon access to moisture. The swelling potential and the magnitude of the swelling pressure are controlled by the clay minerals contained in the soil, the structure and fabric of the soil, overburden pressure, and other physical-chemical aspects of the soil (Holtz et al. 2011). These soils usually contain montmorillonite and vermiculite clay minerals. Expansive soils are characterized by a very high dry strength and high plasticity, are often shiny when cut with a knife, and are very weak when wet (Holtz et al. 2011). These soils usually form deep cracks during the dry season and expand closing the gaps creating a homogenous appearance during the wet season.

Even though expansive soils can be encountered at great depth, they are mainly a problem at shallow depths were the effect of variations in water content is greater (FHWA 2017). The zone affected by seasonal variation in water content is also called the *active zone* for expansive soils. This is very important when designing foundations, roads, etc.

According to Holtz et al. (2011) expansive soils can be found around the world. In the United States, the regions with the greatest occurrence of highly expansive soils are North and South Dakota, Montana, eastern Wyoming, eastern Colorado, the Four Corners Region, California, and east Texas. Figure 1-7 illustrates the distribution of expansive soils throughout the United States.

1-5.1.2 Identification and Classification.

Expansive soils can be identified in various ways, and their swelling potential can be nominally predicted. Expansive soils can sometimes be identified during visits to a project site by looking for cracks in nearby structures or desiccation cracks in the soil surface. Another method is identifying the clay minerals in the soil. If the soil has highly expansive clay minerals (e.g. montmorillonite), that is a good indication that the soil could be expansive. Some of the methods that can be used to identify clay minerals are x-ray diffraction, differential thermal analyses, cation exchange capacity, and electron microscopy.

Soil plasticity is often used to identify expansive soils. As the plasticity index or liquid limit of the soils increases, the potential for swelling upon contact with water also tend to increase. Dakshanamurthy and Raman (1973) presented the method shown in Table 1-18 to infer the swelling potential based on the liquid limit. The information presented in Table 1-19 and Figure 1-8 provides another method of assessing the potential for volume change of a given soil.

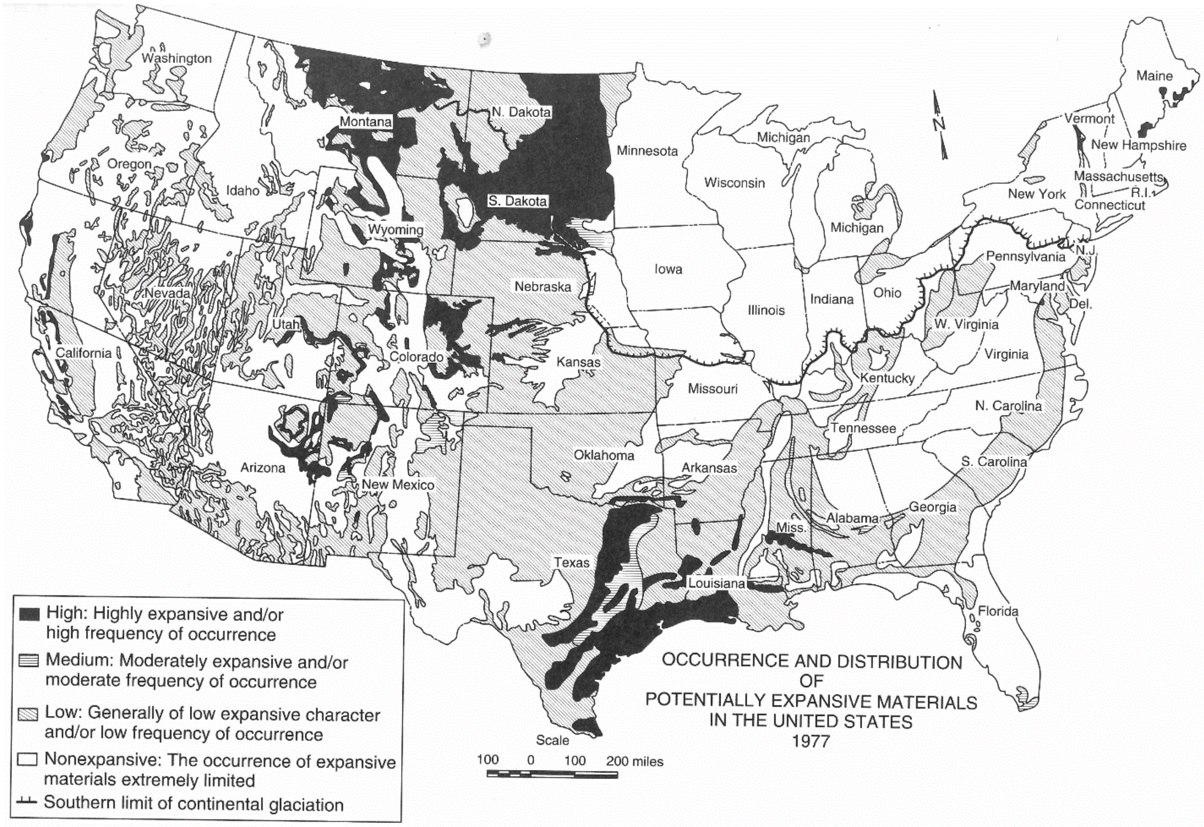

Figure 1-7 Expansive Soils in the United States (Nelson and Miller 1992)

Table 1-18 Swelling Potential (Dakshanamurthy and Raman 1973)

Liquid Limit	Classification
0 to 20	Non-Swelling
20 to 35	Low-Swelling
35 to 50	Medium-Swelling
50 to 70	High Swelling
70 to 90	Very High Swelling
> 90	Extra High Swelling

Table 1-19 Expansion Potential from Classification Test Data (Holtz et al. 2011)

Degree of Expansion	Probable Expansion as a Percent of Total Volume Change (Dry to Saturated Condition)[1]	Colloidal Content (% < 1μm)	Plasticity Index	Shrinkage Limit
Very high	>30	> 28	>35	<11
High	20-30	20-31	25-41	7-12
Medium	10-20	13-23	15-28	10-16
Low	<10	<15	<18	>15

[1]Under a surcharge of 1 psi.

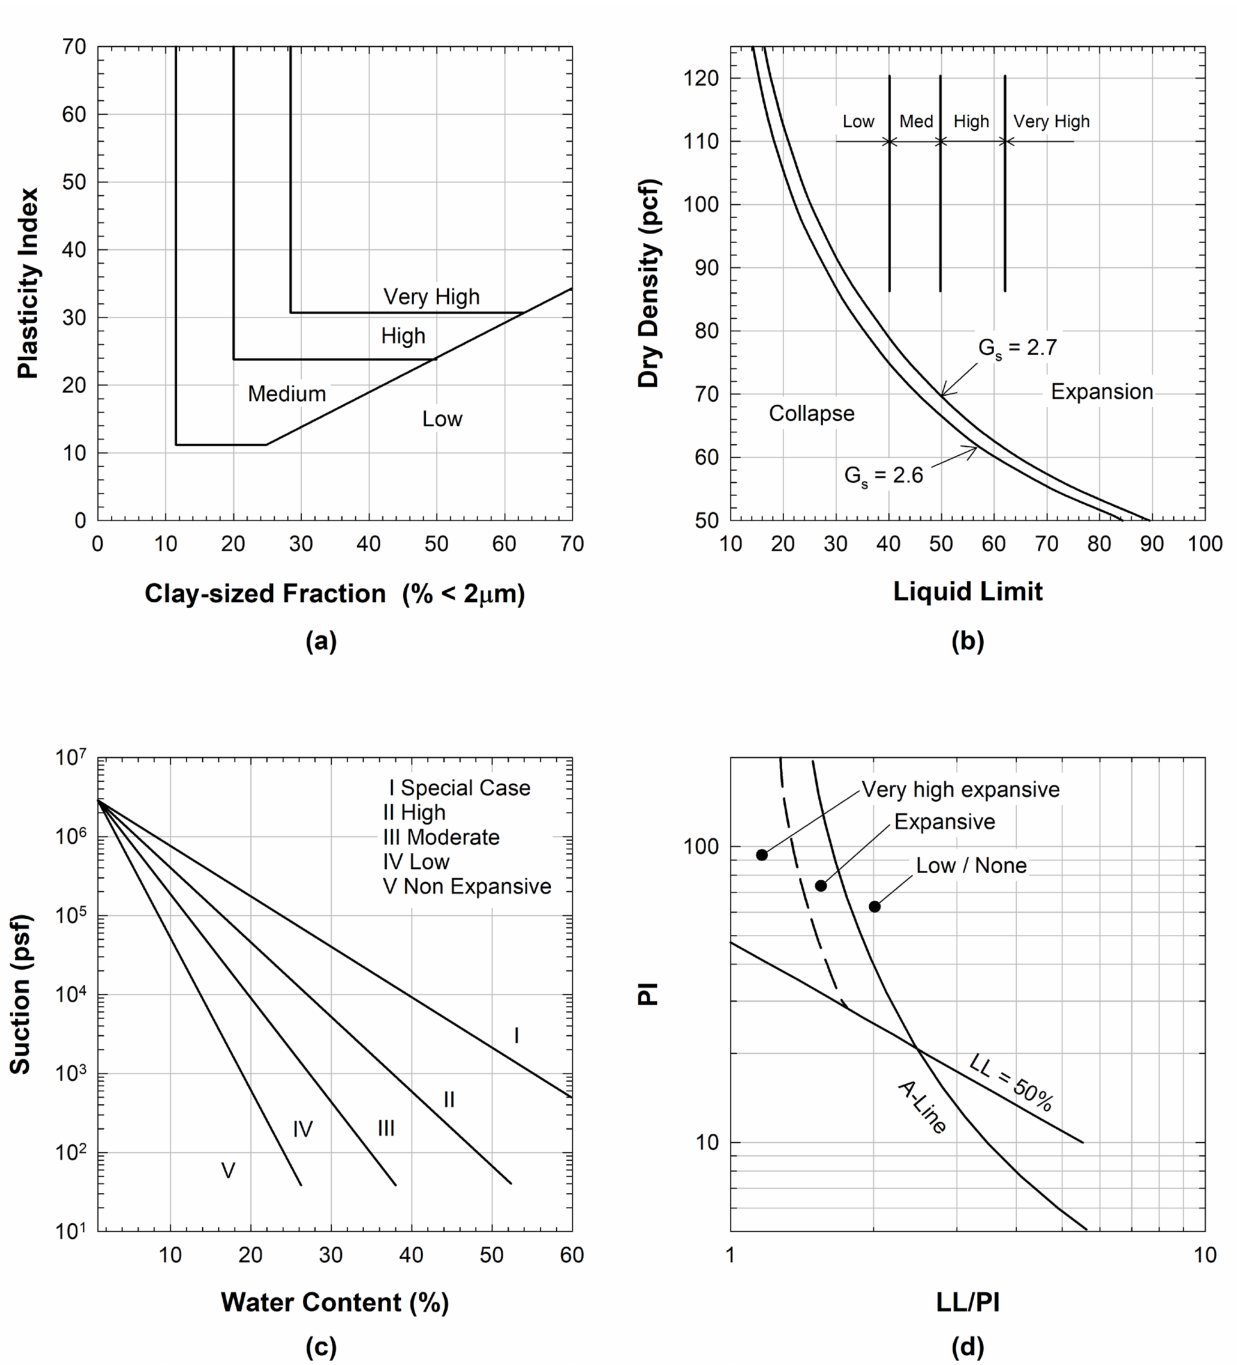

Figure 1-8 Soil Expansion Prediction (after Holtz et al. 2011)

The International Building Code 2018 (ICC 2018) considers a soil to be expansive if these four criteria are met:

1) Plasticity index equal or greater than 15 as determined using ASTM D4318,
2) More than 10% of soil particles passing a No. 200 (75 μm) sieve, as determined using ASTM D6913 or D1140,
3) More than 10% of soil particles are less than 5 μm in size, as determined using ASTM D7928, and
4) Expansion index is greater than 20, as determined using ASTM D4829 (described below).

If the soil shows compliance with Item 4, it is not necessary to show compliance with Items 1 through 3.

Two laboratory tests have standardized procedures to measure the swelling potential of soils. In the *Expansion Index test* (ASTM D4829), the soil is compacted in a rigid mold at a water content and unit weight that gives a degree of saturation of 50% ± 2%. A vertical confining pressure of 1 psi is applied to the specimen before the specimen is submerged in distilled water, and the deformation of the specimen is recorded for 24 hours or until the rate of deformation is below 0.0002 inch/hour, whichever occur first with a minimum recording time of 3 hours. This test is used to obtain the expansion index of the soil, defined as follows:

$$EI = \frac{\Delta H}{H_i} \times 1000 \tag{1-6}$$

where,
EI = expansion index,
ΔH = change in height during the test, and
H_i = initial height of the test specimen.

According to ASTM D4829, the expansion index can be used to estimate the swelling potential of soils as described in Table 1-20.

Table 1-20 Classification of Potential Expansion of Soils using EI (ASTM D4829)

Expansion Index, EI	Potential Expansion
0-20	Very low
21-50	Low
51-90	Medium
91-130	High
>130	Very High

The one-dimensional swell or collapse test (ASTM D4546) can also be used to measure expansion potential. This test method allows intact samples and samples compacted at different water contents and compactive effort to be tested. In addition, this test allows different loading conditions, wetting and drying schedules, and reading intervals to be used.

1-5.2 Collapsing Soils.

1-5.2.1 Characteristics.

Collapsing soils are distinguished by their potential to undergo large decrease in volume upon increase in moisture content without an increase in external loading. When dry, these soils are stable and able to support significant structural loads. Examples of soils exhibiting this behavior are loess, weakly cemented sands and silts where cementing agent is soluble (e.g., soluble gypsum, halite, etc.), and certain granite residual soils. A common feature of collapsible soils is loose bulky grains held together by capillary stresses. Collapsible soils are also characterized by loss of strength when wetted, low density, moisture sensitivity, and the presence of gypsum or anhydrite. Deposits of collapsible soils are usually associated with regions of moisture deficiency (arid or semi-arid regions). According to FHWA (2017), the following conditions are necessary for collapse to occur:

1) an open, and partially saturated and unstable fabric,
2) enough total stress to make the soil structure metastable,
3) existence of a bonding agent or negative pore pressures to create a metastable structure, and
4) addition of water to destroy the metastable structure.

The collapse of soils supporting structures can cause significant damage as a result of total and differential settlement. The magnitude of the collapse depends on factors, such as the soil composition, dry density, water content, confining stress, and the agent causing the metastable structure. For this reason, it is important to identify collapsible soils during the subsurface investigation so they can be remediated or considered in the design phase.

1-5.2.2 Identification and Classification.

One method to identify the potential of soils to collapse is presented by Holtz et al. (2011) using data from the USBR and is shown in Figure 1-9. From this figure, the potential for collapse increases with decreasing liquid limit and *in situ* dry density.

Ayadat and Hanna (2007b) presented a detailed study on the potential of collapse of soil. In this study, they investigated the effect of the uniformity coefficient, water content, and dry unit weight on the collapse potential. Figure 1-10 was presented as a method to assess the potential for a soil to be collapsible along with a detailed method to estimate the strain caused by collapsing for different soils. Ayadat and Hanna (2007a) also presented a method to assess the potential for a soil to be collapsible using the fall cone apparatus (Section 3-2.4.2.6).

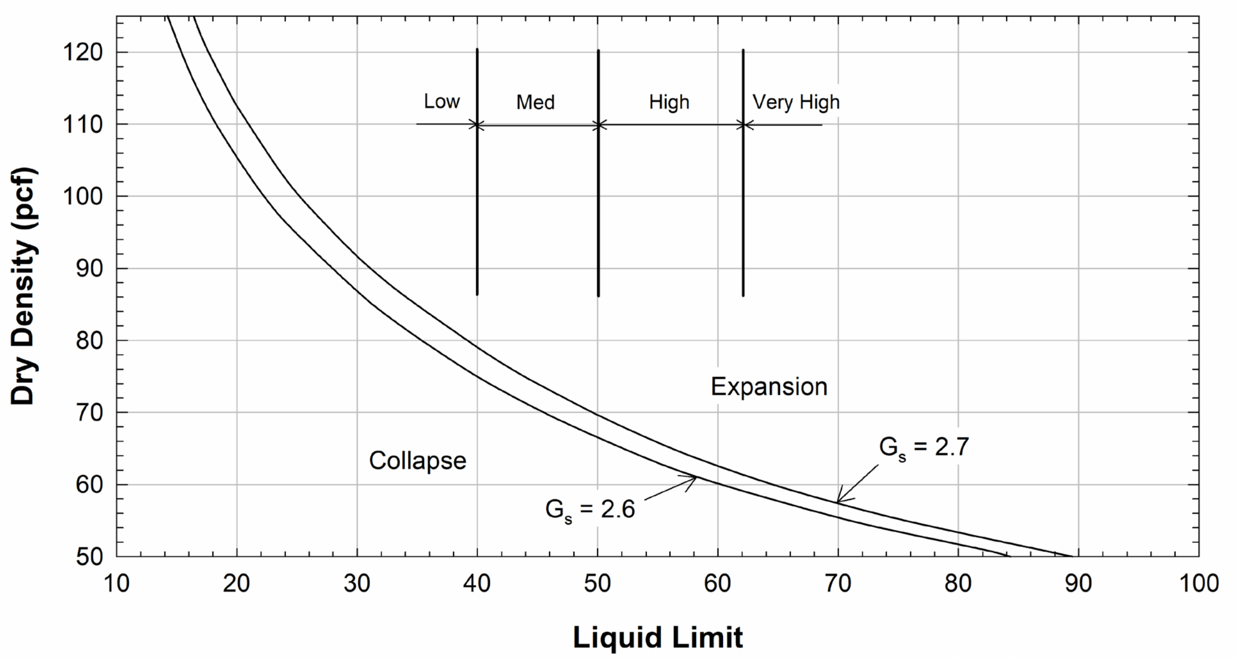

Figure 1-9 Collapsibility Based on *In situ* Dry Density and Liquid Limit (after Holtz et al. 2011)

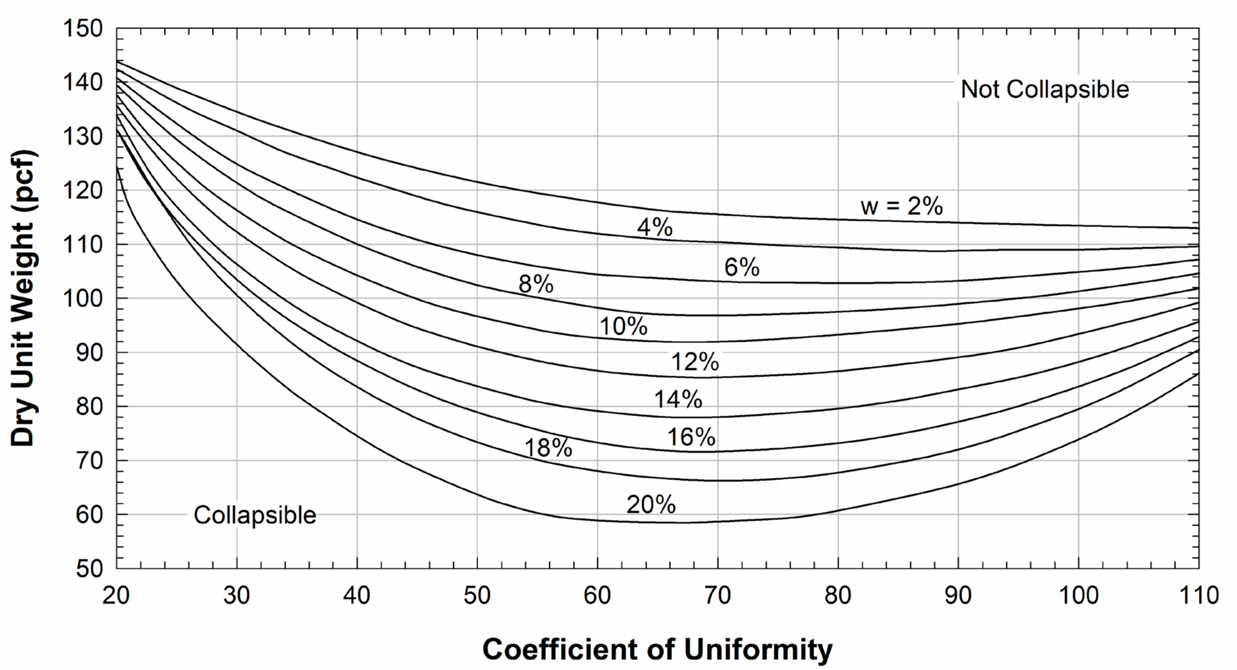

Figure 1-10 Design Charts for Predicting Collapse Behavior of Soils (after Ayadat and Hanna 2007b)

A method for quantifying the collapse potential of soils is presented in ASTM D4546. This test method allows intact samples and samples compacted at different water contents and compactive effort to be tested in a one-dimensional apparatus. In this test, the specimen is loaded to a desired normal stress using any loading sequence, water is added, and the vertical displacement is monitored.

1-5.3 Frost Susceptibility and Permafrost.

1-5.3.1 Characteristics.

In non-frost susceptible soil, a typical volume increase due to ground freezing is about 4%. This volume increase is caused by the increase in water volume as it freezes. In soils susceptible to frost, soil heave is much greater as water flows to colder zones forming ice lenses. The formation of ice lenses typically is not uniform, meaning that the increase in volume is not evenly distributed throughout a site and can cause distress to structures. During warmer weather, the soil and ice lenses will tend to thaw from the top down. Water can become trapped in the soil near the surface, leading to an increase in water content and softening of the soil. The associated loss of support can be even more detrimental to structures than the frost heave itself. This is specially a problem for pavement structures and structures supported on shallow foundations, as well as utilities, if not buried well below the depth of freezing.

Permafrost refers to a thick top later of soil that stays frozen throughout the year. Permafrost particularly occurs in the Northern Hemisphere, including Canada and Alaska. Construction in permafrost is very challenging and requires special considerations during design and construction.

1-5.3.2 Identification and Classification.

Problematic frost action requires both frost penetration into the ground and frost susceptible soils. According to Holtz et al. (2011), if the frost penetration during the worst part of the winter is less than about 0.30 m, frost heave should not be of concern to structures. The maximum depths of frost penetration in the United States are shown in Figure 1-11. These depths are for extremely cold winters without much snow cover. Snow cover, especially early in the winter, will decrease the frost depth significantly.

Silts are the most susceptible to frost heave, but most soils with some fines content have also some susceptibility to freezing. This includes soils classifying as SM, ML, GM, SC, GC, and CL. Holtz et al. (2011) presented the information shown in Table 1-21 summarizing a design classification system for frost susceptible soils. This system uses the soil classification system and the percent of soil finer than 0.02 mm ($8x10^{-4}$ inches) to assess the susceptibility to freezing.

Figure 1-11 Maximum Depths (in meters) of Frost Penetration in the Continental United States (NOAA 1978)

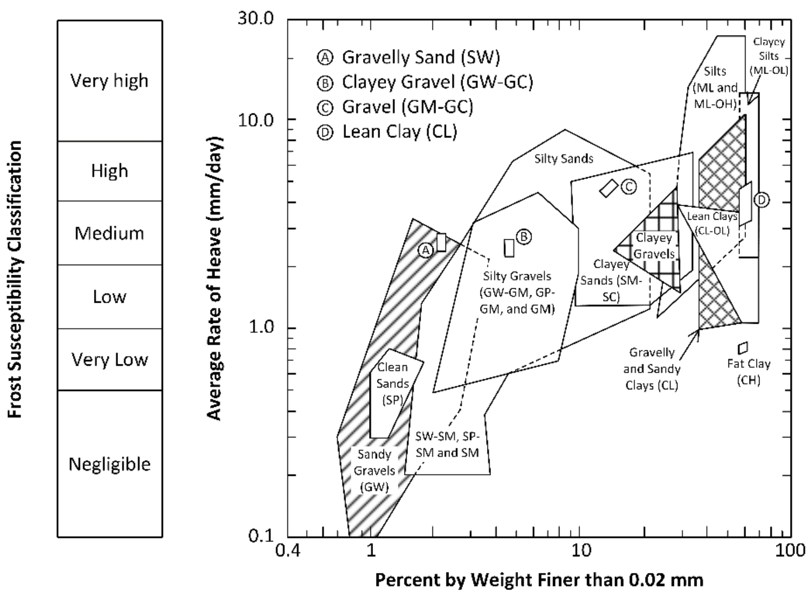

Figure 1-12 Rates of Heave in Laboratory Freezing Tests on Remolded Soils (U.S. Department of the Army 1984)

Table 1-21 U.S. Army Corps of Engineers Frost Design Soil Classification

Frost Group	Frost Susceptibility	Soil Type	Percent Finer than 0.02 mm	Typical USCS Classification
Not frost-susceptible (NFS)	Negligible to low	Gravels, crushed stone and rock	0-1.5	GW, GP
		Sands	0-3	SW, SP
Possibly frost-susceptible (PFS)	Possibly	Gravels, crushed stone and rock	1.5-3	GW, GP
		Sands	3-10	SW, SP
S1	Very low to medium	Gravelly soils	3-6	GW, GP, GW-GM, GP-GM
S2	Very low to medium	Sandy soils	3-6	SW, SP, SW-SM, SP-SM
F1	Very low to high	Gravelly soils	6-10	GM, GW-GM, GP-GM
F2	Medium to high	Gravelly soils	10-20	GM, GM-GC, GW-GM, GP-GM
		Sands	6-15	SM, SW-SM, SP-SM
F3	Medium to very high	Gravelly soils	>20	GM, GC
		Sands except very fine silty sands	>15	SM, SC
	Low	Clays, PI >12		CL, CH
F4	Low to very high	All silts		ML, MH
		Very fine silty sands	>15	SM
	Low to high	Clays, PI <12		CL, CL-ML
	Very low to very high	Varved clays and other fine-grained banded sediments		CL and ML; CL, ML, and SM; CL, CH, and ML; CL, CH, ML and SM.

Figure 1-12 relates the rate of frost heave to the percent of particles finer than 0.02 mm ($8x10^{-4}$ inches) based on USCS classification. This figure also includes the susceptibility classification for each type of soil. The information presented in this figure is based on laboratory testing by the U.S. Department of the Army (1984). According to Holtz et al. (2011), these rates are higher than those expected in the field, and soils with a laboratory rate of frost heave of up to 1 mm/day (0.04 inches/day) can be used under pavements, unless severe conditions are expected, but some frost heave should be expected.

1-5.4 Limestone and Related Materials.

1-5.4.1 Characteristics.

Limestone, dolomite, gypsum, and anhydrite are characterized by their solubility and thus the potential for the presence and/or development of cavities. Limestones are defined as those rocks composed of more than 50% carbonate minerals of which 50% or more consist of calcite and/or aragonite. Some near-shore carbonate sediments (also called limestone, marl, and chalk) could fit this description. Such sediments are noted for erratic degrees of induration, and thus variability in load supporting capacity and uncertainty in their long-term performance under sustained loads. The most significant limestone feature is its solubility. An extremely soluble limestone can contain many solution caves, channels, or other open, water, or clay-filled features. These features are often referred to as *karst* geology or topography.

Karst features that present important engineering challenges include vertical and horizontal fissures and joints, pinnacles, and sinkholes. Fissures and joints may contain very weak soil and also provide conduits for the flow of water, which are particularly problematic for water retaining structures. *Pinnacles* are spires or spines of rock left behind by the dissolution process and result in very uneven foundation support. *Sinkholes* are the result of soil erosion into karst voids or the sudden collapse of voids. Structures and pavements can be catastrophically damaged by sinkholes.

1-5.4.2 Identification and Classification.

The identification of karstic areas should start by desk studies and site visits to look for surface expressions of solution features. Sinkholes are the surface expression of rock dissolution and can be used to infer that karstic rocks are found in the area. Aerial photos, local geology maps, LIDAR data, etc. are also a useful source of information to identify features that are caused by karstic rocks. A map of the karst and potential karst areas in the United States presented by USGS (2014) is shown here in Figure 1-13.

A subsurface investigation program is very important in karstic areas to better characterize the possible caverns, sinkholes, pinnacles, etc. Drilling is a very powerful tool for this purpose and should be done more extensively in this type of terrain (FHWA 2017). Geophysical techniques, including shallow seismic refraction, resistivity, and gravimetry, are often found to be valuable supplements. The suggested methods by ASTM D6429 to estimate the depth to bedrock and the occurrence of sinkholes and voids is presented in Table 1-22.

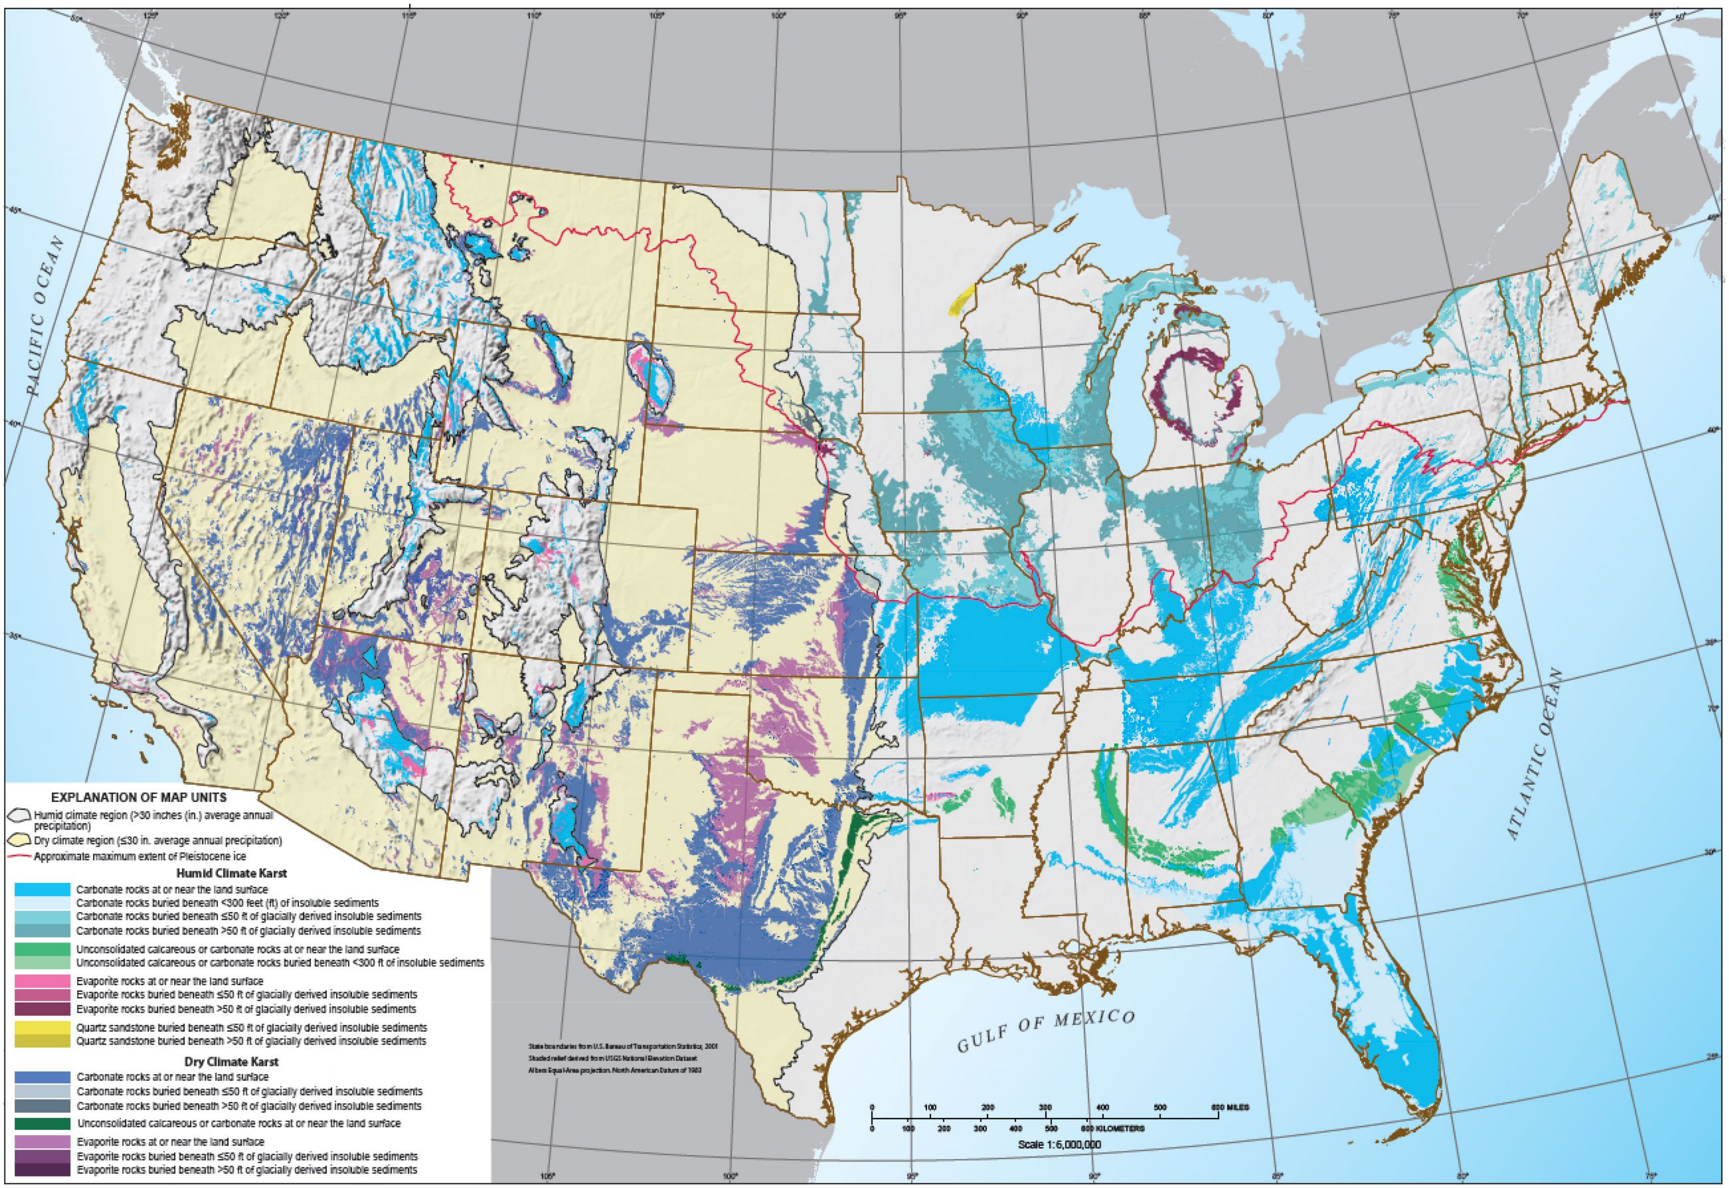

Figure 1-13 Karst and Potential Karst Areas in Soluble Rocks in the Contiguous United States (USGS 2014)

Table 1-22 Selection of Geophysical Method (after ASTM D6429)

Application or Method	Seismic		Electrical	Electromagnetic				
	Refraction or Reflection	MASW	DC Resistivity	Freq. Domain	Time Domain	Very Low Frequencies	Ground Penetrating Radar	Gravity
Depth to rock	A	A	B	B	B	B	A	B
Voids and sinkholes	B	A	B	B	B		A	A

Notes: "A" means preferred method and "B" alternate method based on the 2020 version of the standard.

1-5.5 Coral and Coral Formation.

1-5.5.1 Characteristics.

Living coral and coralline debris are generally found in tropical regions where the water temperature exceeds 20°C. Coral is a term commonly used for the group of animals which secrete an outer skeleton composed of calcium carbonate, and which generally grow in colonies. The term *coral reef* is often applied to large concentrations of such colonies which form extensive submerged tracts around tropical coasts and islands. In general, coralline soils deposited after the breakdown of the reef, typically by wave action, are thin (a few meters thick) and form a veneer upon cemented materials (limestones, sandstones, etc.).

Coralline deposits are generally poor foundation materials in their natural state because of their variability and susceptibility to solution by percolating waters, and their generally brittle nature. Coralline materials are often used for compacted fill for roads and light structures. Under loads, compaction occurs as the brittle carbonate grains fracture and consolidate. They can provide a firm support for mats or spread footings bearing light loads, but it is necessary to thoroughly compact the material before using it as a supporting surface. Heavy structures in coral areas are generally supported on pile foundations because of the erratic induration. Predrilling frequently is required.

Because of extreme variability in engineering properties of natural coral formations, it is not prudent to make preliminary engineering decisions on the basis of "typical properties." Unconfined compression strengths of intact specimens may range from 50 tsf to 300 tsf.

1-5.5.2 Identification and Classification.

Because the granular coralline and algal materials are derived from organisms which vary in size from microscopic shells to large coral heads several meters in diameter, the fragments are broadly graded and range in size from boulders to fine-grained muds. Similarly, the shape of these materials varies from sharp, irregular fragments to well-rounded particles. Coralline deposits are generally referred to as "biogenic materials" by geologists. When cemented, they may be termed "reefrock," or "beachrock," or other names which imply an origin through cementation of particles into a hard, coherent material.

1-5.6 Quick Clays.

1-5.6.1 Characteristics.

Quick clays are clays from marine origin that are characterized by their very high sensitivity or strength reduction upon disturbance. Quick clays are formed when the formation water containing salts is replaced with fresh water. Disturbance of these clays can be caused by construction activities or seismic ground shaking. In their undisturbed state, they are relatively strong. Following disturbance, they become very weak and possibly liquid. Because of their brittle nature, collapse occurs at relatively small strains. This type of clay is normally found in Norway, Canada, Sweden, Finland, Russia, the United States and other locations around the world. The Leda clay and Champlain Sea clay in Canada are examples of quick materials.

1-5.6.2 Identification and Classification.

Quick clays are readily recognized by measured sensitivities greater than about 15 and by the distinctive, strain-softening shape of their stress-strain curves from strength or compressibility tests. The sensitivity of clays is defined as the ratio of the undrained shear strength in the undisturbed state to that in the disturbed state. The *in situ* liquidity index of quick clays is typically above one, which means the water content is in excess of the liquid limit.

1-5.7 Other Materials and Considerations.

1-5.7.1 Man-made Fills.

Man-made fills can be divided into engineered fills and uncontrolled fills. Engineered fills are fills that were properly compacted to a specified density within a specified range of water contents. These fills are normally strong, have low compressibility, and are very favorable for building foundations. More detail on engineered fill can be found in NAVFAC DM 7.2 (NAVFAC 1982).

Uncontrolled fills are very problematic because these fills were placed under conditions that were not controlled and/or the materials that compose these fills were not controlled. These fills can be made from uncompacted soils and may contain deleterious building debris, old pavement, or concrete. Because of the variability of the materials and uncontrolled placement conditions, the engineering properties are very unpredictable and should be analyzed on a case-by-case basis.

1-5.7.2 Chemically Reactive Soils.

For foundation construction, the main concerns related to chemically reactive soils are usually are corrosion and gas generation. Corrosive soils can be problematic when dealing with foundations, especially steel foundation systems. Potential for corrosion must be considered in the design of foundations compared to the design life of the structure. Protection systems can be used to reduce the corrosion rate. For concrete foundations, increasing the cover thickness over the steel, the use of additive treated concrete, or a specialized cement for this purpose can help mitigate the effect of corrosion on the reinforcement.

Corrosion potential is determined in terms of pH, resistivity, stray current activity, groundwater position, chemical analysis, etc. Based on this information, a compatible foundation treatment, (e.g., sulfate resistant concrete, lacquers, creosote, cathodic protection, etc.) can be prescribed. According to AASHTO (2017), a soil is considered have high corrosion potential if: (1) the resistivity is less than 2,000 ohm-cm, (2) the pH less than 5.5, (3) pH between 5.5 and 8.5 for soils with high organic content, (4) the sulfate concentration is greater than 1,000 ppm, (5) is subjected to mine or industrial drainage, or (6) the chloride concentration is greater than 500 ppm.

The location of the water table also influences the corrosion rate. Decker et al. (2008) observed higher corrosion rate on steel piles in the section located above the water table in the fluctuation zone.

FHWA (2009) presents an extensive study on the corrosion potential of soils focused on MSE walls. Table 1-23 indicates regions in the United States with soils with high potential for corrosion.

Table 1-23 Corrosive Soil Environments (FHWA 2009)

Environment	Prevalence	Characteristics
Acid-Sulfate Soils	Appalachian Regions	Pyritic, pH < 4.5, SO_4 (1000 to 9000 ppm), Cl^- (200 to 600 ppm)
Sodic Soils	Western States	pH > 9, high in salts including SO_4 and Cl^-
Calcareous Soils	FL, TX, NM and Western States	High in carbonates, alkaline but pH<8.5, mildly corrosive
Organic Soils	FL (Everglades), GA, NC, MI, WI, MN	Contain organic material in excess of 1% facilitating microbial induced corrosion
Coastal Environments	Eastern, Southern and Western Seaboard States and Utah	Atmospheric salts and salt laden soils in marine environments
Road Deicing Salts	Northern States	Deicing liquid contain salts that can infiltrate into soils
Industrial Fills	Slag, cinders, fly ash, mine tailings	Either acidic or alkaline and may have high sulfate and chloride content

For gas concentration, organic matter content and field testing for gas are usually performed. If gas generation is expected, some form of venting system is designed. The potential presence of noxious or explosive gases should be considered during the construction excavations and tunneling.

1-5.7.3 Lateritic Soils.

Lateritic soils are found in tropical climates throughout the world. These soils are rich in iron and aluminum. Because of the high iron content, most of these soils have a rusty-red color. Extensive weathering of the parent rock normally develops these soils. These soils can be problematic because of their loss in strength with time, high void ratio and permeability, aggregate deterioration, and shrinkage cracks. These soils tend to have shear strength characteristics between those of sands and silts. They are prone to cause landslides, have highly variable moisture content, and provide erratic conditions for foundations.

1-5.7.4 Calcareous Sands.

Calcareous sands are composed mainly of the skeletal remains of marine organism having high carbonate content. These sands have significant intra-particle voids created by shells that have not broken yet and by the cavities in the corals. These sands are also characterized by having angular particles. The engineering properties of these sands vary over a wide range and are controlled by the cementation and the structure of the sand. More information on calcareous sands can be found in an ASTM Special Technical Publication on the topic (ASTM International 1981).

1-5.7.5 Submarine Soils.

Ocean environments contains the following main topographic features: (1) the continental margin including the continental shelf fringing the coast and the continental slope; (2) the continental rise; and (3) the abyssal plains with local seamounts and trenches (Randolph and Gourvenec 2011). The distribution of marine sediments along those geomorphological regions varies with thickest sediment deposits being mostly near continents and thinnest on recently formed mid-oceanic ridges. Continental margins contain almost 75% of marine sediments, while only representing 20% of the seabed area. The continental rise is also considered a depositional feature with sediment thickness reaching locally up to 1.6 km (Randolph and Gourvenec 2011).

Marine sediments are either terrigenous (i.e. transported from land to the ocean), or pelagic (i.e. settled through the water column). Coastal and nearshore zones are dominated by terrigenous sediments. Terrigenous sediments are often granular silicate minerals formed from erosion (lithogenous). Pelagic sediments are often finer and derived from insoluble remains of marine organisms. Poulos (1988) presented samples from abyssal plain and hill environments and found that most samples from abyssal plains and hills characterized as clayey silt to clay. Ocean sediment mapping also revealed that deep ocean floors are widely covered with calcareous ooze that classified as mostly silty clay (Poulos 1988).

Marine sediments that were deposited slowly and remained undisturbed from physical, chemical, benthic biogenic, and/or anthropogenic processes are commonly normally consolidated. Overconsolidated sediments can result from glaciation, recent sediment erosion, or submarine landslides. Underconsolidated marine sediments can follow from rapid sedimentation events and recent sediment dynamics, as well as from benthic biogenic processes, amongst others. More information on the stress states of marine sediments can be found in Randolph and Gourvenec (2011).

The following key differences between marine and terrestrial sediments can be listed:

- Environmental conditions cover a wider range of pressures (depending on water depth) and temperature and can affect the engineering behavior of marine sediments, particularly in deep ocean environments.
- Oceans feature saline water. Local salinity may affect the engineering behavior, particularly of clays.
- Hydrodynamic conditions (i.e., waves, tides, currents) vary on spatial and temporal scales, particularly in nearshore environments and on the continental shelf. Hydrodynamic forcing can exert stresses onto the seabed and change pore pressures. It also drives sediment dynamics, potentially leading to complex sediment dynamics including erosion, transport, and deposition, and resulting in geomorphodynamics including the formation, destruction, and migration of bedforms on scales of centimeters to hundreds of meters. These processes affect sediment composition, texture, and thus, engineering properties.

1-7 NOTATION.

Symbol	Description
C_u	Coefficient of uniformity
C_c	Coefficient of curvature
d	Distance between the loaded points in rock point load test
D_e	Equivalent core diameter
D_{10}	Particle size diameter corresponding to 10% passing
D_{30}	Particle-size diameter corresponding to 30% passing
D_{60}	Particle-size diameter corresponding to 60% passing
EI	Expansion index

Symbol	Description
F	Percentage passing a No. 200 (75 μm) sieve (only considering the particles passing a 3-inch sieve)
F	Size correction factor for rock point load test
GI	Group index
GSI	Geological strength index
H_i	Initial height of the test specimen in the expansion index test
LL	Liquid limit of the soil
P	Applied force at failure
PI	Plasticity index of the soil
PL	Plastic limit of the soil
RMR	Rock mass rating
RQD	Rock quality designation
ΔH	Change in height during the expansion index test

CHAPTER 2 FIELD EXPLORATION, TESTING, AND INSTRUMENTATION

2-1 INTRODUCTION.

2-1.1 Scope.

This chapter contains information on exploration methods including use of geologic maps, air photos, and remote sensing; geophysical methods; test borings and test pits, and penetration resistance tests. Also presented is information on methods of drilling and sampling, obtaining groundwater measurements, measuring *in situ* properties of soil and rock, selecting field instrumentation and geotechnical performance monitoring equipment.

2-1.2 Planning for Field Investigations.

The initial phase of field investigations should commence with a thoughtful assessment of the data needs for the specific project, which will help define the objectives of the subsequent field investigation. Prior to mobilizing to the field, readily available information should be located that is relatively inexpensive and often invaluable. In cases where the new project is adjacent to an existing project (e.g., highway widening, lateral expansion of an existing levee, etc.), the initial research should focus on information and data that have previously been collected and/or compiled for the project. For a new project, the initial effort should include a detailed review of geological conditions at the site and within the region where the site is located. This should then be followed by a "desk top" study, utilizing sources of available data, including historical and current aerial photography, remote sensing imagery, and (whenever possible) a field reconnaissance. The collective information obtained from these activities should be used as a guide in planning the project-specific field exploration.

To the extent possible as dictated by project data needs, individual test borings should be supplemented by lower cost exploration techniques that include test pits, test probes, and geophysical surveys. This is particularly true for remote sites, sites exhibiting wide variability in subsurface conditions, projects occupying a large footprint, linear projects (e.g., roadways, pipelines, etc.), and projects in the offshore environment where mobilizations and test borings can be exceptionally expensive.

Project explorations generally have three distinct phases: (1) reconnaissance/feasibility exploration; (2) preliminary exploration; and (3) detailed/final exploration. These phases usually have different objectives. A fourth phase of exploration that involves additional sampling and/or *in situ* testing may be desired and/or required during or after construction to confirm conditions. Frequently (and most common for relatively small projects), these three phases are combined into a single exploration effort.

Reconnaissance includes a review of available topographic, geologic, and hydrogeologic information; aerial photographs; data from previous investigations and projects; and a site visit. Geophysical methods may prove to be helpful in many cases, particularly for large projects where subsurface conditions are variable and for linear projects (e.g., levees, highways, etc.). Reconnaissance/feasibility exploration frequently reveals difficulties which may be expected in later exploration phases and assists in determining the type, number and locations of borings required. Examples of information that can be obtained from field reconnaissance activities are presented in Table 2-1.

Table 2-1 Items that can be Evaluated During Field Reconnaissance (NCHRP 2018 and FHWA 2002)

Item	Things to Note	Comments
Access	Rank access using one of the following criteria: (1) easy, (2) accessible by four-wheel drive, (3) dozer and grading required, and (4) inaccessible.	Evaluating access helps determine the types of equipment that will be required.
Utilities	Existing overhead lines, marked gas lines, manholes, sewer outfalls, and power substations.	Utilities information helps select appropriate *in situ* testing, drilling, and sampling locations.
Surface soils	Presence of fill, debris, pollutants, slope instabilities, heave, subsidence, and scour	Evaluating surface soils can reveal evidence of abandoned landfills, historic landslides, contamination, subsidence, and flooding.
Shallow subsurface materials	Visual soil and rock classifications, loose cobbles, boulders, rock outcrops, rock joint patterns, faults, discontinuities, weathering, planes of weakness, talus, karst features	Subsurface materials can provide evidence for subsidence, landslide activity, unstable soil and rock, and stratigraphy.
Surface drainage	Swamps, ponds, lakes, streams, and rivers	Surface drainage information provides indications of the depth to groundwater level, hydraulic conductivity of the underlying materials, and potential for flooding.
Subsurface drainage	Major aquifers, water wells, and pumping from deep wells	Subsurface drainage information provides indication of groundwater level, natural springs, and potential artesian conditions.
Terrain	Rank terrain in terms of (1) level ground, (2) sloping, (3) hummocky, (4) rolling hills, and (5) mountainous.	Evaluating terrain helps with selecting appropriate exploration and construction equipment, assessing the need for slope stability investigations, and site access.
Past investigations	Existing test pits, boreholes, coreholes, and past blasting operations	Past investigations can provide information regarding stratigraphy, types of soil and rock, and groundwater levels.

Preliminary exploration may include borings and/or penetration soundings to identify specific features (e.g., top of rock, etc.) and/or to recover samples. The collected samples are generally used for index testing only. Penetration sounding test results are often used to help identify the location of strata or formations where detailed exploration activities will be advanced.

The detailed investigation phase typically includes subsurface borings, disturbed and intact sampling for laboratory testing, standard penetration resistances, cone penetration test soundings, and other *in situ* measurements. At critical sites it may also include test pits, piezometer installation and measurements, pumping tests, etc. Following completion of this phase and the associated testing, the site conditions and soil/rock properties should be sufficiently known to design the project.

Monitoring of the site or structure is recommended throughout the construction and the post-construction phases. Performance monitoring instrumentation (e.g., piezometers and/or settlement plates to assess consolidation during staged loading) may need to be installed. In some cases, further evaluation of foundation conditions may be required during the construction phase. This is particularly true when foundation conditions have the potential to vary widely across the project site (e.g., when using deep foundations for project sites underlain by karst).

2-2 PUBLISHED REFERENCE MATERIALS.

When starting an investigation, the first step is to identify sources of readily available and pertinent information. In general, this information comes from two sources: (1) previous investigations; and (2) published literature in the public domain.

2-2.1 Previous Investigations.

For studies in developed areas, subsurface conditions and selected foundation recommendations may be available from previous work for surrounding projects. Earlier site-specific data may be “dated” and while the underlying geology is unchanged, the site-specific information may have been superseded by recent activities. For example, industrialized waterfront areas near major cities may undergo cycles of expansion and reconstruction, causing subsurface conditions to change. Often old foundations and wharf structures remain buried in place. Records of former construction may contain information on borings, field tests, groundwater conditions, and potential or actual sources of construction difficulties. Note that explorations from state departments of transportation (DOT), the United States Geological Survey (USGS), and United States Environmental Protection Agency (USEPA) may be publicly available.

Review of data from previous work should receive the greatest attention of any phase in a reconnaissance investigation because it is likely very relevant. Additionally, this information generally comes at relatively little cost and allows the project team to quickly become familiar with the project location and noted problems related to geology and construction.

2-2.2 Published Geologic and Hydrogeologic Maps.

Data on the physical geology and topography of the United States (and foreign countries) are available in maps and reports by government agencies, universities, and professional societies. An example of documents and sources of available information is provided in Table 2-2. While providing excellent regional and general information, the information from these sources may not be entirely “site-specific.” However, this information often can be used to identify specific data gaps that need to be addressed during subsequent phases.

2-3 REMOTE SENSING DATA METHODS.

2-3.1 Sources.

Aerial photographs are a common type of remote sensing, including older printed images (scales from 1:12,000 to 1:80,000) and reasonably high-resolution digital images for most of the United States (scale of 1:1000 or better). Some regions possess a wealth of “historic” imagery that may extend before the current site was developed. Photos are useful for topographic and/or geologic mapping in addition to identifying drainage patterns, locations of existing structures, vegetation, access routes and site locations for planned explorations. Remote sensing also refers to non-photographic data gathering satellites, from which data, such as vegetation development, water sources, etc., are available. Table 2-3 summarizes sources and types of remote sensing data that have been historically (i.e., pre-2019) used by geotechnical engineers. The technologies identified in Table 2-3 generally require the purchase of images from the entities that generated the images.

Table 2-4 provides a summary of more recent remote sensing technologies. Data from some of these are free to the user and are often available on the internet. Data from remote sensing technology can be incorporated into developing augmented reality (AR) platforms, which provide an interactive experience where objects are projected into a perceived real-world environment. This requires computer-generated information presented in a geospatial environment through the use of special lenses and headsets.

2-3.2 Utilization.

Remote sensing represents a well-adopted resource by geotechnical engineers. The emergence of internet-based mapping tools coupled with the cross-section profiling capabilities using geographic information system (GIS) tools currently exceed the capabilities and functionality of earlier tools.

Table 2-2 Sources of Readily Available Subsurface Information (after NCHRP 2018, FHWA 2002, and FHWA 2016)

Types of Documents	Sources of Information	Type of Available Information	Comments
Topographic maps	USGS and state geological survey agencies	Site topography, physical features, and index map of site area	Maps can be used to evaluate access issues for field equipment and identify areas susceptible to slope instability.
Soil survey reports	National Resource Conservation Service, Web Soil Survey, and local soil conservation agencies	AASHTO and USCS classifications, moisture contents, Atterberg limits, organic contents, chemical properties (e.g., pH), permeability of soils, climate, stratigraphy, and groundwater level	Available information is for shallow depths (6 ft. or less) and is useful for identifying near-surface problematic soils (e.g., soils susceptible to swelling and shrinkage) or identifying potential borrow sources.
Geologic maps and reports, including sinkhole and karst maps	USGS and state geological survey agencies	Soil and rock formations (rock types, fracture, orientation and approximate age), groundwater flow patterns, and bedrock contours that provide approximate estimates of rock depths, and potential geologic hazards	These documents can be used to identify areas susceptible to sinkholes, landslides, subsidence, and other hazards.
Aerial photographs	Internet mapping sites, National Agriculture Imagery Program (NAIP), and aerial survey companies	Man-made structures, geologic and hydrogeologic information, current and past land use, borrow sources, and potential geologic and man-made hazards	Photographs can track site changes over time to identify potential problematic past land use activities or geologic events, including landslides.
Hydrological and well maps and well logs	USGS, state natural resources and soil survey agencies	Hydrogeological features (e.g., springs), groundwater hazards, stratigraphy, and groundwater depths	Well maps and logs can be useful to evaluate the need for construction dewatering and permanent groundwater control.
Utility maps	Utility companies and local government agencies	Locations of buried utilities	Very useful to identify locations for *in situ* testing, drilling, and sampling, useful to map equipment access routes
Flood insurance maps	FEMA, USACE, USGS, State and local government agencies	100- and 500-year floodplains, data for evaluating scour potential	This information can be used to ensure that the site isn't in the 100- and 500-year floodplains.
Sanborn fire insurance maps	Library of Congress, state and university libraries, and Sanborn Company	Environmental hazards and historical land use	Sanborn maps are available for urban areas.
Agencies: United States Geological Service (USGS), American Association of State Highway and Transportation Officials (AASHTO), Unified Soil Classification System (USCS) , Federal Emergency Management Agency (FEMA), United States Army Corps of Engineers (USACE)			

Table 2-3 Historic Remote Sensing Data Sources

Type	Description and General Use	Availability
Aerial photography	Available in 9-inch frames with overlap for stereoscopic viewing. Valuable because of high resolution and available scales could range from 1:12,000 (or larger) to 1:80,000.	USGS, NCIC, NCRS, USFS, BLM, TVA
	Satellite imagery with repetitive coverage every 18 days in four spectral bands: • BAND 4: emphasizes movement of sediment-laden water and delineates areas of shallow water and useful in differentiating lithology • BAND 6: emphasizes cultural features, such as metropolitan areas • BAND 7: emphasizes vegetation, the boundary between land and water, landforms and useful in structural interpretation of geology; • BAND 8: provides the best penetration of atmospheric haze, the best band for detecting faults, lineaments, mega-joint patterns or other structural features, and also emphasizes vegetation, the boundary between land and water, and landforms.	EROS
Skylab	High-quality photography of Earth's surface useful for regional planning, environmental studies, and geologic analyses. Images cover an area of 100 x 100 miles or 70 x 70 miles depending on the camera used. Images are from 1973-74 and do not provide full coverage.	EROS
NASA	Black and white, color, or false-color infrared aerial photography produced from NASA Earth Resources Aircraft Program with scales ranging from 1:120,000 to 1:60,000. Coverage not available for all areas. Useful for planning, environmental and site-oriented studies, and fault/lineament evaluation (color IR).	EROS
SLAR	Side-looking airborne radar (SLAR) is a valuable complement to photos for regional studies especially applicable in areas of persistent cloud cover. Scales range from 1:2,000,000 to 1:250,000. Best imagery for identifying regional faults/lineaments.	NCIC, Goodyear Aerospace Corporation and Motorola, Westinghouse Electric Corp.,
Thermal IR	Thermal infrared (IR) imagery can be useful where temperature contrasts are significant. Useful for special projects or as a complement to other remote sensing data Useful in fault detection in covered alluvial areas, geothermal exploration, location of seepage, location of near surface peat deposits, covered meander scars, and heat loss studies.	Obtained as needed by aerial survey firms. Images may be available from an HCMM.
Agencies: United States Geological Service (USGS), National Information Center (NCIC), National Resources Conservation Service (NCRS), U.S. Forest Service (USFS), U.S. Bureau of Land Management (BLM), Tennessee Valley Authority (TVA), Earth Resources Observation System (EROS), Heat Capacity Mapping Mission (HCMM) by National Space Science Data Center Goddard Space Flight Center		

For project sites where limited information is available, aerial images greatly aid in planning and layout of an appropriate boring program and currently be considered a minimal requirement for projects. For large engineering studies, including highway and airfield work, a three-dimensional (3D) visualization may be beneficial. Individual users can develop digital terrain model (DTM) files using data from UAVs data, and commercial companies can economically develop local 3D topography with the use of UAVs.

Table 2-4 Current Remote Sensing Data Sources

Type	Description and General Use	Availability
Aerial Photography	Recent and historical aerial maps (including approximate topography) for most of the United States. Generally, very good resolution at <1:1000 scale. Excellent to see regional and site-specific topography, roads, drainage features. In many areas, it is possible to get a relatively recent “street view” 3D image to depict observations from the ground surface.	Various internet map tools are available, with some databases updated quarterly. Most images are generally less than 3 years old.
LIDAR	Light Detection and Ranging (LIDAR) uses a pulsed laser light whose signal is reflected back to a sensor to record distance. The signal source is usually positioned on a moving vehicle and recovered data can be used to generate 3D images of terrain.	Usually provided by commercial vendors as a specialized commodity due to high equipment and processing costs.
SAR	Synthetic Aperture Radar (SAR) is an advanced form of SLAR that uses radio waves from a moving platform. Data can be used for high resolution 2D and 3D images, with the larger aperture (or larger antennae) providing higher resolution.	Provided by commercial vendors with specialized electronic equipment for data capture and processing, Images may be available to the general public at reasonable cost in the future.
UAV	Unmanned Aerial Vehicles (UAVs) or drones are increasingly useful for project aerial imagery. UAVs can carry digital and infrared cameras and other sensors. High resolution is possible. Overlapping passes allows for generation of 3D imagery and topography. Excellent resource for tracking construction progress.	Equipment is readily available at low cost for individual users. Commercial services are also widely available.

Interpretation of information from aerial photographs and other remote sensed data requires experience and skill. The interpretation process combined with other information from the published reference material often informs the interpretation of what features may be present at the project site. Spot checking in the field is an essential element in the interpretation of geologic features from aerial photographs. Aerial photographs are most helpful when assessing similarities and differences between areas. Use of these images in urbanized and develop areas is of limited quantitative subsurface informational value. As with any aerial image, whether photographic or remote data, vegetation and cloud cover can often obscure the underlying topography. Recently, computer enhancements of multi-spectral imagery have made LANDSAT data compatible with conventional aerial photography.

2-4 GEOPHYSICAL METHODS.

2-4.1 Utilization and Applications.

With increasing regularity, geophysical investigations are being used to estimate subsurface conditions because of improved interpretation techniques and the overall acceptance within the professional community of the geophysical characterization techniques. Table 2-5 provides a summary of the common geophysical testing techniques and the objectives/characterizations that are obtained from these techniques. Information regarding the selection of appropriate surface geophysical testing techniques is also presented in ASTM D6429.

Geophysical methods are best suited when investigating relatively large and/or linear sites, including dams, reservoirs, tunnels, highways, and large groups of structures. Techniques are available for both onshore and offshore exploration. Geophysics have been used to locate gravel deposits and sources of other construction materials, particularly for stratified materials where properties differ substantially from adjacent soil/rock. As shown in Table 2-5, many of the geophysical testing methods are helpful in identifying different subsurface strata and anomalies in the subsurface.

Table 2-5 Surface Geophysical Methods and Investigation Objectives (after NCHRP 2018, Fenning and Hasan 1995, USACE 1995a, Sirles 2006, FHWA 2006, and Anderson et al. 2008)

	Seismic		Electrical and Electromagnetic				Potential Field	
Information Obtained	Refraction and Reflection	Surface Wave	Resistivity	Electromagnetic	Ground-Penetrating Radar	Microgravity	Magnetometry	Self-Potential

Ferrous anomalies			✓		✓		✓	
Conductive anomalies			✓	✓	✓			✓
Corrosion potential			✓					

2-4.2 Advantages and Limitations.

In contrast to borings, geophysical surveys explore large areas rapidly and economically. Because they evaluate conditions over a large area, the results reflect average conditions in an area rather than a specific result that one would obtain from a series of vertically advanced borings. Geophysical testing can prove most advantageous in geologic conditions that display a strong contrast between adjacent strata (i.e., rock beneath soil, interface between hard and soft rock, water- or air-filled voids in soil or rock, etc.). Geophysical testing can often detect irregularities of bedrock surface and the interface between soil and rock strata, and may be particularly useful in karst topography.

Geophysical surveys can often distinguish boundaries between strata, but most methods can only indicate approximate soil properties. These “approximate” properties should be considered the average properties within the subsurface, as delineation of specific properties of specific strata are generally not possible.

Interpretation of geophysical testing results is often difficult and subjective to the experience of the operator or interpreter. In many cases, there are no definite criteria for the interpretation of geophysical testing techniques. Some techniques are highly specialized and almost all techniques require experienced operators and interpreters for each application. Spot checks of “interpreted” versus “actual” conditions are strongly recommended for each site using boring methods. Previously successful techniques and an experienced interpreter should be used.

Differences in degree of saturation, presence of mineral salts in groundwater, or similarities of strata that effect transmission of seismic waves may lead to vague or inaccurate conclusions. These limitations notwithstanding, geophysical testing is anticipated to see more widespread use and acceptance in the future. Further reference and extensive discussion are found in FHWA (2003) and NCHRP (2018).

2-5 SOIL AND ROCK EXPLORATION METHODS.

Soil borings are the most commonly used method for subsurface soil exploration in the field. They allow a vertical profile of soil to be established at a specific location and for the collection of samples at selected vertical intervals at specific locations. Rock drilling and coring techniques are more specialized than those used for soils and are used less frequently.

2-5.1 Drilling and Boring Methods.

Most geotechnical borings in soils have historically utilized either hollow-stem augers or rotary wash techniques, where numerous variations technologies are available. Recent advancements that are gaining popularity and acceptance include the use of direct-push and sonic boring techniques. Table 2-6 identifies the applicability of the several methods for advancing soil borings. Table 2-7 provides similar information for rock.

The drilling equipment used for geotechnical investigation is selected based on a combination of: (1) ground conditions encountered at the site (i.e., soft ground, steep terrain, over water, etc.) and (2) the type of drilling that is selected (i.e., auger, rotary, percussion, etc.). Table 2-8 provides a summary of various types of drilling equipment and their application. Figure 2-1 provides a schematic of the various drilling methods.

Table 2-6 Methods of Advancing an Exploration Hole in Soil (NCHRP 2018 and Day 1999)

Method	Procedure	Applications	Limitations / Remarks
Auger boring (ASTM D1452)	Dry hole drilled with hand or power auger; samples recovered from auger flights	Identify geologic units and water content above water table in soil and soft rock	Stratification destroyed; sample mixed with water below the water table.
Hollow-stem auger boring	Hole advanced by hollow-stem auger; soil sampled with auger in place	Typically used in soils that would require casing to maintain an open hole for sampling.	Sample limited by larger gravel; maintaining hydrostatic balance in hole below water table is difficult.
Wash-type boring	Light chopping and strong jetting of soil; cuttings removed by circulating fluid and discharged into settling tub	Soft to stiff cohesive materials and many granular soils.	Coarse material tends to settle to bottom of hole; Should not be used in boreholes above water table where intact samples are desired.
Becker hammer penetration test (BPT)	Hole advanced using double acting diesel hammer to drive a 168 mm double-walled casing into the ground.	Typically used in soils with gravel and cobbles; casing driven open-ended if sampling of materials is desired.	Skin friction of casing difficult to account for; repeatability of test unclear.
Bucket auger boring	Rotates and advances a 600- to 1200-mm diameter drilling bucket with cutting teeth; bucket retrieved and emptied on the ground.	Most soils above water table; can penetrate harder soils than above types; can penetrate soils with cobbles and boulders if equipped with a rock bucket.	Not applicable in running sands; used for obtaining large volumes of disturbed samples; used to provide access to enter a boring for observations.
Direct push	Static weight and percussion used to advance a 90- to 115-mm diameter casing;	Most cohesive and granular soils; near-continuous sample	Recovered samples are generally disturbed
Sonic drilling	High-frequency resonant vertical oscillations advance a 75- to 300-mm diameter core barrel; recovers a continuous 3.3-m long core; after sample is retrieved, overcore barrel advanced to bottom of core barrel by similar technique and process is repeated	Applicable in nearly all soils and much bedrock; returns continuous stratigraphy; applicable for conditions both above and below the water table; process does not require drilling fluids	Not cost effective in very dense and hard rock where coring is desired; recovered samples are disturbed

Table 2-7 Rock Core Drilling Methods (NCHRP 2018 and Day 1999)

Method	Procedure	Type of sample	Applications	Limitations / Remarks
Rotary coring of rock (ASTM D2113)	Outer tube with diamond (or tungsten carbide) bit rotated to cut annular hole in rock; core protected by stationary inner tube; cuttings flushed by drill fluid	Rock cylinder 22 to 100 mm wide and as long as 3 m, depending on rock soundness; standard size is 54 mm diameter.	Obtain continuous core in sound rock (percent of core recovered depends on fractures, rock variability, equipment, and driller skill)	Core loss in fractured or variable rock; blockage prevents drilling in badly fractured rock; dip of bedding and joint evident but not strike
Rotary coring of rock, wire line	Same as ASTM D2113, but core and stationary inner tube retrieved from outer core barrel by lifting device or "overshot" suspended on thin cable (wire line) through large-diameter drill rods and outer core barrel	Rock cylinder 28 to 85 mm wide and 1.5 to 3 m long	Better core recovery in fractured rock; much faster cycle of core recovery and efficiency in deep holes	Core loss in fractured or variable rock; blockage prevents drilling in badly fractured rock; dip of bedding and joint evident but not strike
Rotary coring of swelling clay, soft rock	Similar to rotary coring of rock; swelling core retained by third inner plastic liner	Soil cylinder 28.5 to 53.2 mm wide and 600 to 1500 mm long encased in plastic tube	Soils and soft rocks that swell or disintegrate rapidly in air (protected by plastic tube)	Small sample; equipment more complex than other soil sampling techniques
Sonic drilling	High-frequency resonant vertical oscillations advance a 75- to 300-mm diameter core barrel; recovers a continuous 3.3-m long core	Continuous core sample when overcore barrel is advanced	Applicable most bedrock; applicable for conditions both above and below the water table; process does not require drilling fluids	Not cost effective in hard rock where coring is desired; recovered rock cores may be disturbed in fractured rock, provides good recovery and continuous stratigraphy
Percussive Method	Impact drill used; cuttings removed by compressed air	Rock dust and chips	To locate rock, soft seams, or cavities in sound rock; advance through boulders	Drill may become plugged by wet soil

Table 2-8 Soil and Rock Investigation Equipment and Their Applications (NCHRP 2018 and Australian Drilling Industry Training Committee 2015)

Rig Type	Application
Truck-mounted drill rigs	Areas with easy access
All-terrain vehicles drill rigs	Sites with soft ground and rugged terrain
Track-mounted drill rigs	Sites with swampy and very soft ground
Skid drill rigs	Sites with steep terrain
Wireline drill rigs	Rock sampling
Hydraulic direct-push rigs	Fast, continuous sampling, cleaner (no spoils)
Sonic rigs	Continuous sampling of soil and rock
Barges – regular	Over water drilling for shallow water depths (10 ft. [3 m] or less)
Jack up platforms	Over water drilling for areas with deep water (up to 40 ft. [12 m])

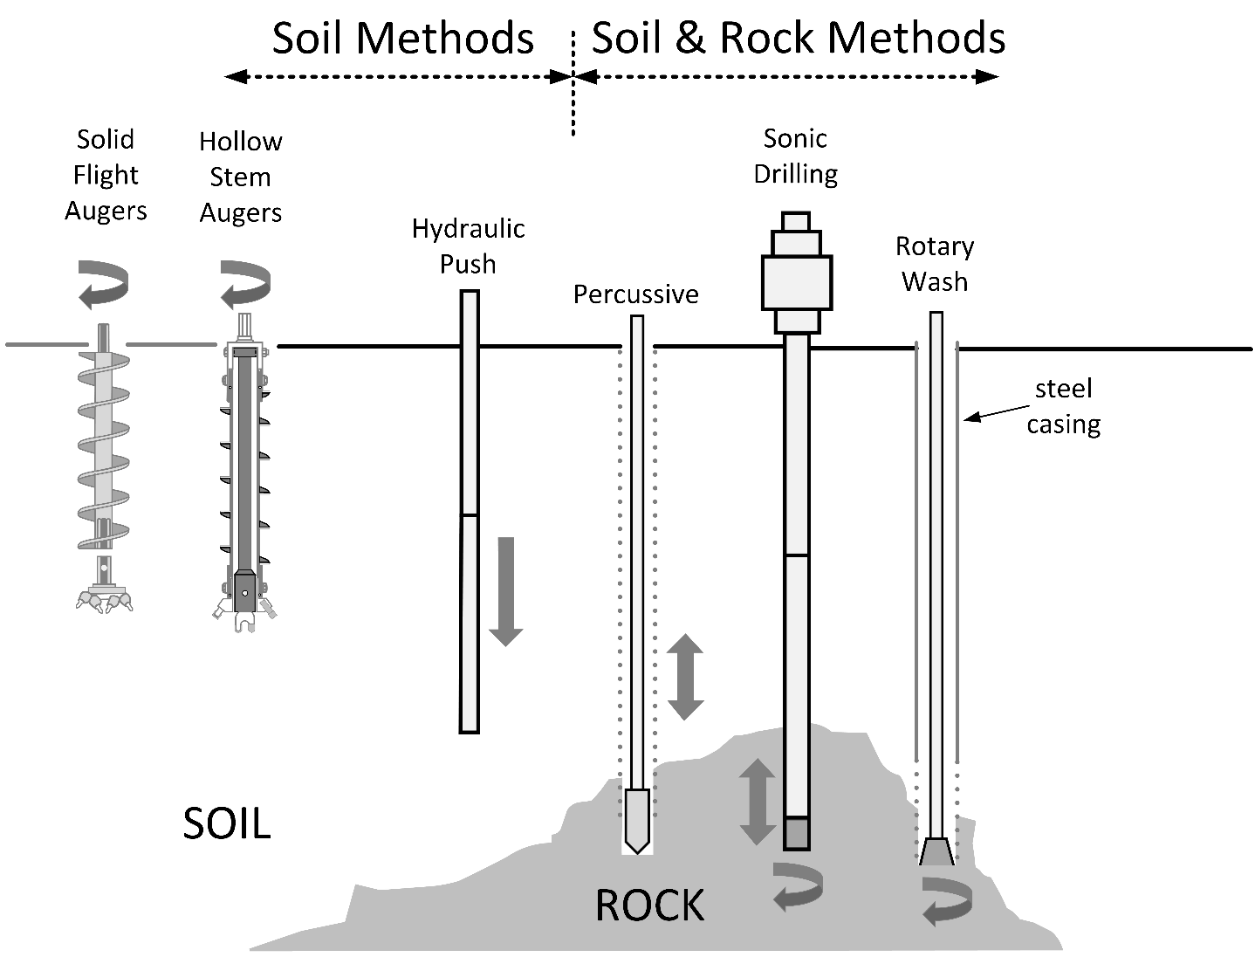

Figure 2-1 Schematic of Various Drilling Techniques for Soil and Rock (after NCHRP 2018 and Mayne 2012)

2-5.1.1 Boring Layout and Depth.

General guidance for preliminary and final boring layout (i.e., location and number of borings) and the depth of the borings is presented in Table 2-9 according to the type of structure and/or problem being investigated. Additional discussion of the spacing and number of borings is presented in FHWA (2002). In addition to structure type, boring layout and depth are strongly dependent on past experience in the region (or at the site) and the site/region geology. When a project is in an unfamiliar area, at least one boring should extend well below the zone necessary for apparent stability to verify that the site conditions are consistent with the anticipated geology and to assure no unusual or unanticipated condition exist at depth.

The site geology is an important factor in developing the boring layout and should influence the arrangement of borings so that geological sections may be viewed in the context of the final design. This requires review of geologic maps of the area and compilation of the information in a format that allows the geology, existing topography, current site plans, and boring locations to be presented at similar scales on the same figure/drawing.

In cases where detailed settlement, slope stability, or seepage analyses are required, the boring plan should include a minimum of two borings in each critical stratum to obtain intact samples (if applicable). For some site investigation programs this may mean that preliminary sample borings and/or cone penetration soundings may be needed to determine the most representative location and depth for intact sample borings.

Table 2-9 Selecting Number, Locations, and Depths of Investigation (after NCHRP 2018, FHWA 2002, FHWA 2016, NYDOT 2013, and SCDOT 2010)

Project	Minimum Number of Investigation Locations	Minimum Depth of Investigation[a]
Bridge - shallow foundations	• One location per pier if width of foundation is less than 100 ft. • Two locations per pier if width of foundation is greater than 100 ft. • Additional investigation locations should be included if uncertain or highly variable subsurface conditions are encountered.	• For $L \leq 2B$, use depth of $2B$ • For $2B \leq L \leq 5B$, use depth of $3B$ • For $L \geq 5B$, use depth of $4B$ • Extend below any soft compressible material into competent material • Extend 10 ft. into competent rock if encountered before the above are met.
Bridge - deep foundations	• One location per pier if width of foundation is less than 100 ft. • Two locations per pier if width of foundation is greater than 100 ft. • Additional investigation locations should be included if uncertain or highly variable subsurface conditions are encountered • At each shaft location for rock sockets	• In soil, extend below the anticipated tip or base elevation the greater of 20 ft. or 2x the maximum group dimension. • In rock, extend below anticipated tip or base elevation a minimum of 10 ft. or 3x shaft diameter for isolated piles/shafts or 2x maximum group dimension, whichever is greater.

[a] B = footing width and L = footing length

Table 2-9 (cont.) Selecting Number, Locations, and Depths of Investigation (after NCHRP 2018, FHWA 2002, FHWA 2016, NYDOT 2013, and SCDOT 2010)

Project	Minimum Number of Investigation Locations	Minimum Depth of Investigation[a]
Retaining structures	• A minimum of one location for each wall. If the wall is greater than 100 ft. long, spacing should be 100 to 200 ft. with locations alternating in front to behind the wall. • Anchored walls: Additional locations in the anchorage zone spaced at 100 to 200 ft. • Soil nail walls: Additional locations behind the wall at a distance of 1 to 1.5x the wall height; spacing should be at intervals of 100 to 200 ft	• Extend below bottom of the wall 2x the wall height or 10 ft. into hard rock. • Should extend below any soft compressible material into competent material.
Roadway - embankment foundations	• Along embankment centerline: spacing of 200 ft. in uncertain or highly variable conditions to 400 ft. in uniform conditions • At critical locations (maximum height or maximum depth of soft strata): a minimum of three locations along the transverse direction • Bridge approach embankment: a minimum of one location per abutment	• Depth of 2x the embankment height unless a hard stratum is encountered above this depth. • If soft strata are encountered extending to a depth greater than 2x embankment height, extend below the soft strata into competent material.
Roadway cuts	• Along centerline of cut: spacing of 200 ft. in uncertain or highly variable conditions to 400 ft. in uniform conditions • At critical locations (maximum cut depth or maximum depth of soft strata): a minimum of three locations along the transverse direction • For cut slopes in rock: perform geologic mapping along the length of the cut slope.	• Minimum depth of 15 ft. (4.5 m) below lowest cut elevation unless a hard stratum is encountered before the minimum depth is achieved. • If soft strata are encountered, extend investigation to a competent layer. • If base of cut extends below groundwater level, extend depth of investigation to determine the depth of the underlying pervious strata.
Pavements	• Spacing of 100 to 300 ft. depending on the subsurface conditions. Closer spacing for uncertain or highly variable conditions and longer spacing for uniform conditions.	• Minimum depth of 10 ft. from the proposed top of subgrade elevation.
Culverts and pipes	• One boring at each end of the culvert. • Additional borings between the end of culvert spaced at 100 to 300 ft. depending on the variability of the subsurface conditions • For culvert extensions: one boring every 50 to 100 ft. with a minimum of one boring	• Large culverts: same criteria as for bridge foundations • Small culverts: Minimum of 10 ft. below anticipated invert elevation
Poles, masts and towers	• One boring at each foundation location	• 30 ft. below the anticipated top of foundation in soil or 10 ft. of rock coring whichever is shallower.

[a] B = footing width and L = footing length

2-5.1.2 Abandoning or Sealing Boreholes.

Boreholes should be backfilled. Often, backfilling with the drill cuttings is sufficient. However, boreholes must be sealed with grout in cases where the borings are advanced below groundwater, in all cases where artesian pressures are encountered, and whenever environmental borings are advanced. Under these conditions, boreholes may be left temporarily unfilled to use for water-level observations after the initial field investigation drilling is completed. In boreholes for groundwater observations, the casings should be placed in tight contact with walls of boreholes or the annular space between the standpipe and borehole should be backfilled using the appropriately graded sand or gravel. Many agencies, such as the USACE and state DOTs have specific guidelines for sealing boreholes, and these are part of the project specifications. Additional discussion of details regarding groundwater investigation is presented in Section 2-8.

2-5.2 Test Pits and Test Trenches.

Test pits are commonly used to examine and sample soils *in situ* at relatively shallow depths. Test pits can be used to determine the depth to shallow groundwater, thickness of topsoil or surficial deposits, and/or to assess near surface conditions. Test pits are often used to determine sources of construction materials for earthwork projects, such as dams and embankments. Test pits range from shallow, hand-excavated pits or (more commonly) machine-advanced excavations.

Test trenches are essentially long test pits and are particularly useful for exploration in very heterogeneous deposits (e.g., rubble fills) where borings may be misleading, meaningless, or not feasible. Test trenches are used commonly for detection of fault traces in seismicity investigations and for investigating conditions near a slide plane in a landslide investigation. Safety precautions need to be recognized when working in and around test pits and trenches.

Table 2-10 provides guidance for the use and limitations of test pits and trenches. Hand-cut, block samples are frequently obtained from these explorations and may be necessary for sensitive soils, brittle and weathered rock, and soil formations exhibiting a honeycomb structure.

2-5.3 Other Exploratory Techniques.

Once a hole is advanced in either soil or rock, downhole tools can be placed in the open hole to make specific measurements or serve as carriers for geophysical testing instruments. Borehole cameras are commonly used for open holes in rock to assess stratigraphy, as well as strike and dip of the formation. Geotechnical performance monitoring instruments (i.e., slope inclinometers, water pressure transducers, borehole extensometers, etc.) can also be placed in the advanced borehole.

2-6 SAMPLING.

Recovery of representative samples of the subsurface soil and rock for testing is perhaps the most common goal of the techniques in Section 2-5. These samples are commonly referenced as *disturbed* or *undisturbed* depending on how well the recovered sample maintains the structure of the *in situ* material. Disturbance is initiated by the process of removing the soil/rock from the confined conditions in the subsurface. Thus, an "undisturbed" sample is actually a misnomer, as it (hopefully) represents a *minimally* (or *nominally*) *disturbed* sample. The term *intact sample* has largely replaced *undisturbed sample* in geotechnical engineering vernacular.

Table 2-10 Use and Limitations of Test Pits and Test Trenches (after NCHRP 2018)

Exploration Method	General Use	Capabilities	Limitations
Hand-excavated test pits and shafts	Bulk sampling, *in situ* testing, visual inspection	Provides data in inaccessible areas, less mechanical disturbance of surrounding ground.	Expensive, time-consuming, limited to depths above groundwater level.
Backhoe excavated test pits and trenches	Bulk sampling, block sampling, *in situ* testing, visual inspection, depth of bedrock and groundwater.	Fast and economical, generally less than 15-feet deep, can be up to 30-feet deep	Equipment access, generally limited to depths above groundwater level, limited intact sampling.
Drilled shafts	Pre-excavation for piles and shafts, landslide investigations, drainage wells.	Fast, more economical than hand excavated, min. 30-inches dia., max. 6-feet dia.	Equipment access, difficult to obtain intact samples, casing obscured visual inspection.
Dozer cuts	Bedrock characteristics, depth of bedrock and groundwater level, rippability, used in conjunction with backhoes for deeper excavations, used to level areas for other exploration equipment.	Relatively low cost, create exposures for geologic mapping.	Exploration limited to depth above groundwater level.
Trenches for fault investigations	Evaluation of presence and activity of faulting and sometimes landslide features.	Definitive location of faulting, subsurface observation up to 30 feet.	Costly, time-consuming, requires shoring, only useful where dateable materials are present, depth limited to zone above groundwater level. Specialized application.

Disturbed samples are primarily used for index tests that are performed for classification. A disturbed sample needs only to be representative of the soil composition and moisture because the soil structure is disturbed. Intact samples are obtained primarily for laboratory strength, compressibility, and permeability tests. The *in situ* structure and composition significantly influence the strength, compressibility and permeability (i.e., engineering) properties of the soil. Most of the discussion in this section focuses on sampling from terrestrial or shallow-water locations. Offshore samplers are specialized and are treated separately in Section 2-6.3.

The number and type of samples depend on the stratification of the subsurface, the type of material encountered, the quantity needed for testing, and the criticality of the application. For most projects, both disturbed and intact samples are obtained for testing.

2-6.1 Soil Sampling.

2-6.1.1 Disturbed Soil Samples.

In general, representative disturbed samples are obtained at vertical intervals of no less than 5 feet and at every change in strata. Continuous samples are occasionally required or justified. This may be the case when a relatively thin layer of critical material is anticipated. Table 2-11 lists common types of disturbed samples and samplers. Recommended procedures for obtaining disturbed samples are provided in ASTM D1586. The split barrel (a.k.a., split spoon) sampler, depicted in Figure 2-2, is the most commonly used sampler.

Table 2-11 Samplers to Collect Disturbed Soil Samples

Sampler (Method of Penetration)	Typical Dimensions	Soils that Give Best Results	Cause of Low Recovery	Remarks
Split Barrel (140-lb hammer driven)	2.0-inch outside diameter (OD), 1.375-inch inside diameter (ID)	All soils finer than gravel-size particles; gravels invalidate drive data; soil retainer may be used in coarse-grained soils	Gravel-sized particles and larger	Standard Penetration Test (SPT) performed using this hammer and sampler and hammer; samples are extremely disturbed
Continuous helical-flight auger (Rotation)	3- to 16-inch diameter; penetration to depths exceeding 50 ft.	Most soils above water table; will not penetrate hard soils or those containing cobbles or boulders	Hard soils, cobbles, boulders	Method of determining soil profile, bag samples can be obtained; log and sample depths must account for lag time between penetration of bit and arrival of sample at surface
Bucket auger (Rotation)	Up to 48-inch diameter common; with extensions, depth over 80 ft. are possible	Most soils above water table; can penetrate harder soils than above types, can penetrate cobbles and boulders with a rock bucket	Soil too hard to penetrate	Several bucket types available, including those with ripper teeth and chopping tools; progress is slow when extensions are used
Large Penetration Test (LPT) (Up to 300-lb hammer driven)	2- to 3-inch ID, 2.5- to 3.5-inch OD samplers, (e.g., Converse and California samplers)	Sandy to gravelly soils	Particles large than coarse gravel	Sample is intact but very disturbed; A resistance can be recorded during penetration, but is not equivalent to the SPT N value and is more variable due to no standard equipment and methods

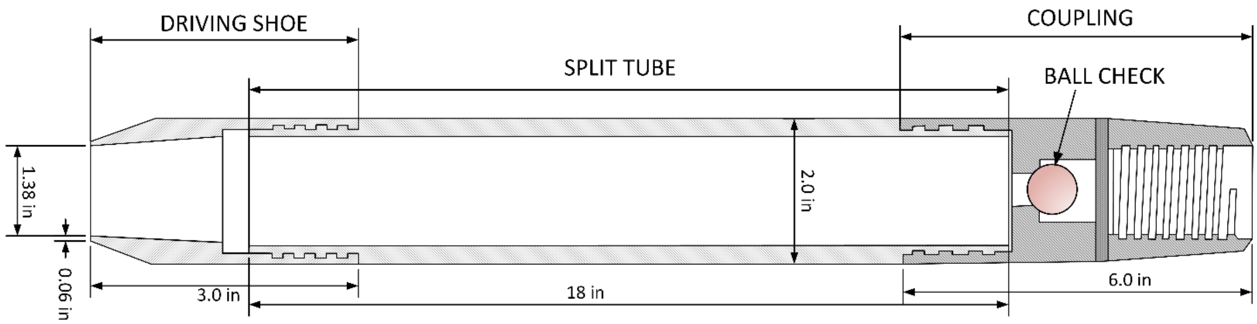

Figure 2-2 Cross Section of Split Barrel Sampler

2-6.1.2 Intact Soil Samples.

Intact (or “undisturbed”) samples are most commonly obtained using a thin-walled steel tube (Shelby tube) that is pushed at a relatively rapid and constant rate following procedures in accordance with ASTM D1587. Intact sampling and samplers should provide samples that comply with the following criteria: (1) show no visible distortion of strata, (2) include no visible openings or softened material, (3) exhibit a recovery ratio (i.e., sample length divided by distance of sample push) that exceeds 95 percent, (4) have an area ratio (i.e., area displaced by the sampler tube divided by the area of the sample) of less than 15 percent, and (5) have a clearance ratio (i.e., the difference between the diameter of inside of the tube and the diameter of the opening at the bottom of the tube divided by the diameter of the opening at the bottom of the tube) as small as possible but less than 3 percent. A schematic and photograph of a thin-walled Shelby tube that meets these criteria is presented in Figure 2-3.

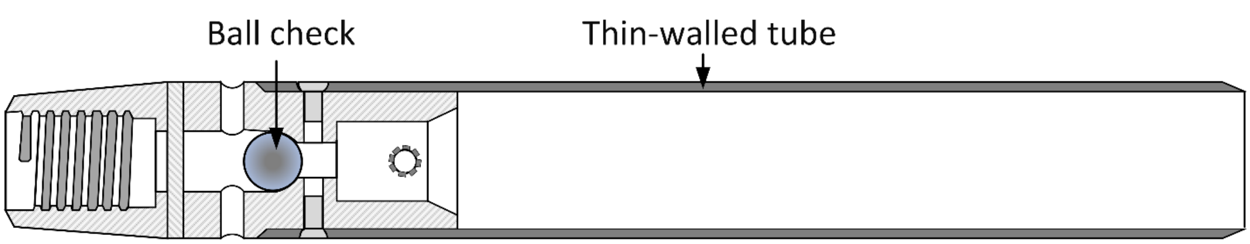

Figure 2-3 Cross Section of Shelby Tube Sampler with Ball-check Valve Head

In general, intact samples of clean sands and gravels cannot be obtained, even when using thin-walled samplers. For this reason, *in situ* testing methods are commonly used in these soils, and intact sampling focuses on silts, clays, and coarse-grained soils with a significant amount of silty and clayey fines. Because fine-grained soils can vary from very soft to very hard, different types of samplers have been developed to facilitate the recovery of intact samples. Table 2-12 summarizes common types of samplers used for intact soil samples.

Table 2-12 Samplers Used to Collect Intact Soil Samples

Sampler	Typical Dimensions	Method of Penetration
Shelby tube (ASTM D1587)	3.0-inch OD and 2.87-inch inside diameter (ID) most common; available from 2- to 5-inch OD; 30-inch sampler length standard	Pressing with relatively rapid, smooth stroke; can be carefully hammer driven but this will induce additional disturbance
Fixed or Stationary piston	3-inch OD most common; available from 2- to 5-inch OD; 30-inch sampler length standard	Pressing with continuous, steady stroke
Foil Sampler	Continuous samples with 2-inch ID; up to 65 ft. long	Pushed into the ground with steady stroke; Pauses occur to add segments to sampler
Hydraulic piston (Osterberg)	3-inch OD is most common; available from 2- to 4-inch OD; 36-inch length standard	Hydraulic or compressed air pressure
Denison	3.5- to 7-inch OD, producing samples 2.4 to 6.3 inches; 24-inch sampler length standard	Rotation and hydraulic pressure
Pitcher sampler	4-inch OD; uses 3-inch diameter Shelby tubes; sample length 24 inches	Same as Denison

Sampler	Soils that Give Best Results	Cause of Disturbance or Low Recovery	Remarks
Shelby tube (ASTM D1587)	Cohesive fine-grained or soft soils; gravelly / very stiff soils will crimp tube	Erratic sampling pressure, hammering, gravel particles, crimping of tube edge, improper soil types, pressing more than 80% of tube length	Simplest device for undisturbed samples; clean boring before sampler is lowered; little waste area in sampler; not suitable for hard, dense or gravelly soils
Fixed or Stationary piston	Soft to medium clays and fine silts; not for hard, dense, sandy, or gravelly soil	Erratic pressure during sampling, allowing piston rod to move during press, improper soil types for sampler	Piston at end of sampler prevents entry of fluid and contaminating material, requires heavy drill rig with hydraulic drill head; less disturbance than Shelby tube
Foil sampler	Soft sensitive clays, silts, and varved clays	Samplers should not be used in soils containing fragments or shells	Samples surrounded by thin strips of stainless steel, stored above cutter, to prevent contact of soil with tube
Hydraulic piston (Osterberg)	Silts and clays, some sandy soils	Inadequate clamping of drill rods, erratic pressure	Needs only standard drill rods; requires adequate hydraulic or air capacity to activate sampler; samples generally less disturbed compared with Shelby tube; not suitable for hard, dense, or gravelly soil
Denison	Stiff to hard clay, silt, and sands with some cementation, soft rock	Improper operation of sampler; poor drilling procedures	Inner tube face projects beyond outer tube, which rotates; amount of projection can be adjusted; generally good samples; not suitable for loose sands and soft clays
Pitcher sampler	Same as Denison	Same as Denison	Differs from Denison in that inner tube projection is spring controlled; often ineffective in cohesionless soils

For soft soils, a stationary (or fixed-piston) sampler (Figure 2-4) or hydraulic piston sampler is commonly deployed. For very soft soils and varved clays, a foil sampler may be deployed, although limited in use in the United States.

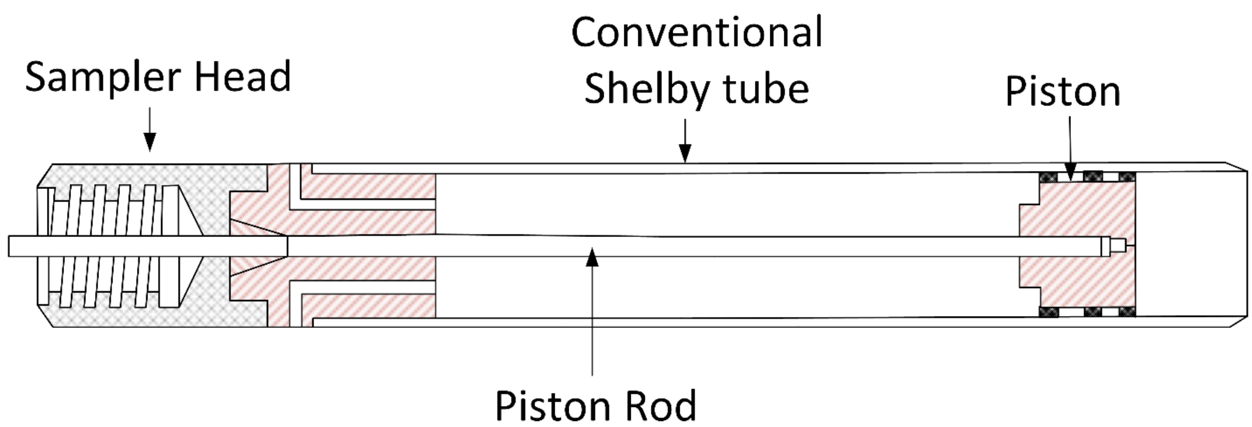

Figure 2-4 Cross Section of a Stationary or Fixed Piston Sampler

For stiff fine-grained soils, or for layers of soft and hard materials, special samplers have been developed that have the ability to "core" around the recovered stiff materials while capturing the softer materials in the same thin-walled tube. The Denison sampler and the Pitcher sampler are two types of common samples for these subsurface conditions.

2-6.1.3 Intact Samples from Test Pits and Test Trenches.

One of the advantages of test pits and test trenches is that hand-trimmed (i.e., block) samples may be obtained from the bottom or the sidewalls of the test pits and test trenches. These block samples are potentially the least disturbed of all types of samples. Unfortunately, the test pits and trenches are only feasible to a limited depth.

To obtain a block sample, a column of soil is trimmed the same size or slightly smaller than the container that will be used for transporting the sample. The container should be placed over the top of the sample and should provide as small an annular space as possible. This annular space ideally would be filled using wax. A tight fit in a stiff container that can be sealed provides the ideal conditions for retrieving and transporting block samples with least disturbance.

2-6.2 Rock Sampling.

Rock is sampled with core barrels that have either tungsten carbide or diamond core bits at the cutting face. Drill rods and core barrels come in a variety of standard sizes (see Table 2-13), depending on the size of the recovered rock core.

Table 2-13 Standard Size of Rock Casing, Drill Rods, Core Barrels, and Coreholes (after ASTM D2113)

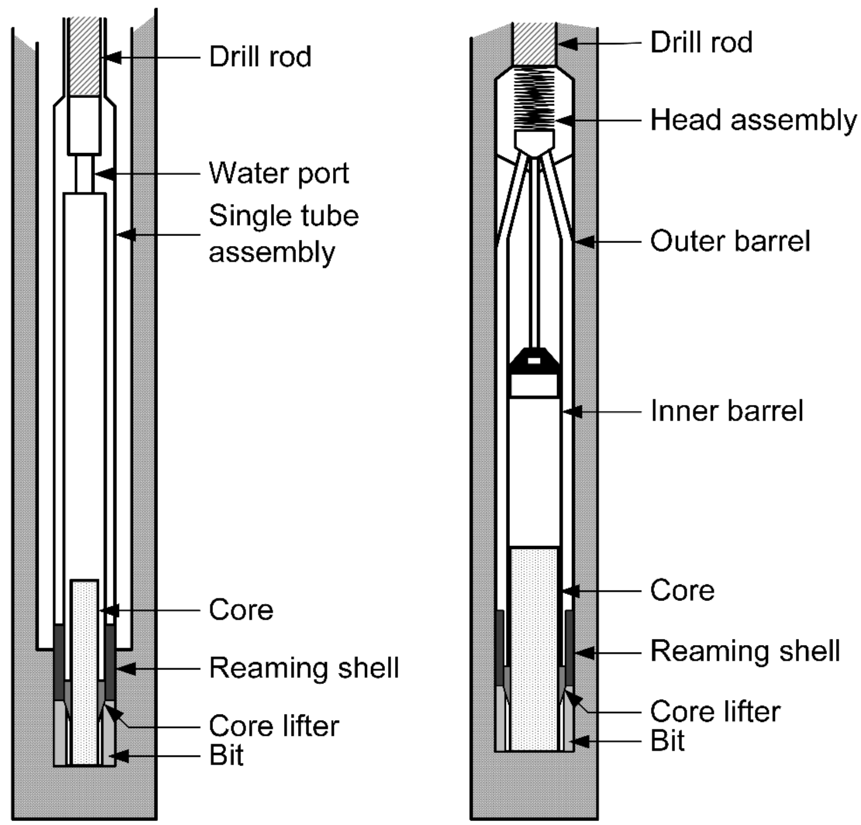
Casing, Core Barrel	Drill Rod	Casing OD (in.)	Casing Bit OD (in.)	Core Barrel Bit OD (in.)	Drill Rod OD (in.)	Approx. Diameter of Corehole (in.)	Approx. Diameter of Core (in.)
EX	E	1-13/16	1-7/8	1-7/16	1-5/16	1-1/2	7/8
AX	A	2-1/4	2-11/32	1-27/32	1-5/8	1-7/8	1-3/16
BX	B	2-7/8	2-31/32	2-5/16	1-29/32	2-3/8	1-5/8
NX	N	3-1/2	3-5/8	2-15/16	2-3/8	3	2-1/8

For hard and massive rock, relatively undisturbed rock samples may be obtained using just the core barrel to recover the sample. More commonly, a tube (or series of tubes) is used to contain the rock core and the tube is isolated from the core barrel to minimize disturbance. Inner tubes must be used for undisturbed rock sampling whenever the rock includes discontinuities. Table 2-14 lists summarizes techniques for recovery of relatively undisturbed samples of rock.

Table 2-14 Common Samplers for Rock Cores (after NCHRP 2018)

Diamond Core Barrels			
Dimensions		**Best Results in Soil or Rock Types**	**Methods of Penetration**
Standard sizes: 1-1/2” to 3” OD, 7/8” to 2-1/8” core. Barrel lengths 5 to 10 feet for exploration.		Hard rock. All barrels can be fitted with insert bits for coring soft rock or hard soil.	Rotary drilling using water or slurry
Details for tube sampling			
Type	**Causes of Disturbance or Low Recovery**	**Best Results in Soil or Rock Types**	**Remarks**
Single Tube	Fractured rock. Rock too soft.	Primarily for strong, sound and uniform rock.	Drill fluid must circulate around core – rock must not be subject to erosion. Single tube not often used for exploration.
Double Tube	Improper rotation or feed rate in fractured or soft rock.	Non-uniform, fractured, friable and soft rock.	Has inner barrel or swivel which does not rotate with outer tube. For soft, erodible rock. Best with bottom discharge bit.
Triple Tube	Same as Double Tube	Same as Double Tube.	Differs from Double Tube by having an inner split tube liner. Intensely fractured rock core best preserved in this barrel.

Double tube core barrels are the most commonly used in practice. Depending on the number of discontinuities in the rock, the recovered sample may be considered either disturbed or undisturbed. Schematics of single and double tube rock core samplers are provided in Figure 2-5(a) and (b), respectively.



(a) Single Tube (b) Double Tube

Figure 2-5 Rock Core Samplers (after NCHRP 2018)

The suitability of rock cores for structural property tests depends on the quality of individual recovered samples. If the properties of the intact rock are desired, then smaller diameter cores are recommended because large-diameter rock cores likely include more discontinuities than small-diameter rock cores.

The percentage of core recovery (i.e., recovered core length divided by the recorded core run) provides an indication of soundness and degree of weathering of rock. The Rock Quality Designation, *RQD,* (i.e., total length of recovered core pieces greater than 4 inches in length divided by the recorded core run) provide a better indication of the soundness and degree of rock weathering because it essentially disallows the consideration of the fractured and weathered rock intervals. The *RQD* is also a major factor in assessing the behavior of the *in situ* rock mass, as defined by the Rock Mass Rating (*RMR*) of the rock. The engineer and geologist should carefully examine rock core samples exhibiting low recovery and/or low *RQD* to assess the reasons for low recovery and the interpreted poor rock quality. Details regarding on rock classification and rock properties are presented in Chapter 1 and in NCHRP (2018).

Sampling of highly (or partially) weathered, fractured, or disintegrated rock is extremely difficult. These materials often occur near the interface between soil and rock and represent the transition between these two materials, especially in the case of residual soils. The best samples of these materials are obtained by experienced drillers using double- or triple-core barrel samplers.

2-6.3 Offshore Sampling.

In some cases, samples of soil and rock must be obtained from the bottom of rivers, lakes, or the ocean. For water depths less than about 60 feet, the conventional soil and rock boring equipment can be used on small jack-up platforms, small barges, or barrel floats. The challenge is that floating equipment requires suitable anchoring and is limited to fairly calm water, although tidal fluctuations can be easily accommodated. For deep water sites and/or extreme ocean settings, large dedicated drill ships, specialized equipment, and experience are required to obtain quality intact samples. Table 2-15 identifies some of the specialized equipment used for underwater sampling.

Numerous types of oceanographic samplers, both open-tube and piston types, are available for use when drilling from ships. Some of these depend upon free-fall penetration and are limited in the depth of exploration. Drilling and sampling from the ocean floor can be accomplished using specialized equipment deployed remotely from portable equipment that is deployed in underwater vessels or on underwater platforms operating on the ocean floor. The quality of samples obtained by most oceanographic samplers is not high because of their large length to diameter ratio and because air/gas in the dissolved state in the underwater environment comes out of solution when the sample is recovered at the ground surface. For detailed information on underwater sampling equipment, refer to ASTM STP 501 (ASTM 1972).

2-6.4 Field Logging and Boring Logs.

While monitoring drilling and sampling activities, an engineer, geologist, or experienced driller prepares a *field boring log* to document the findings and observations. This field logging is an important part of documenting the soil and rock conditions that exist at the project site. A typical field log includes all the relevant information for the boring that was completed, including a unique boring identification number, date of drilling, personnel on-site, boring advancement method (i.e., auger, rotary wash, direct push, sonic), depths where samples were obtained, type of samples (i.e., split-barrel and Shelby tube), hammer type, raw SPT N values, water level observations, and preliminary estimates of stratigraphy. If available, the global positioning system (GPS) coordinates should be included. The field log provides a unique designation of each recovered sample, whether disturbed or intact, as well as a field visual classification of the sample in accordance with ASTM D2488.

Table 2-15 Common Underwater Samplers (after NCHRP 2018)

Sampler	Size of Sample	Length of Sample	Water Depth Limitations	Method of Penetration	Remarks
Peterson Dredge	Grab	± 6-inch depth	To 200 ft. and more with additional weight	Clam shell jaw	Reliable grab sampler; intact samples may be obtained with jaws that precisely mate
Open Barrel Gravity Corer	2.5- to 6-inch diameter	Core barrels length from 6 to 30 ft	No limit on depth but required weight, amount of line or size of vessel may control	Spooled freely off the winch drum	
Pflueger Corer	About 1.5-inch diameter	Core barrels available in 12, 24 and 36 in. length	From 25 to 200 ft	Free fall from 10 to 20 ft. above bottom	Relatively light weight core for upper 1 to 3 ft. of bottom sediments; usually not suitable for strength tests
Piston Gravity Corer	Standard corer has 2.5-in. barrel	Standard barrel is 10 ft. Additional 10 ft. sections can be added	No depth limit except that available weight, amount of line, or size of vessel may control	Free fall from calibrated height above bottom such that piston does not penetrate sediments	Capable of obtaining samples suitable for strength tests with experienced crew; samples may be seriously disturbed
Vibratory Corer	Sample is 3.5-in. diameter	20 ft. standard, can be lengthened to 40 ft.	Minimum depth limited by draft of support vessel; maximum depth about 200 ft.	Pneumatic impacting vibratory hammer	Samples are disturbed because of vibration and large area ratio; not suitable for strength testing; Penetration resistance can be measured; obtains continuous samples in marine soils
