(3) Selection of Design Strength. The designer should base the pavement thickness design on a strength that is readily achievable with local materials. Design strengths on past projects at the base or discussions with local producers should allow selection of a design strength that is readily achievable with local materials. If no such information is available, some trial laboratory mixtures should be prepared to evaluate local aggregate sources. Traditionally, pavement thickness design for military airfields is based on the 90-day strength of laboratory-cured specimens. This lengthy cure time takes maximum advantage of the long-term gradual strength gain characteristic of conventional portland-cement concrete. On many rehabilitation projects today, pavements are returned to the user after much shorter periods. Consequently, design strengths are often specified based on these shorter periods when the pavement is returned to the user. Fly ash and GGBF slag gain strength more slowly than portland cement, so the designer must be aware that strength tests at early ages for concrete mixtures containing these materials may not reflect the ultimate long-term strength well at all. Specifying very high strengths, particularly at early ages, usually requires very rich mixtures with liberal use of admixtures. This may introduce workability and construction problems, excessive shrinkage, or other undesirable characteristics that negate the economies of higher strength. In general, design ASTM C 78 flexural strengths of 414 to 448 MPa (600 to 650 psi) are readily achievable with most local materials, and the designer should use higher design strengths only with caution.

f. Special Airfield Exposure Conditions. Properly proportioned, placed, and cured portland-cement concrete requires no surface sealers, coatings, or treatments to withstand normal military aircraft operations such as startup, warmup, taxiing, takeoff, and landing.

(1) Heat Effects on Portland-Cement Concrete. Rapid heating of moist concrete can vaporize water in the concrete capillaries and cause explosive spalling. As the concrete temperature begins to rise above about 149 °C (300 °F), the progressive cement paste dehydration, thermal incompatibilities between paste and aggregate, and aggregate deterioration lead to irreversible damage and progressive loss of strength that is more pronounced as the temperature rises. Aggregates have a major impact on the thermal behavior of concrete and in decreasing order of desirability for thermal resistance they are lightweight aggregates (e.g., expanded slags, clays, and shales or natural pumice or scoria), fine-grained igneous rocks such as basalt or diabase, calcareous aggregates, and siliceous aggregates. Including slag cements in the concrete mixture also seems to enhance thermal resistance. Heat resistant conventional concrete can be achieved by proper mixture proportioning, use of appropriate aggregates, inclusion of slag cement, and high-quality concrete placement, finishing, and curing. However, if the concrete temperature will reach 204 °C (400 °F), conventional concrete probably will not be sufficient, and thermal cycling at lower temperatures can cause damage. HQUSACE (CEMP-ET), appropriate Air Force MAJCOM pavements engineer, or Naval Facilities Engineering Service Center should be consulted for guidance for concrete that will be exposed to high temperatures or that will be exposed to repeated cycles of high thermal exposure. Concrete is a moderately good insulator so there

is a significant lag between exposure to an elevated temperature and heating of the concrete to that temperature. Normal military aircraft operations do not heat concrete pavements to temperatures that cause damage.

(2) Power Check Pads and Similar Facilities. If the jet engine exhaust plume is allowed to impinge directly on the concrete surface, severe erosion can occur. This is a potential problem for facilities such as power check pads where engines have to be operated for extended periods and where the configuration of some aircraft will project the engine exhaust plume into contact the pavement surface. For this reason, these facilities are often specifically designed to have larger slopes than normal to keep the exhaust plume from directly impinging on the pavement surface. Pavement damage can arise when parking ramps, old taxiways, etc. are converted to use as power check pads, and the conventional slopes on these facilities allow the exhaust to come into direct contact with the pavement surface.

(3) Pavements Exposed to Vertical/Short Take-Off and Landing Aircraft Exhaust. The introduction of the Harrier aircraft exposed pavements to new higher levels of heat and blast than conventional aircraft. This trend is likely to continue with development of new aircraft like the joint strike fighter currently scheduled for deployment in about 2008. The Naval Facilities Engineering Services Center has conducted extensive research in support of deployment of the Harrier in the Marine Corps. They found that reinforced conventional concrete made with diabase aggregate has provided good performance in the field for up to 15 years. Recent studies have also found that improved performance could be achieved with portland-cement concrete with lightweight aggregate and nylon fibers, a proprietary blended cement with lightweight aggregate, and nylon fibers, and a proprietary magnesium phosphate cement with lightweight aggregate. The Naval Facilities Engineering Service Center, 1100 23rd Avenue, Port Hueneme, CA 93043-4370, should be contacted for current guidance and research results in this area.

(4) Pavements Exposed to Auxiliary Power Unit (APU) Exhaust. The APU on the B-1, FA-18, and certain models of aircraft currently under development are mounted so that the exhaust is directed downward and into contact with the pavement surface. With extended operation of these units, the surface of the concrete may be heated to temperatures approaching 177°C (350°F). This leads to scaling and spalling in the limited area around the exhaust impingement area. Studies by the Naval Engineering Service Center, Air Force Wright Laboratories, and the U.S. Army Engineer Research and Development Center have identified two mechanisms contributing to this damage. Repeated heating and cooling lead to thermal fatigue and surface failure. At these elevated temperatures, fluids high in esters such as fuel, lubricants, and hydraulic fluids can chemically react with portland-cement concrete and lead to scaling of the pavement. In parking areas for these aircraft, the APU exhaust impinges on the concrete where there is significant collection of these fluids that have leaked from the aircraft in normal maintenance and operation. At present there is no technical solution to this problem. Ad-hoc solutions and trials in the field have included bolting steel plates to the pavement in the area where the exhaust contacts the pavement, various coatings, refractory concretes, and specialty concretes with generally mixed or unsatisfactory results. HQUSACE (CEMP-ET), appropriate Air Force MAJCOM pavements engineer, or Naval Facilities Engineering Service Center should be contacted for guidance when designing parking areas for these aircraft.

g. Specification and Construction. It is crucial that proper material and construction specifications be developed to accompany the thickness design and geometric design and detailing. There have been numerous problems with military concrete airfield pavements in recent decades as the result of improper construction techniques, poor finishing, inadequate curing, late saw-cutting of joints, use of aggregates susceptible to alkali-aggregate reactions without proper countermeasures, inclusion of deleterious materials, and inadequate durability when exposed to freezing and thawing or sulfates. The result has been unsatisfactory performance, increased maintenance, and dissatisfied users in some cases. The designer should be certain to consult current versions of each service's guide specification and TM 5-822-7/AFM 88-6, Chapter 8, for assistance in preparing project specifications.

4. ASPHALTIC CONCRETE. Asphaltic Concrete is the normal surfacing for flexible pavements. Unlike portland cement concrete, it normally functions as a relatively thin wearing surface and is not the major structural element of the pavement. Asphaltic concrete on airfields is exposed to much more severe loads than on highways and is quite different from highway asphaltic concrete mixes. Substitution of asphaltic concrete highway mixes for asphaltic concrete airfield mixes is not acceptable and is a major engineering blunder. The requirements of TM 822-08/AFMAN 32-1131 V8(1)/DM 21.11 will provide an asphaltic concrete that will stand up to the loads of modern military aircraft in all environmental conditions.

a. Constituents. Asphaltic concrete is composed of well-graded aggregates (approximately 95 percent by weight) and an asphalt cement binder (approximately 5 percent by weight).

(1) Binder. Asphalt cement from the distillation of petroleum is the most common binder in asphaltic concrete. Liquid asphalts from emulsifying asphalt cement with water or dissolving the asphalt cement in a solvent have many applications in pavements but are not normally used as a binder for high-quality airfield pavements. Tars from the distillation of coal are seldom used as binder in airfield pavements today. There are also natural asphalts that occasionally are used as binder material for asphaltic concrete.

(a) Characteristics. Asphalt is a complex hydrocarbon product whose composition and properties vary depending on the petroleum source and distillation process. Asphalt is probably the most viscoelastic material used by civil engineers in routine construction. Its stiffness increases as its temperature drops or as the speed of loading increases, and in reverse the stiffness drops as temperature increases or as the speed of loading is slowed. Asphalt cement functions as a cohesive binder for the aggregate and helps provide a nominally waterproof surface.

(b) Specification. The asphalt binder should be specified in accordance with the new Strategic Highway Research Program (SHRP) pavement grading (PG) system (AASHTO PP6). This new system matches specific characteristics of the asphalt cement with environmental exposure conditions. This improved matching of binder properties and project environmental conditions should extend the effective life of asphaltic concrete pavements. TM 822-08/AFMAN 32-1131 V8(1)/DM 21.11 provides guidance on selecting PG grades of asphalt cement for different project locations. SHRP PG grading is not used universally worldwide, therefore alternate specification methods based on viscosity (ASTM D 3381) and penetration (ASTM D 946) can be substituted depending on the local market practice. Polymer additives are increasingly being used with asphalt binders and have been particularly effective for enhancing cold-weather properties. This is an evolving area so TM 822-08/AFMAN 32-1131 V8(1)/DM 21.11 and HQUSACE (CEMP-ET), appropriate Air Force MAJCOM pavements engineer, or Naval Facilities Engineering Service Center should be consulted for up-to-date guidance.

(2) Aggregates. The deformation resistance of asphalt concrete exposed to military aircraft traffic is primarily a function of the aggregate, and the binder's contribution is secondary in comparison. The aggregate gradation, particle shape, and control of these parameters during production are crucial in providing an asphalt concrete that will resist the high tire pressure of modern military aircraft. Limiting the natural sand that has rounded particles to no more than 15 percent of the total aggregate by weight is an important requirement in the military requirements for asphalt concrete for military airfields. At

higher natural sand contents, there have been repeated problems with rutting under military aircraft. TM 822-08/AFMAN 32-1131 V8(1)/DM 21.11 provides detailed guidance on aggregate requirements.

b. Mix Design. Mix design of asphalt concrete requires balancing durability, load resistance, and economics. Relatively lean mixes tend to have high load resistance but suffer environmental aging more quickly than richer mixes. Rich mixes tend to be unstable but are more resistant to environmental aging.

(1) Military Requirements. Asphalt concrete for military airfields will be designed based on the 75-blow Marshall mix design method. Details are provided in TM 822-08/AFMAN 32-1131 V8(1)/DM 21.11 and the Asphalt Institute MS-2 procedures.

(2) SHRP Mix Design. The SHRP produced an asphalt concrete mix design procedure and recommended aggregate gradations that are being widely used by state Departments of Transportation. These gradations and mix design procedures were developed for highway use and have not been evaluated for airfield use. These SHRP mix design procedures and aggregate gradations are not approved for military airfields until testing and trials demonstrate their adequacy for airfield loads and conditions. Approval from HQUSACE (CEMP-ET), appropriate Air Force MAJCOM pavements engineer, or Naval Facilities Engineering Service Center is needed before these new guidelines are used on military airfields.

c. Special Asphalt Mixes. Porous friction courses are relatively thin (~ 25 to 38 mm (~1 to 1-1/2 in.)) surface layers of a special open-graded asphalt concrete with clearly visible voids. This mix provides high skid resistance and combats aircraft hydroplaning, but its open texture allows more rapid environmental aging of the asphalt binder and makes it very vulnerable to fuel spills. These mixes were widely used by the Air Force in the 1970s and 1980s, but their use has declined as improved grooving of conventional asphalt concrete mixes provides similar skid resistance without the disadvantages of the porous friction courses. Stone mastic asphalt (SMA), sometimes also called stone matrix asphalt, has a coarse aggregate gradation that provides stone-to-stone contact with the voids between aggregate particles filled with a relatively rich mastic of asphalt cement, sand, and fibers. The stone-to-stone contact of the coarse aggregate provides a stiff rut-resistant mineral skeleton, while the rich mastic provides improved environmental resistance. Two trial applications of SMA by the Air Force for airfield pavements in the United Kingdom and Italy have performed well to date. Thin applications of fuel resistant sealers to asphalt concrete pavements provide limited resistance to fuel spills. The fuel-resistant sealers economically available in the United States are usually coal tar based and are prone to environmental induced cracking that limits their effectiveness. This cracking often occurs at early ages. Polymer modification of some of these products has helped but not solved the cracking problem. Slurry seals are thin applications of emulsified asphalt and sand to oxidized asphalt concrete surfaces to try to extend the pavement life. They have problems with low skid resistance and are prone to localized failures that generate FOD. Slurry seals are not allowed on military airfield pavements. Highly polymerized proprietary systems known as *microtexturing* that use thin surface applications of a binder and aggregate to oxidized asphalt concrete surfaces have shown promise but are still in the evaluation stage. Rejuvenators are composed of lighter-end hydrocarbons that, when sprayed on an oxidized asphaltic concrete surface, soften the binder and counter some of the aging effect. These materials have given mixed results in practice and invariably lower the skid resistance of the pavement. Consequently, they are not allowed to be used on military airfields. The military has used an open-graded asphalt concrete mix with its voids filled with a proprietary modified hydraulic cement grout to provide a surface more abrasion and fuel resistant than conventional asphalt concrete. This system is referred to as resin-modified pavement, and several successful pavements have been built with this material. HQUSACE (CEMP-ET), appropriate Air Force MAJCOM pavements engineer, or Naval

Facilities Engineering Service Center should be consulted for up-to-date guidance on these and other specialty asphalt mixes.

d. Durability.

(1) Aging and Oxidation. Asphalt oxidizes and stiffens over time which leads to a loss of cohesion and flexibility. This eventually leads to cracking and raveling. Asphalt cements from different sources oxidize and age differently. Research suggests that additives to the asphalt cement may slow oxidation, but firm conclusions and guidance are not available yet.

(2) Cold Weather Cracking. As the temperature drops, asphalt cement becomes stiffer and more brittle. With repeated exposure to cold temperatures and in conjunction with other stiffening and aging mechanisms, the asphalt concrete will develop cracking. The SHRP PG grading system of rating asphalt binders that has been adopted by the military specifically tries to select binder characteristics to resist this cracking based on the exposure at the project location.

(3) Fuel Spillage. Fuels, oils, hydraulic fluids, and similar liquids are solvents for the asphalt binder. Hence asphalt concrete should not be used where it will be exposed to such materials. Resin-modified pavement may be used as a surfacing over conventional asphalt concrete to obtain fuel resistance. Coal-tar based fuel resistant sealers have only a temporary life expectancy before cracking reduces their effectiveness.

(4) Stripping. Several mechanisms contribute to moisture damage to asphalt concrete and are generally referred to as stripping. These mechanisms include displacement of the asphalt film coating the aggregate by water, emulsion of the asphalt cement, and pore pressure development. Stripping seems to require water, stripping susceptible aggregates (e.g., siliceous aggregates), and repeated loads. Lime and proprietary liquid antistrip agents can combat the problem. Also, proper aggregate selection, and drainage to reduce the asphalt concrete's exposure to water can help mitigate the dangers of stripping. Fortunately, stripping seems to be relatively uncommon in military airfield pavements. Stripping potential and the need for countermeasures should be addressed in the mix design process.

e. Construction. Production and placement of high-quality asphaltic concrete suitable for military airfields is a demanding and skillful operation. Proper mixing and delivery of the asphaltic concrete, proper placement procedures that prevent segregation, skillful construction of the longitudinal joints, and compaction with equipment of adequate size and at appropriate temperatures are all required to achieve a suitable final product.

5. RECYCLED MATERIALS. Today, portland-cement concrete and asphaltic concrete are routinely recycled as aggregate for subbase and base course material, drainage layers, fill, and as aggregate in new asphaltic and portland-cement concrete. In all recycling operations, maintaining consistency in the recycled product is a challenge. If the recycled product all comes from a single project with consistent properties and constituents, the recycled product will probably have consistent properties and can be incorporated into construction without difficulty. If recycled materials from different projects are intermingled, the recycled product properties are likely to be highly variable, and meeting stringent airfield pavement material requirements with such mixed-source materials is highly problematic. Including debris from building demolition in the recycled product to be used in the airfield pavement structure is not allowed as contamination with undesirable material such as brick or gypsum board is likely and the recycled material from such sources tends to be highly variable. Recently, major problems developed on a project that used recycled portland-cement concrete as fill and as base course in an

environment with abundant sulfates in the soils and water. The recycled concrete suffered from sulfate attack causing heaving of the overlying surfaces. This occurred even though the recycled concrete came from nearby airfield pavements that were built to be sulfate resistant and had existed in the same environment for 30 years without problem. Reliable guidance on use of recycled concrete to be exposed to sulfate exposure is not available, and HQUSACE (CEMP-ET), appropriate Air Force MAJCOM pavements engineer, or Naval Facilities Engineering Service Center should be consulted for guidance if recycled concrete is to be exposed to sulfates. As a general policy, the military encourages use of recycled materials in airfield pavements, but this should not be done at the expense of quality or performance of the final pavement. More extensive guidance and specific limitations used by each service can be found in TM 5-822-14/AFJMAN 32-1019, TI 822-08/AFMAN 32-1131 V8(1)/DM 21.11, and TM 5-822-7/AFM 88-6, Chapter 8, and each service's guide specifications.

Table 9-1
Types of Portland Cement

Type of Cement	Characteristics
I	Ordinary
II	Moderate sulfate resistant
I/II	Meets ASTM C 150 for both Type I and II cements
III	High, early strength
IV	Low heat of hydration
V	Sulfate resistant for more severe sulfate exposure conditions

CHAPTER 10

FLEXIBLE PAVEMENT DESIGN - CBR METHOD

1.REQ UIREMENTS. Flexible pavement designs must provide sufficient compaction of the subgrade and each layer during construction to prevent objectionable settlement under traffic; provide adequate thickness above the subgrade and above each layer together with adequate quality of base and subbase materials to prevent detrimental shear deformation under traffic; provide adequate subsurface drainage control or reduce to acceptable limits the effects of frost heave or permafrost degradation where frost conditions are a factor; and provide a stable, weather-resistant, wear-resistant, waterproof pavement. Attention must also be given to providing adequate friction characteristics.

2.BASI S FOR DESIGN. The thickness design procedures included herein for conventional flexible pavement construction are based on CBR design methods. Design procedures for pavements that include stabilized layers are based on modifications of the conventional procedures utilizing thickness equivalencies developed from research and field experience. Design of flexible pavements using the elastic layer method is covered in Chapter 11.

3.T HICKNESS DESIGN CURVES. Figures 10-1 through 10-32 are design curves for use in determining the required pavement thickness for Army, Navy, Marine Corps, and Air Force airfield pavements. The individual curves indicate the total thickness of pavement required above a soil layer of given strength for a given gross aircraft weight and aircraft passes.

4.THICKNESS DESIGN. The thickness design procedure consists of determining the CBR of the material to be used in a given layer and applying this CBR to design curves (Figures 10-1 through 10-32) to determine the thickness required above the layer to prevent detrimental shear deformation in that layer during traffic. The specific steps to follow are:

a.Det ermine design CBR of subgrade.

b.Det ermine total thickness above subgrade.

(1) For Army and Navy design and Air Force design for a specific aircraft, enter appropriate design curve with subgrade design CBR and follow it downward to the intersection with design gross weight curve, then horizontally to design aircraft passes curve then downward to the required total thickness above the subgrade.

(2) For Air Force standard designs, enter the appropriate design curve with the design subgrade and read the thickness required above the subgrade for a given traffic area.

c.Det ermine design CBR of subbase.

d.Det ermine thickness of material required above the subbase by entering the appropriate design curve with the design subbase CBR and using above procedures to read the required thickness.

e.Det ermine the minimum thickness of surface and base course from Tables 8-3, 8-4, or 8-5. When the minimum thickness of surface and base is less than the thickness of surface and base required above the subbase, the minimum thicknesses would be increased to the actual thickness required.

f. Subtract thickness of the surface and base from total thickness required above subgrade to obtain the required thickness of subbase. If thickness of subbase is less than 150 millimeters (6 inches), consider increasing thickness of base course.

5. ADDITIONAL CONSIDERATIONS FOR THICKNESS DESIGN.

a. CBR Values less than 3. Normally, sites which include large areas of the natural subgrade with CBR values of less than 3 are not considered adequate for airfield construction. However, CBR values of less than 3 are included on the flexible pavement design curves so that thickness requirements for occasional isolated weak areas can be determined.

b. Frost Areas. Pavement sections in frost areas must be designed and constructed with nonfrost-susceptible materials of such depth to prevent destructive frost penetration into underlying susceptible materials. Design for frost areas in accordance with Chapter 20.

c. The thickness of the rapid-draining or open-graded material is determined from AFJMAN 32-1016 and is substituted for an equivalent thickness of base or subbase according to design requirements.

d. Expansive Subgrade. Ensure that moisture condition of expansive subgrade is controlled and that adequate overburden is provided.

e. Limited Subgrade Compaction. Where subgrade compaction must be limited for special conditions, pavement thickness must be increased in conformance with reduced density and CBR of the prepared subgrade.

f. Rainfall and Water Table. In regions where the annual precipitation is less than 380 millimeters (15 inches) and the water table (including perched water table) will be at least 4.6 meters (15 feet) below the finished pavement surface, the potential for subgrade saturation is reduced. Where in-place tests on similar construction in these regions indicate that the water content of the subgrade will not increase above the optimum, the total pavement thickness, as determined by CBR tests on soaked samples, may be reduced by as much as 20 percent. The reduction will be effected in the subbase course having the lowest CBR value. When only limited rainfall records are available, or the annual precipitation is close to the 380-millimeter (15-inch) criterion, careful consideration will be given to the sensitivity of the subgrade to small increases in moisture content before any reduction in thickness is made. For assistance in interpolating limited rainfall data, the USAF Environmental Technical Applications Center, USAFETAC/ECE Scott AFB, IL 62225-5000, may be contacted.

6. DESIGN EXAMPLES.

a. Example 1.

(1) Design an Air Force heavy-load pavement type B traffic area. Design CBR of the lean clay subgrade is 13; the natural in-place density of the clay is 87 percent extending to 3 meters (10 feet). The analysis that follows assumes that subgrade does not require special treatment and frost penetration is not a problem.

(2) Enter Figure 10-19 at a CBR equal to 13, move down to type B traffic area curve, then move horizontally to the required total thickness of pavement above the subgrade, 735 millimeters (29 inches).

(3) The design CBR of the subbase material has been determined to be 30. Enter Figure 10-19 at a CBR equal to 30 and find that the required thickness of base and surface is 405 millimeters (16 inches) for the design aircraft. From Table 8-5, the required minimum thickness of the surface course is 127 millimeters (5 inches) and of the 100 CBR base, 228 millimeters (9 inches). Use a 127-millimeter (5-inch) asphalt concrete (AC) surface and 280 millimeters (11 inches) of 100 CBR base to provide the 405 millimeters (16 inches) required above the 30 CBR subbase.

(4) The required thickness of subbase is 330 millimeters (13 inches), 735 minus 405 millimeters (29 less 16 inches).

(5) From Table 6-2, it is determined that for cohesive subgrade soils, 95 percent compaction is required for 864 millimeters (34 inches) below pavement surface and 90 percent compaction for a 1,320-millimeter (52-inch) depth.

(6) The design section for type B traffic area is illustrated below:

127-mm (5-in.) AC surface
280-mm (11-in.) 100 CBR Base[1]
330-mm (13-in.) 30 CBR Subbase[1]
Top of Subgrade
203-mm (8-in.) 95 percent compaction
457-mm (18-in.) 90 percent compaction

[1] Base and subbase compacted to 100 percent.

(7) Design for drainage layers is illustrated in TM 5-820-2/AFJMAN 32-1016.

b. Example 2.

(1) Design an Army Class III airfield apron (type B traffic area) for a single-wheel tricycle gear aircraft with a gross weight of 11,200 kilograms (24.6 kips) for 50,000 passes plus 10,000 passes of a CH-47 with a gross weight of 22,680 kilograms (50,000 pounds). The runway length is less than 1,220 meters (4,000 feet). Subgrade is a poorly graded sand with a design CBR of 16; in-place density of the subgrade is 90 percent to a depth of 3 meters (10 feet).

(2) From Figure 10-3, the total pavement section required is 240 millimeters (9.5 inches).

(3) From Table 8-3, the minimum required surface and base thicknesses are 50 and 152 millimeters (2 and 6 inches), respectively, for a total of 203 millimeters (8 inches).

(4) Use a 240-millimeter (9.5-inch) pavement section consisting of 50 millimeters (2 inches) of AC surface and 190 millimeters (7.5 inches) of 100 CBR base on subgrade to provide the 241 millimeters (9.5 inches) required above the subgrade.

(5) Determine the compaction requirements from Table 6-5.

(6) The design section is as follows:

50-mm (2-in.) AC surface

190-mm (7.5-in.) Base[1]

Top of Subgrade

152-mm (6.0-in.) 95 percent compaction

[1] Base is compacted to 100 percent.

Since the existing subgrade has an in-place density of 90 percent, the compaction of the 152-millimeter (6.0-inch) upper layer of the subgrade may be achieved by moistening and compacting in place.

c. Example 3.

(1) Design a secondary traffic area pavement for a Navy single-wheel aircraft with a gross weight of 31,750 kilograms (70 kips) and 2.75-MPa (400-psi) tire pressure for 300,000 passes. The subgrade consists of a silty sand (SM) with a design CBR of 6 and an in-place density of 86 percent. Subbase is a sand-shell mixture with a CBR rating of 30. Base is also a sand-shell mixture with a CBR of 80.

(2) From Figure 10-8 (2.75-MPa (400-psi) tire pressure) for a design subgrade CBR of 6 and a gross weight of 31,750 kilograms (70 kips) and 300,000 passes, the pavement section required is 635 millimeters (25 inches). The thickness of base and surface required above the 30 CBR subbase is 228 millimeters (9 inches).

(3) From Table 8-4, the minimum thickness requirements are 102 millimeters (4 inches) of bituminous surface and 203 millimeters (8 inches) of base. Use 330-millimeter (13-inch) subbase.

(4) Determine the compaction requirements from Table 6-6. This table would require the top 102 millimeters (4 inches) of the subgrade to be compacted to 90 percent of maximum density. However, there is an overriding requirement that the top 152 millimeters (6 inches) of the subgrade be compacted to 95 percent of maximum density.

(5) The design section is as follows:

102-mm (4-in.) AC surface

203-mm (8-in.) Base[1]

330-mm (13-in.) Subbase[1]

Top of Subgrade

152-mm (6-in.) 95 percent compaction

In situ density of 86 percent is satisfactory

[1] Base and subbase compacted to 100 percent maximum density.

d.Example 4.

(1) The design curves may be used to design an airfield pavement for a mix of aircraft traffic. This example will demonstrate the procedure for an Air Force airfield using the aircraft, gross weights, and pass levels shown in Table 10-1. The subgrade has a CBR of 6 and the traffic area is type B.

(2) The procedure is demonstrated as follows using Table 10-1 as an example.

(a) Column 1. List aircraft to be considered in design.

(b) Column 2. List pavement design curve figure no. for respective aircraft.

(c) Column 3. List gross weight of aircraft at which they will operate on pavement.

(d) Column 4. List number of passes anticipated at indicated gross weight.

(e) Column 5. Select the thickness required for each aircraft at the pass level and gross weight shown from the appropriate design curve (Figures 10-1 to 10-32).

(f) Column 6. Determine the pass level permissible for each aircraft for the greatest thickness in column 4. The C-141 and the F-15 both require 635 millimeters (25 inches) of total thickness. In this case, the larger aircraft would normally be selected for comparisons, although it may be necessary to check design in terms of both aircraft. The C-141 is therefore selected for comparisons. The design curves are entered with the subgrade CBR of 6, then move downward to intersection with the aircraft gross weight curve, then horizontally to intersection with the 635-millimeter (25-inch) thickness line. The pass level occurring at this intersection should be recorded in column 6.

(g) Column 7. Divide the passes in column 6 by the passes permissible at 635 millimeters (25 inches) for the C-141 (1,000) and enter in column 7. Column 7 gives the equivalent passes on a 635-millimeter (25-inch) pavement by each aircraft in terms of one pass of the C-141. That is, one pass of the C-141 is equivalent to 1.2 passes of the B-52 or is equivalent to 7.5 passes of the P-3.

(h) Column 8. Divide the number of passes in column 4 by the equivalencies in column 6 to determine the design passes in terms of the C-141 and record in column 8. The total equivalent passes of all aircraft in terms of the C-141 is 2,910. Figure 12-31 is entered with the subgrade CBR of 6, the C-141 gross weight of 145,150 kilograms (320 kips,) and the equivalent pass level of 2,910 to select the required thickness of pavement of 711 millimeters (28 inches). The thickness of the individual layers will then be determined in the conventional manner using the minimum thicknesses of pavement and base for the C-141.

7.ST ABILIZED PAVEMENT SECTIONS. Stabilized layers may be incorporated in the pavement sections to make use of locally available materials which cannot otherwise meet the criteria for base course or subbase course. The major factor in deciding whether or not to use a stabilized layer is usually economic. Additional factors include moderate reduction of the overall pavement section and increased design options. The strength and durability of the stabilized courses must be in accordance with requirements of Chapter 9. For Air Force and Army, see requirements in TM 5-822-14/ AFJMAN 32-1019. For Air Force design, stabilized subbase may not be used without a stabilized base unless the base course has adequate drainage. (Approval from Air Force major command is required when use of stabilized components is contemplated.)

Table 10-1
Example Design Using Mixed Traffic

a. Navy and Marine Corps Design.

(1) Thickness reduction factors. Stabilized base course and subbase course materials meeting the requirements for strength and durability in Chapter 8 may be substituted for unstabilized materials. Procedures for pavement design with stabilized layers are as follows:

(a) Design a conventional pavement section as previously described.

(b) Convert the base or subbase courses into equivalent thicknesses of stabilized materials by use of the equivalency factors shown in Chapter 9.

(c) Adjust the thicknesses of stabilized base and subbase courses so that the minimum base course thickness requirements are met.

(2) Design examples. Design a primary traffic area pavement section for a C-5A aircraft with a gross weight of 385,560 kilograms (850 kips) at 100,000 passes. Design CBR of subgrade is 5; CBR of unstabilized subbase is 20; CBR of unstabilized base is 100.

(a) Alternative design 1, Conventional Section. From Figure 10-18 the required conventional pavement section is 1,093 millimeters (43 inches) for a subgrade CBR of 5, and the required cover over the subbase is 355 millimeters (14 inches). The required minimum thickness of base and surface from Table 8-3 is 203 millimeters (8 inches) of aggregate base course and 102 millimeters (4 inches) of AC surface. The conventional section is as follows:

Conventional Flexible Pavement Section, mm (in.)	Layer Description
102 (4)	Bituminous surface
254 (10)	Aggregate base course
737 (29)	Aggregate subbase course
1,093 (43) Total thickness	

(b) Alternative design 2. A 102-millimeter (4-inch) surface over cement stabilized base with unbound aggregate subbase is required.

Conventional Thickness, mm (in.)		Stabilized Section Thickness, mm (in.)	
Surface	102 (4)	Surface	102 (4)
Base	254 (10)	CT base 254/1.5 (10/1.5) =	169 (6.7)
Subbase	737 (29)	Subbase	737 (29)
Total	1,093 (43)	Total	1,008 (39.7)

CT = Cement treated

(c) Alternative design 3. A 102-millimeter (4-inch) surface over unbound aggregate base with lime stabilized subbase is required.

Conventional Thickness, mm (in.)		Tentative Stabilized Section Thickness, mm (in.)	
Surface	102 (4)	Surface	102 (4)
Base	254 (10)	Base	254 (10)
Subbase	737 (29)	Lime stabilized subbase 737/1.2 (29/1.2) =	614 (24)
Total	1,093 (43)	Total	990 (38)

(d) Alternative design 4. Bituminous base and lime-stabilized subbase are required.

Conventional Thickness, mm (in.)		Tentative Stabilized Section Thickness, mm (in.)	
Surface	102 (4)	Surface	102 (4)
Base	254 (10)	Bituminous base 254/1.5 (10/1.5) =	169 (6.7)
Subbase	737 (29)	Lime stabilized subbase 737/1.2 (29/1.2) =	614 (24)
Total	1,093 (43)	Total	882 (34.7)

b. Army and Air Force Design.

(1) Equivalency factors. The use of stabilized soil layers within a flexible pavement provides the opportunity to reduce the overall thickness of pavement structure required to support a given load. An equivalency factor represents the number of millimeters (inches) of conventional base or subbase that can be replaced by 25 millimeters (1 inch) of stabilized material. Equivalency factors will be determined for Army and Air Force designs from Table 10-2 and for Navy and Marine Corps designs from Table 10-3.

(2) Design. The design of a pavement having stabilized soil layers is accomplished through the application of the equivalency factors to the individual unbound soil of a pavement. A conventional flexible pavement is first designed, and then the base and subbase are converted to an equivalent thickness of stabilized soil. This conversion is made by dividing the thickness of unbound material by the equivalency factor for Army and Air Force airfields. For example, assume that a conventional pavement has been designed consisting of 102 millimeters (4 inches) of AC, 254 millimeters (10 inches) of base, and 381 millimeters (15 inches) of subbase for a total thickness above the subgrade of 737 millimeters (29 inches). It is desired to replace the base and subbase with cement-stabilized GW material having an unconfined compressive strength of 6.27 MPa (910 psi). The equivalency factor from Table 9-1 for the base-course layer is 1.15; therefore, the thickness of stabilized GW to replace 254 millimeters (10 inches) of base course is 254/1.15 (10/1.15) or 220 millimeters (8.7 inches). The equivalency factor for the subbase layer is 2.3, and the thickness of stabilized GW to replace the 381-millimeter (15-inch) subbase is 381/2.3 (15/2.3) or 165 millimeters (6.5 inches). The thickness of stabilized GW needed to replace the base and subbase would be 406 millimeters (16 inches).

c. All-Bituminous Pavement Section. Alternate procedures have been developed for design of Army and Air Force airfield pavements composed entirely of AC. These procedures are based on layered elastic theory and incorporate the concept of limiting tensile strain in the AC and vertical compressive strain in the subgrade. The procedures are applicable for trial optional designs with the approval of TSMCX, for Army airfields and the appropriate Major Command for Air Force airfields. These design procedures are contained in Chapter 11.

8. SPECIAL AREAS. Areas such as overrun areas, airfield and heliport shoulders, blast areas, and reduced load areas require special treatment as described in the following text for the various services.

a. Air Force Bases.

(1) Overrun areas. Overrun areas will be paved for the full width of the runway exclusive of shoulders, and for a length of 305 meters (1,000 feet) on each end of heavy, modified heavy, medium, light, and auxiliary runways and for 90 meters (300 feet) on each end of an assault landing zone runway. Surface the overrun areas with double-bituminous surface treatment except for the first 45 meters (150 feet) abutting the runway pavement end which will have a wearing surface of 51 millimeters (2 inches) of dense graded AC. That portion of the overrun used to certify barriers or that must support snow removal equipment may also be surfaced with dense graded AC. Design the pavement thickness in accordance with Figures 10-17 to 10-32 herein, except that the minimum base-course thickness will be 152 millimeters (6 inches). The strength of the assault overrun shall be equal to the strength of the runway. Minimum base-course CBR values are as follows:

Table 10-2
Equivalency Factors for Army and Air Force Pavements

Material	Equivalency Factors: Base	Equivalency Factors: Subbase
Asphalt-Stabilized		
All-Bituminous Concrete	1.15	2.30
GW, GP, GM, GC	1.00	2.00
SW, SP, SM, SC	--[1]	1.50
Cement-Stabilized

Unbound Aggregate	–[1]	1.00

[1] Not used as base course.
[2] For Air Force Bases, cement is limited to 4 percent by weight or less.

Table 10-3
Equivalency Factors for Navy and Marine Corps Pavements

Stabilized Material	Equivalency Factors
1 mm (in.) of lime-stabilized subbase	1.2 mm (in.) of unstabilized subbase course
1 mm (in.) of cement-stabilized subbase	1.2 mm (in.) of unstabilized subbase course
1 mm (in.) of cement-stabilized base	1.5 mm (in.) of unstabilized base course
1 mm (in.) of bituminous base	1.5 mm (in.) of unstabilized base course

Design Loading	Minimum Base-Course CBR for Overruns
Heavy-load pavement	80
Modified heavy-load pavement	80
Medium-load pavement	80
Light-load pavement	50
Assault landing zone pavement	50
Auxiliary pavement	50

(2) Paved shoulders. Paved shoulders will be provided adjacent to runways, taxiways, aprons, and pads where authorized by AFM 86-2. The remaining shoulder width will be constructed of existing soils, select soils, or stabilized soils with a turf cover. Design the paved shoulders in accordance with Table 3-1, Table 8-4, and Figure 10-27.

b.Army Airfields.

(1) Paved shoulders. Paved shoulders should be provided for airfields and heliport/helipad facilities as designated in EI 02C013/AFJMAN 32-1013/NAVFAC P-971. Design paved shoulders in accordance with Chapters 2 and Figure 10-27. Use a 50-millimeter (2-inch) dense graded AC wearing surface on a minimum 150-millimeter (6-inch) base consisting of 50 CBR material or better. The remaining shoulder width will be constructed of existing compacted soils, select soils, or stabilized soils with a vegetative cover or liquid palliative to provide dust and erosion control against jet blast and rotor wash.

(2) Paved overruns. Paved overruns should be provided for runways and landing lanes in accordance with EI 02C013/AFMAN 32-1013/NAVFAC P-971. Design the pave portion of overruns for 75 percent of the gross weight of the design aircraft and 1 percent of the design pass levels. The paved overrun should also be checked for adequacy of supporting crash rescue vehicles. Use a 50-millimeter (2-inch) dense graded AC wearing surface on a minimum 150-millimeter (6-inch) base consisting of 50 CBR material or better. The remaining overrun area will be constructed of double-bituminous surface treatment on a 100-millimeter (4-inch) base course of 40 CBR material or better.

c.Navy and Marine Corps Airfields.

(1) Overrun areas. Pave the overrun areas for a width of 61 meters (200 feet) or the width of the runway if less than 61 meters (200 feet), centered on the runway centerline and for a length of 305 meters (1,000 feet), where feasible. Surface the overrun areas with an AC surface course. Design the pavement thickness for 75 percent of the gross weight of the design aircraft at 200 passes, except that a minimum 152-millimeter (6-inch) base course of 80 CBR or better will be provided.

(2) Blast protection areas. Design the pavement thickness of the blast protection areas for 200 passes at 75 percent of the gross weight of the design aircraft. Normally, these areas are constructed of portland cement concrete for Navy and Marine Corps airfields; where operational experience has shown asphalt surfacing to be satisfactory, use a minimum 76-millimeter (3-inch)

AC surface over 152 millimeters (6 inches) of 80 CBR base. Blast protection pavement design should be checked for adequacy for crash rescue vehicles.

(3) Shoulders.

(a) Fixed-wing aircraft. Pave the first 3 meters (10 feet) of runway shoulders. Design the pavement thickness for 75 percent of the gross weight of the design aircraft at 200 passes. Surface with 50 millimeters (2 inches) of AC on a minimum 152-millimeter (6-inch) base of 80 CBR. Provide the outer 43 meters (140 feet) of runway shoulders and all taxiway shoulders with dust and erosion control using vegetative cover, liquid palliative, such as asphalt, or a combination of methods.

(b) Rotary-wing aircraft. Pave the first 7.5 meters (25 feet) of shoulder adjacent to helicopter pads, runways, and taxiways with 50 millimeters (2 inches) of AC on a minimum 152-millimeter (6-inch) base course of 60 CBR. Provide the outer 15 meters (50 feet) of shoulder with a liquid palliative or vegetative cover, or a combination of methods.

CHAPTER 11

LAYER ELASTIC DESIGN OF FLEXIBLE PAVEMENTS

1. DESIGN PRINCIPLES. The structural deterioration of a flexible pavement caused by traffic is normally evidenced by cracking of the bituminous surface course and development of ruts in the wheel paths. The design procedure handles these two modes of structural deterioration through limiting values of the strain at the bottom of the bituminous concrete and at the top of the subgrade. Use of a cumulative damage concept permits the rational handling of variations in the bituminous concrete properties and subgrade strength caused by cyclic climatic conditions. The strains used for entering the criteria are computed by the use of Burmister's solution for multilayered elastic continua. The solution of Burmister's equations for most pavement systems will require the use of computer programs and the characterization of the pavement materials by the elastic constants of the modulus of elasticity and Poisson's ratio.

2. FLEXIBLE PAVEMENT RESPONSE MODEL. The computer code recommended for computing the pavement response is the JULEA code. When the code is used, the following assumptions are made.

a. The pavement is a multilayered structure, and each layer is represented by a modulus of elasticity and Poisson's ratio.

b. The interface between layers is continuous; i.e., the friction resistance between layers is greater than the developed shear force.

c. The bottom layer is of infinite thickness.

d. All loads are static, circular, and uniform over the contact area.

3. DESIGN DATA.

a. Climatic Factors. In the design system, two climatic factors, temperature and moisture, are considered to influence the structural behavior of the pavement. Temperature influences the stiffness and fatigue of bituminous material and is the major factor in frost penetration. Moisture conditions influence the stiffness and strength of the base course, subbase course, and subgrade.

(1) Pavement temperature. The design procedure requires the determination of a design pavement temperature for consideration of vertical compressive strain at the top of subgrade and horizontal tensile strain at the bottom of cement- or lime-stabilized layers and a different design pavement temperature for consideration of the fatigue damage of the bituminous concrete surface. In either case, a design air temperature from Figure 11-1 is used to determine the design pavement temperature. Temperature data for computing the design air temperatures are available from the National Oceanic and Atmospheric Administration (NOAA) "Local Climatological Data Annual Summary with Comparative Data." These data may be obtained by requesting it from personnel at NOAA's web site: *http://www.noaa.gov/.* With respect to subgrade strain and fatigue of cement- and lime-stabilized base or subbase courses, the design air temperature is the average of the average daily mean temperature and the average daily maximum temperature during the traffic period. For consideration of the fatigue damage of bituminous materials, the design air temperature is the average daily mean temperature. Thus, for each traffic period, two design air temperatures are determined. Normally,

monthly traffic periods should be adequate. For design purposes, it is best to use the long-term averages such as the 30-year averages given in the annual summary. The determination of the design pavement temperatures for 254-millimeter (10-inch) bituminous pavement can be demonstrated by considering the climatological data for Jackson, MS. For the month of August, the average daily mean temperature is 27.5 degrees Celsius (81.5 degrees Fahrenheit) and the average daily maximum is 33.6 degrees Celsius (92.5 degrees Fahrenheit); therefore, the design air temperature for consideration of the subgrade strain is 30.5 degrees Celsius (87 degrees Fahrenheit), and the design pavement temperature (determined from Figure 11-1) would be approximately 37.8 degrees Celsius (100 degrees Fahrenheit). For consideration of bituminous fatigue, the design air temperature for August in Jackson is 27.5 degrees Celsius (81.5 degrees Fahrenheit), resulting in a design pavement temperature of approximately 33.3 degrees Celsius (92 degrees Fahrenheit). These design pavement temperatures are determined for each of the traffic periods. Temperature data for Jackson (from "Local Climatological Data Annual Summary with Comparative Data, Jackson, Mississippi") are shown in Table 11-1.

Table 11-1
Temperature Data for Jackson, Mississippi

	Temperature, degrees C (degrees F)	
Month	Average Daily Maximum	Average Daily Mean
January	14.7 (58.4)	8.4 (47.1)
February	16.5 (61.7)	9.9 (49.8)
March	20.4 (68.7)	13.4 (56.1)
April	25.7 (78.2)	18.7 (65.7)
May	29.4 (85.0)	22.6 (72.7)
June	32.8 (91.0)	26.3 (79.4)
July	33.7 (92.7)	27.6 (81.7)
August	33.6 (92.5)	27.5 (81.5)
September	31.1 (88.0)	24.4 (76.0)
October	26.7 (80.1)	18.8 (65.8)
November	20.3 (68.5)	12.9 (55.3)
December	15.8 (60.5)	9.4 (48.9)

(2) Thaw periods. The effects of temperature on subgrade materials are considered only with regard to frost penetration. The basic requirement of frost protection is given in Chapter 20. If the pavement is to be designed for a weakened subgrade condition, the design must consider a period of time during which the subgrade will be in a weakened condition.

(3) Subgrade moisture content for material characterization. In most design situations, pavement design will be predicated on the assumption that the moisture content of the subgrade will approach saturation. If sufficient data are available that indicate the subgrade will not reach saturation, then the design may be based on a lower moisture content. Sufficient data for basing the design on a

moisture content lower than saturation would normally consist of field moisture content measurements under similar pavements located in the area. These measurements should be made during the most critical period of the year when the water table is at its highest elevation. Extreme caution should be exercised when the design is based on other than the saturated condition.

b. Traffic Data. The traffic parameters to be considered are the type of design aircraft, aircraft loading, traffic volume, and traffic area.

(1) Traffic volume. The design traffic volume is expressed in terms of total operations of the design aircraft expected during the life of the pavement. This traffic volume must be converted to a number of expected strain repetitions. In converting operations to strain repetitions, the concept of effective gear print is introduced. The effective gear print is the width of pavement that sustains an effective strain repetition at a given depth in the pavement. The effective gear print is a function of the number of tires in a transverse line, the transverse spacing, the width of the contact area, and the effective thickness of pavement above the location of strain. The effective thickness of the pavement is the sum of the thickness of unbound material plus twice the thickness of bound material where a bound material is an asphalt concrete or stabilized layer. Thus, for a pavement having 76 millimeters (3 inches) of asphalt and 381 millimeters (15 inches) of unbound gravel, the effective thickness with reference to the strain at the top of the subgrade would be 381+(2×76) (15+(2×3)), or 533 millimeters (21 inches), and with respect to the strain at the bottom of the asphalt, the effective thickness would be 2×76 (2×3), or 152 millimeters (6 inches). With the determination of the effective thickness, the gear print is computed as illustrated in Figures 11-2 and 11-3. If the gear is composed of tracking tires such as tandem gear, then the number of strain repetitions may be somewhat greater than if the gear were not tandem. When the tracking tires are located far enough apart, two distinct strain pulses will occur and the multiplication factor for the tandem gear is 2. When the tires are sufficiently close, the strain pulses merge into a single pulse and the multiplication factor is 1. The computation of F is shown in Figure 11-4. In the figure, B is the spacing between tandem tires in the gear; t_e is the effective pavement thickness; and T_w is the length of the ellipse that is formed by the tire imprint. When t_e is less than $B - T_w$, F is 2. When t_e is greater than twice the difference between B and T_w, F is 1. For values of t_e between the two conditions, F is computed based on the equation:

$$F = \frac{3 \bullet (B - T_w) - t_e}{B - T_w} \qquad (11\text{-}1)$$

(a) The concept for conversion of aircraft operations to effective strain repetitions involves assuming that traffic distribution on the pavement can be represented by a normal distribution. For traffic on taxiways and runway ends (first 305 meters (1,000 feet)), the distribution has a wander width of approximately 178 millimeters (70 inches), and traffic on runway interiors has a wander width of approximately 355 millimeters (140 inches). (Note that wander width is defined as the width that contains 75 percent of the applied traffic.) From the normal distribution, the fraction of traffic for which the effective gear print will encompass a given point in the pavement can be computed. This fraction times F gives the number or fraction of the effective strain repetitions at a point in the pavement for each aircraft operation.

(b) The number of effective strain repetitions the pavement sustains at a point for every aircraft operation is the pass-to-strain conversion percentage. For an effective thickness of 0.00 millimeters (0 inches), the percentage is the inverse of the pass-to-coverage ratio multiplied by 100.

The procedure for computing the pass-to-strain conversion percentage has been computerized, and the factors can easily be computed for single, twin, single-tandem, twin-twin, twin-tandem, or other gears.

(c) The distribution of the pass-to-strain conversion percentages as a function of point location and effective thicknesses is given in Appendix E. These pass-to-strain conversion percentages can be used to convert, for any point location, the number of aircraft operations to effective strain repetitions.

(2) Aircraft loading. The aircraft loading and gear characteristics are used in the response model for computing the magnitude of strain. The information needed includes the number of tires, tire spacing, load per tire, and contact pressure. The radius of the loaded area is computed based on the assumption of a uniformly loaded circular area, i.e.,

$$r = \sqrt{\frac{L}{\pi p}} \tag{11-2}$$

where

r = radius of loaded area, millimeters (inches)

L = load per tire, Newtons (pounds)

p = contact pressure, MPa (psi)

Note: units should be consistent with units of the section parameters.

In principle, all main tires should be used in computing the strain, but usually only the tires on one landing gear need to be used. The distance between gears for common aircraft is sufficiently great to prevent interaction between gears. Within a main gear, some searching for the maximum strain may be needed. For most cases the maximum strain will occur under one of the tires, but for closely spaced tires or strains at a great depth, the maximum may move toward the center of the tire group.

(3) Traffic grouping. The traffic is grouped so that within each group each individual pass of an aircraft will cause damage similar a pass of any other aircraft in the group. That is, the pattern of strain of every pass of the group would be almost the same; then the value of the allowable number of passes (N) would be the same. For this to be true, the loading characteristics for aircraft within a group must be similar, and the single set of material properties must be applicable for all passes within the group. Grouping reduces considerably the design effort, and it is advantageous to reduce traffic to as few groups as possible. Grouping of the aircraft by similar pass-to-strain conversion percents has already been accomplished in Appendix E. Additional subgrouping would be necessary to account for other differences, such as load magnitude and tire pressure. Also, other groupings may be necessary to account for changes in material properties such as changes in subgrade modulus caused by thaw and changes in asphalt modulus caused by temperature. For pavements that are relatively unaffected by changes in temperature and are designed based on a single critical aircraft, it may be possible to reduce the aircraft operations to a single group. In this case, the design procedure simplifies to determining allowable strains for the design aircraft and to adjusting the pavement thicknesses to obtain the

allowable strain. Where the grouping cannot be reduced to a single group, then the concept of the cumulative damage must be used in the design process.

4. MATERIAL CHARACTERIZATION. Characterization of the pavement materials requires the quantification of the material stiffness as defined by the resilient modulus of elasticity and Poisson's ratio and, for selected pavement components, a fatigue strength as defined by a failure criterion. Inasmuch as possible, repeated load laboratory tests designed to simulate aircraft loading are used to determine the resilient stiffness of the materials. For some materials, such as unbound granular bases and subbases, an empirically based procedure was judged a better approach for obtaining usable material parameters. Failure criteria have been provided; thus, fatigue testing will not be necessary. In general, the use of layered elastic design procedures does not negate the material requirements set forth in Chapters 7, 8, and 9. In particular, the gradation, strength, and durability requirements as stated must be maintained.

a. Modulus of Elasticity.

(1) Bituminous mixtures. The term "bituminous mixtures" refers to a compacted mixture of bitumen and aggregate designed in accordance with standard practice. The modulus for these materials is determined by use of the repetitive triaxial test. The procedure for preparation of the sample is given in Appendix F with the procedure for the conduct of the repetitive triaxial test given in Appendix G.

(a) The stiffness of the bituminous mixtures will be greatly affected by both the rate of loading and by temperature. For runway design, a loading rate of 10 hertz is recommended. For taxiway and apron design, a loading rate of 2 hertz is suggested. These loading rates are appropriate for aircraft speeds of over 45 meters/second (100 miles/hour) on runways and less than 9 meters/second (20 miles/hour) on taxiways and aprons. Specimens should be tested at temperatures of 44, 21, and 38 degrees Celsius (40, 70, and 100 degrees Fahrenheit) so that a modulus-temperature relationship can be established. If temperature data indicate greater extremes than 4.4 and 38 degrees Celsius (40 and 100 degrees Fahrenheit), tests should be conducted at these extreme ranges if possible. The modulus value to be used for each strain computation would be the value applicable for the specific pavement temperature determined from the climatic data.

(b) An indirect method of obtaining an estimated modulus value for bituminous concrete is presented in detail in Appendix H. Use of this method requires that the ring-and-ball softening point and the penetration of the bitumen as well as the volume concentration of the aggregate and percent air voids of the compacted mixture be determined.

(2) Unbound granular base- and subbase-course materials. The terms "unbound granular base-course material" and "unbound granular subbase-course material" as used herein refer to materials meeting grading requirements and other requirements for base and subbase for airfield pavements, respectively. These materials are characterized by use of a chart in which the modulus is a function of the underlying layer and the layer thickness. The chart and the procedure for use of the chart are given in Appendix I.

(3) Stabilized material. The term "stabilized material" as used herein refers to soil treated with such agents as bitumen, portland cement, slaked or hydrated lime, and fly ash or a combination of such agents to obtain a substantial increase in the strength of the material. Stabilization with portland cement, lime, fly ash, or other agent that causes a chemical cementation to occur shall be referred to as chemical stabilization. Chemically treated soils having unconfined compressive strengths greater than the minimum strength specified for subbases are considered to be stabilized materials and should be tested

in accordance with the methods specified for stabilized materials. Chemically treated soils having unconfined compressive strengths less than that specified for subbases are considered to be modified subgrade soils and should be tested under the provisions for subgrade soils. Most likely this will result in using the maximum allowable subgrade modulus. Bituminous-stabilized materials should be characterized in the same manner as bituminous concrete. Stabilized materials other than bituminous-stabilized should be characterized using flexural beam tests or cracked-section criteria. Flexural modulus values determined directly from laboratory tests can be used when the effect of cracking is not significant and the computed strain based on this modulus does not exceed the allowable strain for the material being used.

(a) The general approach in the flexural beam test is to subject the specimen to repeated loadings at third points, measure the maximum deflection at the center of the beam (i.e., at the midpoint of the neutral axis), and calculate the values for the flexural modulus based on the theory of a simply supported beam. A correlation factor for stress is applied.

(b) Procedures for preparing specimens of and conducting flexural beam tests on chemically stabilized soils are presented in detail in Appendix J.

(c) The stabilized material for the base and subbase must meet the strength and durability requirement of TM 5-822-14/AFJMAN 32-1019. The strength requirements are as summarized in Chapter 9.

(4) Subgrade soils. The modulus of the subgrade is determined through the use of the repetitive triaxial test. For most subgrade soils, the modulus is greatly affected by changes in moisture content and state of stress. As a result of normal moisture migration, water table fluctuation, and other factors, the moisture content of the subgrade soil can increase and approach saturation with only a slight change in density. Since the strength and stiffness of fine-grained materials are particularly affected by such an increase in moisture content, these soils should be tested in the near-saturation state. Two methods are available to obtain a specimen with this moisture content: the soil can be molded at optimum moisture content and subsequently saturated or molded at the higher moisture content using static compaction methods. Evidence exists that the resilient properties of both specimen types are similar. It is not apparent whether this concept is valid for materials compacted at the higher densities; therefore, for the test procedures presented herein, back-pressure saturation of samples compacted at optimum is recommended for developing high moisture contents in test specimens.

(a) For cohesive subgrades, the resilient modulus of the subgrade will normally decrease with an increase in deviator stress, and therefore, the modulus is determined as a function of deviator stress. The modulus of granular subgrades will be a function of the first invariant. Procedures for specimen preparation, testing, and interpretation of test results for cohesive and granular subgrades are presented in Appendix K. For the layered elastic theory design procedure, however, the maximum allowable modulus for a subgrade soil should be restricted to 207 MPa (30,000 psi).

(b) In areas where the subgrade is to be subjected to freeze-thaw cycles, the subgrade modulus must be determined during the thaw-weakened state. Testing soils subject to freeze-thaw requires specialized test apparatus and procedures. Where commercial laboratories are not available, the U.S. Army Cold Regions Research and Engineering Laboratory (CRREL), 72 Lyme Road, Hanover, NH 03755, can conduct tests to characterize subgrade soils subjected to freeze-thaw.

(c) For some design situations, estimating the resilient modulus of the subgrade (M_R) based on available information may be necessary when conducting the repetitive load triaxial tests. An estimate of the resilient modulus in megapascals (pounds per square inch) can be made from the relationship of $M_R = 10.3 \times CBR$ ($M_R = 1{,}500 \times CBR$). The relationship does provide a method for checking the reasonableness of the laboratory results.

b. Poisson's Ratio. Because of the complexity of laboratory procedures involved in the direct determination of Poisson's ratio for pavement materials and because of the relatively minor influence on pavement design of this parameter when compared with other parameters, use of values commonly recognized as acceptable is recommended. These values for the four classes of pavement materials considered herein are presented in Table 11-2.

Table 11-2
Typical Poisson's Ratios for Four Classes of Pavement Materials

Pavement Materials	Poisson's Ratio v
Bituminous concrete	0.5 for E < 3,450 MPa (500,000 psi) 0.3 for E > 3,450 MPa (500,000 psi)
Unbound granular base- or subbase-course	0.3
Chemically stabilized base- or subbase-course	0.2
Subgrade	
Cohesive subgrade	0.4
Cohesionless subgrade	0.3

Note: E = elastic modulus of bituminous concrete (psi)

5. SUBGRADE EVALUATION. Chapter 6 provides for the evaluation of the subgrade for design by the CBR design procedure and also provides the background for evaluation of the subgrade modulus. After the establishment of the grade line, the pavement will be grouped as to soil type, strength, expected moisture content, compaction requirements, and other characteristics. For each soil group, a minimum of six resilient modulus tests should be conducted and the design modulus determined according to procedures given in Appendix K. The design modulus would be the average of the moduli obtained from the testing.

6. DESIGN CRITERIA. The damage factor (DF) is defined as $DF = \frac{n}{N}$, where n is the number of effective strain repetitions and N is the number of allowable strain repetitions. The cumulative damage factor is the sum of the damage factors for all aircraft. The value of n is determined from the number of aircraft operations. The value of N must be determined from the computed strain and the appropriate criteria. Basically, there are three criteria to determine N. These are the allowable number of repetitions as a function of the vertical strain at the top of the subgrade, the allowable number of repetitions as a function of the horizontal strain at the bottom of the bituminous concrete, and the allowable number of repetitions as a function of the horizontal strain at the bottom of a chemically stabilized base or chemically stabilized subbase. It should be noted that there is no strain criterion for unbound base. In the development of the procedure, it has been assumed that an unbound base and subbase that meets the specifications for quality will perform satisfactorily.

a. Subgrade Strain Criteria. The subgrade strain criteria were developed from the analysis of field test data and present the allowable number of strain repetitions as a function of strain magnitude. The data analysis indicated that the relationship between allowable repetitions and strain magnitude is slightly different for subgrades having different resilient moduli. The criteria are presented in graphic form in Figure 11-5 and can be approximated using the following equation:

$$allowable\ repetitions = 10{,}000 \cdot \left(\frac{A}{S_s}\right)^B \tag{11-3}$$

where

A = 0.000247 + 0.000245 log M_R

M_R = resilient modulus of the subgrade, psi

S_s = vertical strain at the top of the subgrade (in./in.)

B = 0.0658 $M_R^{0.559}$

b. Asphalt Strain Criteria.

(1) The primary means recommended for determining values of limiting horizontal tensile strain for bituminous concrete is the use of the repetitive load flexural beam tests on laboratory-prepared specimens. Procedures for the tests are presented in detail in Appendix L. Several tests are run at different stress levels and different sample temperatures such that the number of load repetitions to fracture can be represented as a function of temperature and initial stress. The initial stress is converted to initial strain to yield criteria based on the tensile strain of the bituminous concrete.

(2) An alternate method for determining values of limiting tensile strain for bituminous concrete is the use of the provisional laboratory fatigue data employed by Heukelom and Klomp. These data are presented in Appendix L in the form of a relationship between stress, strain, load repetitions, and elastic moduli of bituminous concrete. The allowable strain repetitions may be approximated by the equation

$$Allowable\ strain\ repetitions = 10^X \tag{11-4}$$

where

X = 2.68 - 5.0 log S_A - 2.665 log E

S_A = tensile strain of asphalt (in/in)

E = elastic modulus of the bituminous concrete (psi)

c. Chemically Stabilized Layers. For cement- and lime-stabilized materials, the criteria are to be developed using test procedures outlined in Appendix B. When flexural fatigue tests are not possible, then a preestablished relationship as shown in Figure 11-6 should be used.

d. Computer Programs for Computing Cumulative Damage Factor. Two computer codes are used for computing the subgrade and asphalt damage factors based on Equations 11-3 and 11-4. Both programs require material strains obtained by the running of the layered elastic computer programs. The listings of the programs contain an explanation of the input and instructions on the use of the programs. An example illustrating the use of the programs is given in this chapter in the paragraph entitled Example Design for Conventional Flexible Pavement.

7. CONVENTIONAL FLEXIBLE PAVEMENT DESIGN. Conventional flexible pavements consist of relatively thick aggregate layers with a 75- to 125-millimeter (3- to 5-inch) wearing course of bituminous concrete. In this type of pavement, the bituminous concrete layer is a minor structural element of the pavement, and thus, the temperature effects on the stiffness properties of the bituminous concrete may be neglected. Also, it must be assumed that if the minimum thickness of bituminous concrete is used as specified in Tables 8-2 through 8-5, then fatigue cracking will not be considered. Thus, for a conventional pavement, the design problem is one of determining the thickness of pavement required to protect the subgrade. The steps for determining the required thickness for nonfrost areas are:

a. The subgrade resilient modulus is determined based on the soil exploration, climatic conditions, and laboratory testing. The resilient modulus of the bituminous concrete is assumed to be 1,380 MPa (200,000 psi).

b. The traffic data determine the design loadings and repetitions of strain.

c. An initial pavement section is determined from the minimum thickness requirements as determined using Chapter 10 or by estimation. The resilient modulus of the base and of the subbase is determined based on the chart and the initial thickness.

d. The vertical strain at the top of the subgrade is computed for each aircraft being considered in the design.

e. The number of allowable strain repetitions for each computed strain is determined from the subgrade strain criteria.

f. The value of n/N is computed for each aircraft and summed to obtain the cumulative damage factor.

g. The assumed thicknesses are adjusted to make the value of the cumulative damage factor approach 1.0. This may be accomplished by first making the computations for three thicknesses and developing a plot of thickness versus damage factor. From this plot the thickness that gives a damage factor of 1.0 may be selected.

8. FROST CONDITIONS. Where frost conditions exist and the design is to be based on a base and subbase thickness less than the thickness required for complete frost protection, the design must be based on two traffic periods as described previously. In some cases, it may be possible to replace part of the subgrade with material not affected by cycles of freeze-thaw but which will not meet the specifications for a base or subbase. In this case, the material must be treated as a subgrade and characterized by the procedures given for subgrade characterization.

9. ASPHALT CONCRETE PAVEMENTS. The asphalt concrete pavement differs from the conventional flexible pavement in that the asphalt concrete is sufficiently thick to contribute significantly to the strength of the pavement. In this case, the variation in the stiffness of the asphalt concrete caused

by yearly climatic variations must be taken into account by dividing the traffic into increments during which variation of the resilient modulus of the asphalt concrete is at a minimum. One procedure is to determine the resilient modulus of the asphalt concrete for each month, then group the months when the asphalt concrete has a similar resilient moduli. Thus, it may be possible to reduce the traffic to three or four groups. Also, since the asphalt concrete is a major structural element, the failure of this element due to fatigue cracking must be checked. The flow diagram for design of the asphalt concrete pavements is given in Figure 11-7.

10. PAVEMENTS WITH A STABILIZED BASE COURSE. For a pavement having a chemically stabilized base course and an unbound aggregate subbase course, damage must be accumulated for subgrade strain, for horizontal tensile strain at the bottom of the bituminous concrete surfacing, and for horizontal tensile strain at the bottom of the chemically stabilized layer. Normally in this type of pavement, the base-course resilient modulus is sufficiently high (≥ 690 MPa (100,000 psi)) to prevent fatigue cracking of the bituminous concrete surface course (where the bituminous concrete surface course has a thickness equal to or greater than the minimum required in Tables 8-2 through 8-5), and thus this mode of failure is only a minor consideration. For most cases, a very conservative approach can be taken in checking for this mode of failure; i.e., all the traffic can be grouped into the most critical time period and the computed bituminous concrete strain compared with the allowable strain. If the conservative approach indicates that the surface course is unsatisfactory, then the damage should be accumulated in the same manner used for conventional flexible pavement. For the pavement having a stabilized base or subbase, checking the subgrade strain criteria becomes more complicated than for conventional flexible or bituminous concrete pavements. Two cases in particular should be considered. In the first case, the stabilized layer is considered to be continuous, with cracking due only to curing and temperature. In the second case, the stabilized layer is considered cracked because of load. The first step in evaluating the stabilized layer is to compute the horizontal tensile strain at the bottom of the stabilized layer and the vertical compressive strain at the top of the subgrade under assumptions that the stabilized layer is continuous and has a modulus value as determined by the flexural resilient modulus test. To account for the increase in stress due to loadings near shrinkage cracks, the computed strains should be multiplied by 1.5 for comparison with the allowable strains. If the analysis shows that the stabilized base will not crack under load, then it will be necessary to compare the adjusted value of subgrade strain with the allowable subgrade strain. If this analysis indicates that the adjusted strain is not less than or equal to the allowable strain, then the thickness should be increased and the process repeated, or the section should be checked under the assumption that the base course will crack and behave as a granular material. The cracked stabilized base course is represented by a reduced resilient modulus value, which is determined from the relationship between resilient modulus and unconfined compressive strength shown in Figure 11-8. When the cracked base concept is used, only the subgrade criteria need to be satisfied. The section obtained should not differ greatly from the section obtained by use of the equivalency factors in Table 9-1 or 9-2. A flow diagram for the design of this type of pavement is shown in Figure 11-9.

11. PAVEMENTS WITH STABILIZED BASE AND STABILIZED SUBBASE. This type of pavement is handled almost identically to a pavement with a stabilized base. If the base is a bituminous-stabilized material, then the cumulative damage procedure must be employed to determine if the subbase will crack. If the analysis indicates that the subbase will crack due to loading, an equivalent cracked-section modulus is determined from Figure 11-8, and the pavement is treated as a bituminous concrete pavement. If both the base and subbase courses are chemically stabilized, then both layers must be checked for cracking. A conservative approach is taken by checking for cracking of one layer by considering the other stabilized layer as cracked and having a reduced modulus. The vertical compressive strain at the top of the subgrade is computed by use of the flexural modulus or the reduced modulus, as appropriate. If either of the two layers is considered uncracked, then the computed

subgrade strain is multiplied by 1.5 to account for the shrinkage cracks that will exist. The basic flow diagram for this type of pavement is shown in Figure 11-10.

12. EXAMPLE DESIGN FOR CONVENTIONAL FLEXIBLE PAVEMENT. To illustrate the application of the design procedure, consider a design for an Army Class IV airfield. The subgrade is a lean clay classified as CL. The design is to be for 200,000 passes of the C-130 aircraft. The design loading for the C-130 on the taxiway is 70,310 kilograms (155,000 pounds) with a tire contact area of 0.258 square meters (400 square inches). For the runway interior the loading is 75 percent of the taxiway loading. The reduction is accomplished by reducing the contact area, giving a contact area of 0.194 square meters (300 square inches). The design process may best be illustrated in steps. The basic steps are material investigation, determination of trial pavement sections, computation of critical strains, determination of applied strain repetitions, and computation of damage factors.

a. Step 1 - Material Investigation.

(1) The evaluation of the subgrade is to be accomplished by field and laboratory studies. The subgrade is to be classified according to different material types and material processing. For this example, it is assumed that the subgrade is fairly uniform and consists of a compacted lean clay placed according to existing compaction requirements. The subgrade evaluation involves conducting a series of resilient modulus tests according to the procedures given in Appendix L. For a location such as Shreveport, LA, it must be assumed that the subgrade would become saturated and thus the resilient modulus tests are conducted on saturated samples. A minimum of six samples should be tested and a design modulus determined for each sample. For determination of a design modulus, the data from the laboratory tests are plotted on a log-log plot of M_R versus σ_d and overlaid on the design curves as shown in Figure 11-11. For the design example, the design modulus obtained using this process is assumed to be 62 MPa (9,000 psi) for both taxiway and runway designs. Base and subbase materials must be obtained that meet the requirements of Chapters 7 and 8. The modulus values for the base and subbase are to be determined by the procedures given in Appendix J. Because the modulus of these materials depends on layer thicknesses, the modulus cannot be obtained until the trial sections are determined.

(2) The bituminous surfacing must meet the requirements of Chapter 9 as to minimum thickness and composition. The modulus-temperature relationship is determined according to the test procedures given in Appendix H or by the provisional procedure given in Appendix I. Assume for the example problem that the relationship as shown in Figure 11-12 is obtained from laboratory test data. (For simplicity, these data will be used for both taxiway and runway.) From the climatic data, the design air temperature is obtained and the design modulus values are determined as shown in Tables 11-3 and 11-4. To reduce the number of computations, the 12 groups are reduced to four groups as shown in Table 11-5. The Poisson's ratio for all materials is selected from Table 11-2.

b. Step 2 - Determination of Initial Section.

(1) From Chapter 10 the total thickness of pavement required for a gross aircraft load of 70,310 kilograms (155,000 pounds), 200,000 passes, and a subgrade CBR of 6 is determined to be 710 millimeters (28 inches). For the runway interior design, the thickness would be based on a gross aircraft load of 52,730 kilograms (116,250 pounds) and would result in an estimated thickness of 610 millimeters (24 inches). For taxiway design, subgrade damage factors will be computed for pavement thicknesses of 680, 760, and 840 millimeters (27, 30, and 33 inches) in an attempt to bracket the final required pavement thickness. The total thickness of pavement is made up of the asphalt

thickness, base thickness, and subbase thickness. The section for a thickness of 760 millimeters (30 inches) is shown in Figure 11-13 as an example.

(2) For runway design, thicknesses of 510, 610, and 660 millimeters (20, 24, and 26 inches) are assumed for the initial sections for computing the subgrade damage factor. The section for 610 millimeters (24 inches) is shown in Figure 11-14. In the initial section, a 13-millimeter (5-inch) asphalt layer is assumed for the taxiway design, and a 10-millimeter (4-inch) asphalt layer is assumed for the runway design. After determining the total thickness required for these asphalt thicknesses, the design can be refined for other asphalt thicknesses.

c. Step 3 - Computation of Strains.

Table 11-4
Bituminous Concrete Moduli for Each Month for Conventional Flexible Pavement Design Based on Bituminous Concrete Strain

Conversion Factors: degrees C = degrees F - 32/1.8, millimeters = 25.4 × inches

(1) The horizontal strain at the bottom of the asphalt layer and the vertical strain at the top of the subgrade are computed for each traffic grouping shown in Table 11-5. The data needed for input into the JULEA computer program for the computation of asphalt and subgrade strains for the 760-millimeter (30-inch) pavement structure for a taxiway design are given in Table 11-6. Note that the input contains data for one run, but four runs would be required to compute the subgrade data, i.e., one run for each grouping to account for variation in asphalt modulus. The strain is computed considering only two of the four main tires; the transverse spacing of the tires is sufficiently large to prevent an overlapping effect for the other two tires. The individual tire loading is computed by considering 90 percent of the gross load on the main gear, equally distributed between the four tires of the main gear, resulting in a weight on each tire of 15,820 kilograms (34,875 pounds). The radius of the loaded area is computed as a circle having an area equal to the tire contact area. A contact area of 0.258 square meters (400 square inches) results in a radius of the contact area of 28.6 millimeters (11.28 inches). The pavement system is a five-layer system having full friction between layers. For a

Conversion Factors: megapascals = 6.894 × kips per square inch

flexible pavement system, the rough computational procedure is sufficiently accurate. The subgrade vertical strain is computed at the top of the subgrade layer and under the center of one of the tires and midway between the tires. The maximum strain is found to occur under the tire. Results of computer runs for the example problem are shown in Table 11-7.

(2) A similar set of runs is made for the computation of the horizontal strain at the bottom of the asphalt layer. This set of runs will use the asphalt moduli determined for consideration of asphalt strains and given in Table 11-5. For computing the strains for the runway design, the load and contact area are reduced by 75 percent. The resulting tire loading is 11,850 kilograms (26,125 pounds) applied over a circular contact area having a radius of 248 millimeters (9.77 inches).

d. Step 4 - Determination of Applied Repetitions.

(1) The design is for 200,000 passes of the aircraft over the life of the pavement. The pavement life has been divided into four periods as shown in Table 11-5. Considering that the traffic is to be equally distributed throughout the year would result in 25, 16.7, 25, and 33.3 percent of the traffic to be applied in the first, second, third, and fourth periods, respectively.

(2) The 200,000 passes will result in a total number of effective strain repetitions that will be a function of transverse location on the pavement and on the depth at which the strain is being considered.

From plots in Appendix E showing the conversion from passes to strain repetitions for the taxiway and runway, the conversion percentages are determined. For the taxiway and depth to the top of subgrade of 760 millimeters (30 inches), the maximum conversion percentage for converting passes to effective strain repetitions from Figure E-10 is approximately 100. This maximum occurs at a distance of 26 meters (86 inches) from the centerline of the taxiway. Thus, the effective number of subgrade repetitions would be 200,000. For consideration of the asphalt strain at a depth of 130 millimeters (5 inches), the conversion percentage is approximately 50, resulting in 100,000 strain repetitions. From Figure E-9, the conversion percentages for the runway are 60 and 30 for consideration of subgrade strain and asphalt strain, respectively.

(3) The effective number of strain repetitions for a traffic group then is determined by multiplying the total strain repetitions by the factor of traffic occurring in a group.

e. Step 5 - Computation of Damage Factors.

(1) The damage factor for one traffic group is defined as n/N where n represents the effective strain repetitions for that group and N equals the allowable numbers of strain repetitions as computed from Equations 11-3 and 11-4. The damage factors for the different periods are summed to obtain the cumulative damage factor.

(2) The computations were performed by use of the computer programs SUBGRADE for the subgrade damage and ASPHALT for the asphalt damage. The data file, SDATA1, required by the program SUBGRADE for computing the subgrade damage factor for 840-, 760-, and 685-millimeter (33-, 30-, and 27-inch) pavements is given in Table 11-8 and the output is given in Table 11-9. The data file ADATA1 required by the program ASPHALT for computing the asphalt damage factor for the asphalt is given in Table 11-10 and for the output in Table 11-11.

(3) To speed the design procedure, the subgrade damage factor was computed for several pavement thicknesses, and the results for the taxiway pavement were plotted as shown in Figure 11-15. For pavements having an asphalt concrete thickness of 130 millimeters (5 inches), the subgrade damage factor was computed for thicknesses of 685, 760, and 840 millimeters (27, 30, and 33 inches). From the plot of damage factor versus pavement thickness, it is determined that the required thickness for the taxiway pavement would be 735 millimeters (29 inches). Using the 735-millimeter (29-inch) overall thickness as a constant thickness, the subgrade damage factor can be computed for varying thickness of asphalt concrete. Lines can then be constructed that will provide the total thickness for each asphalt concrete thickness. Alternate designs, rounded to the nearest inch, might be 152-millimeter (6-inch) asphalt concrete with 710 millimeters (28 inches) in total thickness or 102-millimeter (4-inch) asphalt concrete with 762 millimeters (30 inches) in total thickness. The relationship between pavement thickness and subgrade damage factors for the runway is given in Figure 11-16.

(4) For these designs, the asphalt damage must be computed. Plots of asphalt damage versus asphalt thickness for both the taxiway and runway are given in Figure 11-17. The asphalt damage factor would not control the asphalt thickness since the damage factor for this case is always less than 1.0. The minimum thickness of the asphalt layer would be dictated by the minimum thickness criterion in the basic manual.

13. EXAMPLE DESIGN FOR ALL BITUMINOUS CONCRETE (ABC) PAVEMENT.

a. The thickness of the ABC pavement required for the taxiway design is estimated by considering the thickness of conventional pavement, i.e., 130 millimeters (5 inches) of asphaltic concrete and 610 millimeters (24 inches) of granular base and subbase. For this conventional pavement the effective thickness would be 865 millimeters (34 inches) which when converted to an ABC pavement would give an estimated thickness of 430 millimeters (17 inches) (computed by using the equivalence of 2 for bound materials). For computation of the fatigue damage and subgrade damage, monthly time periods are used as shown in Tables 11-12 and 11-13, respectively. Normally for ABC designs, the subgrade damage will be the controlling criteria and thus the thickness for satisfying the subgrade criteria is first determined. The subgrade strains are computed for six time periods so as to produce a plot as shown in Figure 11-18. From this plot, the subgrade strains for each time period are determined and are given in Tables 11-14 and 11-15. The data shown in Table 11-14 are input into the computer program SUBGRADE to compute the subgrade damage factor. It is noted that an equivalent thickness of 865 millimeters (34 inches) is used to determine the applied strain repetitions, resulting in the same number of strain repetitions as was used for the design of the conventional pavement. Damage factors were computed for pavement thicknesses of 405, 430, 480, and 535 millimeters (16, 17, 19, and 21 inches) from which the plot of damage factor versus pavement thickness (Figure 11-19) was

developed. From Figure 11-19, the taxiway thickness for a damage factor of 1.0 is determined to be 430 millimeters (16.9 inches). The fatigue damage factor based on the asphalt criteria is then computed for a pavement thickness of 430 millimeters (16.9 inches). Also, from Figure 11-19 the runway thickness for a damage factor of 1.0 is determined to be 345 millimeters (13.6 inches).

b. The plot of asphalt strain versus asphalt modulus is shown in Figure 11-20. The asphalt strain for each time period is given in Table 11-14. Using the computer program ASPHALT, the fatigue damage factor is computed to be 0.15, which is considerably less than 1.0. Thus, a pavement thickness of 430 millimeters (16.9 inches) meets both the subgrade criteria and the asphalt fatigue criteria.

c. The runway design is accomplished in the same manner as the taxiway design. The conventional runway section of 102 millimeters (4 inches) of asphaltic concrete and 635 millimeters (25 inches) of granular base and subbase converted to a 840-millimeter (33-inch) effective thickness. An ABC pavement of 370 millimeters (14.5 inches) would be required to give the same effective thickness. Based on the estimated thickness, the subgrade damage factor was computed for pavement thicknesses of 330, 355, and 405 millimeters (13, 14, and 16 inches). The aircraft wheel load and the number of load repetitions for the computations were the same as used in the design for the conventional section. The subgrade strains and the asphalt strains as a function of pavement thickness are given in Figures 11-21 and 11-22, respectively. The data for computing the damage factors are

given in Table 11-15. The plot of the subgrade damage factor versus thickness is given in Figure 11-20. From the plot, it is determined that a 345-millimeter (13.5-inch) ABC pavement would satisfy the subgrade criteria. The asphalt fatigue damage factor for a 330-millimeter (13-inch) pavement was computed to be 0.24, thus determining that the 345-millimeter (13.5-inch) pavement satisfies both criteria.

CHAPTER 12

PLAIN CONCRETE PAVEMENTS

1. BASIS OF DESIGN – ARMY AND AIR FORCE. The pavement thickness requirement is calculated using a mechanistic fatigue analysis. Stresses under design aircraft are calculated using the Westergaard edge-loaded model. These calculated edge stresses are related to the concrete flexural strength and repetitions of traffic through a field fatigue curve based on full-scale accelerated traffic test of aircraft loads. A wide variety of model tests, theoretical analyses, and field measurements over the years have demonstrated that part of the load applied to the edge of a pavement slab is transferred to and carried by the adjacent slab through dowels, aggregate interlock, etc. For design, a load transfer value of 25 percent is routinely used as a reasonable approximation of the load transfer measured over time on the types of joints approved for use in Army and Air Force airfields. The actual load transfer at a joint will vary depending on joint type, quality of construction, slab length, number of load repetitions, temperature conditions, etc. The design charts in this chapter were developed based on a 25 percent load transfer value. If adequate load transfer is not provided at the joints of trafficked slabs, the pavement should be designed for no load transfer using the PCASE pavement design program that allows direct input of the load transfer value or the gross load used in the design charts in this chapter should be increased by 1/3 to remove the load transfer effect. Alternatively, a thickened edge detail can be used at joints without adequate load transfer. This design method also includes a thickness reduction for high-strength subgrades (modulus of subgrade reaction, k, > 54 kPa/mm (200 pci) in recognition that after the initial flexural fatigue crack forms (classical design failure condition for this design method) the continued slab deterioration through additional cracking and spalling proceeds more slowly on high-strength subgrades than on low-strength subgrades.

2. BASIS OF DESIGN – NAVY. The pavement thickness requirement is calculated using a mechanistic fatigue analysis. Stresses under design aircraft are calculated using the Westergaard interior load model for light traffic or training base commands. For medium to heavy loaded pavements, the Army and Air Force design procedure described above should be considered. The Navy recognizes edge stress design as a way to reduce pavement life cycle costs for bases with medium to heavy traffic missions. These calculated interior stresses are related to the concrete flexural strength and repetitions of traffic through a fatigue curve based on a conservative laboratory beam test relation originally developed by the Portland Cement Association. Adequate quality joints at short joint spacing are required to provide load transfer with the Navy assumptions. Alternate thickness design methods are allowed for Navy pavements if the method is approved by the NAVFAC.

3. USES FOR PLAIN CONCRETE. Military airfield experience has found that plain, unreinforced concrete is generally the most economical concrete airfield surface to build and maintain. Unreinforced concrete will be used for concrete military airfield pavements unless special circumstances exist. The most common exception will be for cases requiring conventional reinforcing as noted in Chapter 1, paragraph 7 and Chapter 13. Other reinforcing for which design techniques are provided in this manual are for special circumstances and their use must be approved by TSMCX, AF MAJCOM pavements engineer, or NAVFAC as appropriate.

4. THICKNESS DESIGN - ARMY AND AIR FORCE PAVEMENTS.

a. General. Figures 12-1 through 12-22 are design curves to be used in designing plain concrete pavements as defined in Chapters 2, 3, and 4. Figures 12-1 through 12-5 are for Army Class I to IV airfields, and Figures 12-6 to 12-17 are for Air Force (Figures 12-6 to 12-11 are for standard mixed traffic designs.). Figure 12-17 is a design curve for shoulders and is applicable to all airfields requiring concrete shoulders. Figures 12-6 to 12-12 are design curves for the six Air Force standard airfield types, and Figures 12-13 to 12-16 are individual design curves for various aircraft to be used in designing pavements for conditions other than the basic airfield types. Thicknesses may also be determined using the computer programs referenced in Chapter 1.

b. Plain Concrete Pavements on Nonstabilized or Modified Soil Foundations. For plain concrete pavements that will be placed directly on nonstabilized or modified base courses or subgrade, the thickness requirement will be determined from the appropriate design curve using the design parameters of concrete flexural strength, R; modulus of soil reaction, k; gross weight of aircraft; aircraft pass level; and pavement traffic area type (except for shoulder design). The design gross aircraft weight and pass level may vary depending upon the type of traffic area or pavement facility. When using English units and the thickness from the design curve indicates a fractional value, it will be rounded up to the nearest full- or half-inch thickness. The minimum thickness of plain concrete pavement will be 150 millimeters (6.0 inches). When it is necessary to change from one thickness to another within a pavement facility, such as from one traffic area to another, the transition will be accomplished in one full paving lane width or slab length. SI thickness values will be rounded up to the nearest 10 millimeters.

c. Plain Concrete Pavements on Stabilized Base and/or Subgrade. Stabilized base and/or subgrade layers meeting the strength requirements of Chapter 9 and lean concrete base will be treated as low-strength base pavements, and the plain concrete pavement will be considered an overlay with a thickness determined using the following modified, partially bonded rigid overlay pavement design equation:

$$h_o = \sqrt[1.4]{h_d^{1.4} - \left[\left(\sqrt[3]{\frac{E_b}{E_c}}\right) h_b\right]^{1.4}} \qquad (12\text{-}1)$$

where

h_o = thickness of plain concrete overlay, millimeters (inches)

h_d = design thickness of equivalent single slab placed directly on foundation, millimeters (inches)

E_b = modulus of elasticity of base MPa (psi)

E_c = modulus of elasticity of concrete, usually taken as 27,575 MPa (4×10^6 psi)

h_b = thickness of stabilized layer or lean concrete base, millimeters (inches)

5. EXAMPLES OF PLAIN CONCRETE PAVEMENT DESIGN FOR ARMY AND AIR FORCE.

a. General. It is required that an airfield be designed as a medium-load pavement. Types A and B traffic areas are designed for the F-15 at 36,740 kilograms (81,000 pounds), the C-17 at 263,100 kilograms (580,000 pounds), and the B-52 at 181,400 kilograms (400,000 pounds). Types C and D traffic areas and overruns are designed for the F-15 at 27,555 kilograms (60,750 pounds), the C-17 at 197,100 kilograms (435,000 pounds), and the B-52 at 136,080 kilograms (300,000 pounds). Types A, B, and C traffic areas are designed for 100,000 passes of the F-15, 400,000 passes of the C-17, and 400 passes of the B-52. Type D traffic areas and overruns are designed for 1,000 passes of the F-15, 4,000 passes of the C-17, and 4 pass of the B-52. (Since the B-52 is included in the design, the runway must be 61 meters (200 feet) wide.) On-site and laboratory investigations have yielded the following data required for design: (1) the subgrade material is classified as a silty sand (SM); (2) the modulus of soil reaction, k, of the subgrade is 54 kPa/mm (200 pci); (3) a nearby source of crushed gravel meets the requirements for base course; (4) frost does not enter subgrade material; and (5) 90-day concrete flexural strength, R, is 4.8 MPa (700 psi).

b. Example Design, Slab on Grade. Figure 12-8 is entered with the subgrade k = 200 pci, concrete design flexural strength R = 700 psi, and the pavement thickness is determined for the various traffic areas and overruns as follows:

Traffic Area	**Thickness, mm (in.)**[1]
A	406 (16.0)[1]
B	406 (16.0)
C	302 (12.0)
D and overruns	229 (9.0)

[1] Fractional values would be rounded up to the nearest full- or half-inch for design.

c. Example Design, Slab on Unbound Base. For comparison purposes, designs are developed below for three base-course thicknesses. Field plate bearing tests conducted in a test section to establish the modulus of soil reaction for three thicknesses of base course give k values of 68 kPa/mm (250 pci) for a 152-millimeter (6-inch) base, 81 kPa/mm (300 pci) for a 305-millimeter (12-inch), and 95 kPa/mm (350 pci) for 460-millimeter (18-inch) base. These values are supported by Figure 8-1 and are thus selected for design. Figure 12-8 is entered with the design flexural strength, modulus of soil reaction, and traffic areas to determine the required concrete pavement thicknesses. Thicknesses for shoulders were determined from Figure 12-17. The thicknesses for this example are summarized as follows:

Foundation Condition	**Modulus of Soil Reaction kPa/mm (pci)**	**Thickness, mm (in.)**				
		A	**B**	**C**	**D & Overruns**	**Shoulders**[1]
(1)	(2)	(3)	(4)	(5)	(6)	(7)
150-mm (6-in.) base	68 (250)	370 (14.5)	370 (14.5)	290 (11.5)	215 (8.5)	150 (6)
300-mm (12-in.) base	81 (300)	340 (13.5)	340 (13.5)	260 (10.5)	200 (8.0)	150 (6)
460-mm (18-in.) base	95 (350)	330 (13)	320 (12.5)	250 (10)	200 (8.0)	150 (6)

Note: Final thickness should be rounded values.
[1] Use minimum thickness of 150 millimeters (6 inches) for shoulders.
The final selection of concrete pavement thickness must be based upon a study of the cost of importing and placing base course versus savings in concrete pavements.

d. Example Design, Slab on Stabilized Base. Assume that a cement-stabilized base course will be used. Laboratory tests on base-course material have shown that a cement content of 7 percent by weight will yield a 7-day compressive strength of 6.89 MPa (1,000 psi) and a flexural modulus of elasticity E_b of 3,450 MPa (500,000 psi) at an age of 90 days. According to TM 5-822-14/ AFJMAN 32-1019, the compressive strength of 6.89 MPa (1,000 psi) qualifies as a stabilized layer (that is, permits a thickness reduction), and the design is made using Equation 12-1. The single slab thickness h_d of plain concrete is determined from Figure 12-7 using R = 4.8 MPa (700 psi) and k = 54 kPa/mm (200 pci) for the design load and pass level for each type traffic area. The thicknesses of plain concrete overlay determined with Equation 12-1 for several thicknesses of stabilized layer are shown in the following tabulation:

Type Traffic Area	Thickness of Stabilized Layer h_b, mm (in.)	Thickness of Slab on Grade h_d, mm (in.)	Overlay Thickness h_o, mm (in.)
A	150 (6)	406 (16.0)	380 (15.0)
	300 (12)	406 (16.0)	330 (13.0)
	450 (18)	406 (16.0)	267 (10.5)
B	150 (6)	406 (16.0)	370 (14.5)
	300 (12)	406 (16.0)	330 (13.0)
	450 (18)	406 (16.0)	254 (10.0)
C	150 (6)	300 (12.0)	280 (11.0)
	300 (12)	300 (12.0)	215 (8.5)
	450 (18)	300 (12.0)	150 (6.0)
D & Overrun	150 (6)	229 (9.0)	200 (8.0)
	300(12)	229 (9.0)	150 (6.0)[1]
	450 (18)	229 (9.0)	150 (6.0)[1]

Note: Final design overlay thicknesses should be rounded in accordance with paragraph 4b.
[1] Minimum thickness of plain concrete pavement.

The final selection of plain concrete pavement and stabilized base thicknesses will be based upon the economics involved.

e. Design Example for Mixed Traffic.

(1) General. The design of rigid airfield pavements has been based on a standard definition of aircraft mixture, load, and pass levels. However, pavements may be designed for a mixture of aircraft type, loadings, and repetitions other than the standard. This design example presents a procedure for the design of pavements which will be subjected to a mixture of traffic types and loadings based upon equivalent aircraft loadings.

(2) Procedure. The design of a concrete pavement to accommodate a mixture of aircraft traffic is accomplished using the following steps:

(a) Determine the aircraft traffic that is anticipated to use the pavements during the life of the pavements. Arrange this traffic in accordance with aircraft type, gross weight, and number of passes.

(b) Select the pavement thickness required for each aircraft at the design gross weight, pass level, and pavement characteristics.

(c) Select the controlling aircraft as the one requiring the maximum thickness.

(d) Evaluate the controlling thickness in terms of allowable passes for each aircraft in the design mix using the appropriate design curves from Figures 12-1 to 12-17. Those curves are entered from the left with the flexural strength, modulus of subgrade reaction, and load and from the right with controlling thickness and traffic. The intersection point of these two lines will estimate the allowable number of passes of an aircraft. An example of this operation is shown in Figure 12-18.

(e) Determine the number of each aircraft equivalent to one pass of the controlling aircraft by dividing the allowable passes of each aircraft by the allowable pass level of the controlling aircraft.

(f) The number of design passes for each aircraft is then divided by the equivalent passes to determine the total number of equivalent passes of the controlling aircraft to be considered for final design.

(3) Example problem solution.

(a) Determine the thickness of pavement required for a taxiway having the mixture of aircraft, gross weights, and number of passes as shown in columns 1-3 in Table 12-1. The concrete design flexural strength R is 4.48 MPa (650 psi), and the modulus of soil reaction k is 54 kPa/mm (200 pci).

(b) The pavement thickness required for each aircraft is shown in column 4 as determined from appropriate design curves. (Figures 12-3, 12-4, 12-13 through 12-15)

(c) Determine the allowable number of passes of each aircraft for the controlling thickness in column 4 of 363 millimeters (14.3 inches) for the C-141. These allowable passes are determined from the aircraft respective design curve and listed in column 5.

(d) Divide the allowable number of passes (column 5) by the allowable number of passes for the C-141 (10,000). This gives the number of equivalent passes of each aircraft in terms of one pass of the C-141 and is shown in column 6. For example, one pass of the C-141 is equivalent to 780 passes of the F-15 at the design weights.

(e) Divide the number of design passes in column 3 by the number of equivalent passes in column 6 to determine the total number of equivalent C-141 passes for design. These values are shown in column 7.

(f) Determine the total number of equivalent C-141 passes by totaling the values in column 7. Enter the C-141 design curve (Figure 12-14) with the total number of equivalent passes (20,129), the design load of 156,490 kilograms (345 kips), R of 4.48 MPa (650 psi), k of 54 kPa/mm (200 pci), and traffic area A to determine the final design thickness of 381 millimeters (15.0 inches). These values will be rounded to 380 millimeters (15.0 inches).

Table 12-1
Example of Mixed Traffic Design

(1) Aircraft	(2) Gross Weight, kg (kips)	(3) Aircraft Passes	(4) Preliminary Thickness, in.	(5) Allowable Passes at 14.3 in.	(6) Column 5 Divided by 10,000	(7) Column 3 Divided by Column 6
B-52	181,400 (400)	300	14.2	336	0.03	10,000

6. THICKNESS DESIGN - NAVY AND MARINE CORPS PAVEMENTS.

a. General. Figures 12-19 to 12-23 are design curves for various aircraft to be used in determining thickness requirements for individual aircraft. Figures 12-24 to 12-28 are design curves to be used for mixed aircraft traffic in determining thickness requirements. Thicknesses may also be determined using the computer program DESIGN OF RIGID AIRFIELD PAVEMENTS. See paragraph 8 in Chapter 4 for design policy.

b. Fatigue Damage. Repeated aircraft loading results in fatigue damage in the concrete slabs which results in microcracks at the bottom of the slab. These cracks work their way to the surface of the slab, eventually dividing the slab into two or more pieces. In addition, if pumping and loss of support occur at slab corners, the critical stress could increase until a corner break develops. As the proportion of cracked slabs increases, the airfield pavement requires increasing maintenance and repair.

c. Structural Characterization. The slab and foundation are characterized using the Westergaard theory of a slab loaded at the interior resting on a uniformly supported foundation (as modeled using the k value). Stresses may be computed using the computer program RPDESIGN. A major design assumption is that adequate load transfer is provided at the joints so that the load stresses that occur at the joints are not significantly higher than the stresses at the interior of the slab. Adequate load transfer must be provided by a stabilized base, keyways, mechanical load transfer devices or aggregate interlock.

d. Structural Slab Cracking from Aircraft Loadings. The cracking of a nonreinforced jointed concrete slab with relatively short joint spacing is controlled by:

(1) The magnitude of flexural stress caused by aircraft traffic.

(2) The flexural strength of the concrete.

(3) The number of stress applications.

The number of allowable stress applications to crack the concrete slab is controlled by the ratio of critical stress to flexural strength of the concrete. The relationship used in this design procedure to relate stress/flexural strength ratio to the number of stress applications to cracking was developed by the PCA and is shown in Table 12-2. The lower the ratio of critical stress to flexural strength, the larger the number of load applications that the slab can carry before cracking occurs.

e. Structural Slab Cracking and Mixed Aircraft Loading. When two or more aircraft will utilize a given pavement, each may cause a certain amount of fatigue damage in the concrete slab. The effect of mixed traffic can be provided for in the pavement design by using Miner's cumulative fatigue damage procedure. Fatigue damage is defined as the ratio of the number of loading cycles actually applied (at a given stress level) to the number of allowable load applications to cracking failure (at the same stress level). The resulting fraction represents the proportion of the useful life of the concrete that is consumed by repeated loading.

$$Cumulative\ Fatigue\ Damage = \sum \frac{n_i}{N_i} \qquad (12\text{-}1)$$

where

n_i = number of applied loads (coverages) at a given stress level (as denoted by i)

N_i = number of allowable loads (coverages) at the same stress level to cracking of the concrete

The fatigue damage can be accumulated over any number of stress levels (or different aircraft loadings) as indicated by the summation sign.

f. Thickness Design Inputs. Five key design inputs are needed to determine the required slab thickness.

(1) Design concrete flexural strength. The 28-day third-point loading flexural strength is used for pavement design. The design flexural strength should be as high as practicable and economical but not less than 4.48 MPa (650 psi). The actual mean flexural strength in the field will be greater than the design flexural strength.

(2) Value of k at top of base. The k value on the subgrade and at the top of the base layers will be determined using the procedure presented in Chapter 5. The value used for design is that obtained at the top of the base. The combined base and subgrade should have a minimum design k value of

54 kPa/mm (200 pci) to prevent excessive permanent deformation of the subgrade due to slab corner deflections. A base course of sufficient thickness and quality should be used to achieve this modulus. However, in no case should design be based on a k value greater than 135 kPa/mm (500 pci). A stabilized base or lean concrete base may be used as a substitute for a granular base course on a 1:1.5 thickness replacement ratio. However, the k value used for design remains the same as that determined at the top of the granular base. The design k value is not increased due to the use of a stabilized or lean concrete base. An unbonded stabilized or lean concrete base does not increase the effective k value greatly due to slippage between the slab and base.

Table 12-2
Stress-Strength Ratios and Allowable Coverages

Stress-Strength[1] Ratio	Allowable Coverages	Stress-Strength[1] Ratio	Allowable Coverages
0.45	2,300,000	0.63	14,000
0.46	1,700,000	0.64	11,000
0.47	1,300,000	0.65	8,000
0.48	1,000,000	0.66	6,000
0.49	720,000	0.67	4,500
0.50	540,000	0.68	3,500
0.51	400,000	0.69	2,500
0.52	300,000	0.70	2,000
0.53	240,000	0.71	1,500
0.54	180,000	0.72	1,100
0.55	130,000	0.73	850
0.56	100,000	0.74	650
0.57	75,000	0.75	480
0.58	57,000	0.76	370
0.59	42,000	0.77	280
0.60	32,000	0.78	210
0.61	24,000	0.79	160
0.62	18,000	0.80	120

[1] Interior or edge stress and design flexural strength.

(3) Type and design gear load of aircraft using facility. Pavement thickness design can be determined for a single design aircraft or for a mix of aircraft traffic. Determine the design gear load for a given aircraft by first selecting the design gross aircraft weight. This is normally the maximum gross aircraft weight at departure. Then estimate the design gear load by assuming that 95 percent of the gross weight is carried by the main gears. Design values are given in Chapter 4.

(4) Number of Aircraft Passes. Forecast the total number of passes (not coverages) of each aircraft that is expected to use the pavement feature over its design life. The "number of passes" is normally the number of departures. The exception to this is in touchdown areas on runways where the impact due to aircraft performing touch-and-go operations will cause pavement damage. On pavements that are to be used for touch-and-go operations, add the expected number of touch-and-go operations over the design life to the number of departures to arrive at the design traffic passes. Minimum pass levels for design are given in Chapter 4.

(5) Primary or Secondary Traffic Area. Guidance on determining if the pavement feature is a primary or secondary traffic area is given in Chapter 4.

g. Thickness design procedure for a single design aircraft. Use Figures 12-19 to 12-23 to determine the concrete slab thickness for single-design aircraft. This procedure will provide the required slab thickness for a specified type of aircraft when the flexural strength, k value, gear load, tire pressure for single-wheel gear aircraft, number of passes, and type of design traffic area are specified. The design chart for aircraft with single wheel gear is shown in Figure 12-19 and is used by entering the design flexural strength and the tire load and projecting as shown by the dashed example lines until the required slab thickness is obtained. The design charts shown in Figures 12-20 through 12-23 are also entered with the design concrete flexural strength and projecting as shown by the dashed example lines until the required slab thickness is obtained. The calculated slab thickness is then rounded to obtain the design thickness.

h. Thickness Design Procedure for Mixed Traffic. When an airfield pavement will be loaded by two or more aircraft, the combined damage caused by the aircraft mix must be used in the design. The required slab thickness may be determined for a mix of aircraft types using Miner's damage hypothesis and data on forecasted operations of different aircraft types operating at the facility. The slab thickness design for mixed traffic is an iterative procedure in which the designer selects a trial slab thickness that is normally the thickness required for the most critical aircraft using the feature plus 25 millimeters (1 inch). The designer then computes the proportion of the fatigue life of the pavement consumed as the sum of the individual damage contributions of the forecasted volume of each aircraft type, and subsequently varies the slab thickness until less than 100 percent of the fatigue life of the pavement is consumed by the forecasted mix of traffic. This procedure is described in the following sections and is facilitated by the use of a table for computations as shown in Table 12-3.

(1) Required Inputs. The specific aircraft types and their design gear load (typically 95 percent of the maximum gross departure gear load) are entered in columns 1 and 2 of Table 12-3. The projected number of passes (departures) over the selected design period are entered in column 3 of Table 12-3. Divide the projected passes by the appropriate pass-coverage ratio from Table 12-4 to obtain projected coverages for each aircraft. If the forecasted number of passes is not available, use the minimum pass levels given in Chapter 4. Use the pass-coverage ratios given for primary (channelized) traffic areas when designing for runway ends, primary taxiways, and aprons. Use the pass-coverage ratios given for secondary (unchannelized) traffic areas when designing for other areas. Enter the pass-coverage ratio selected for each aircraft in column 4 of Table 12-3, and the number of coverages computed in column 5. The other required inputs are the concrete flexural strength, the effective k value on top of the base, and the tire pressure for each single wheel aircraft, which should be recorded in the spaces provided at the top of Table 12-3.

(2) Determination of interior flexural stresses. Select a trial slab thickness and record it in the space provided for the iteration being performed. For the initial trial, use the required thickness for the expected critical aircraft (determined from Figures 12-19 through 12-23) plus 25 millimeters (1 inch).

Determine the flexural stress at the bottom of the slab caused by each particular aircraft gear for the interior loading position, using Figures 12-24 through 12-20. For each single wheel gear aircraft, enter Figure 12-24 with the trial slab thickness, tire load, and tire pressure, move either up or down to the base effective k value and continue horizontally to the flexural stress. For each of the multiwheel gear aircraft types listed, enter the appropriate Figures 12-25 through 12-28 with the trial slab thickness, project a horizontal line left to the effective k value, move either up or down to the design gear load, and continue horizontally to the flexural stress. Record the stress values in column 6 of Table 12-3.

(3) Fatigue life consumption. The stress-strength ratio recorded for each aircraft in column 7 of Table 12-3 is the flexural stress in column 6 divided by the design concrete flexural strength. Select from Table 12-2 the allowable number of coverages corresponding to the stress-strength ratio computed for each aircraft type, and record the allowable number of coverages in column 8 of Table 12-3. For each aircraft type, divide the projected number of coverages in column 5 by the allowable number of coverages in column 8 to determine the portion of fatigue life consumed by the forecasted volume of each aircraft type and record in column 9. The sum of the values in column 9 is the total damage, the proportion of total fatigue life of the slab consumed by the forecasted volumes of the aircraft types listed. If this number is considerably less than 1.00 (100 percent), indicating that the slab has considerable remaining fatigue life at the end of the design period not consumed by the forecasted mix of traffic, then the trial slab thickness may be reduced in the next iteration. If the total damage is greater than 1.00 (100 percent), indicating that the fatigue life of the slab will be consumed by lower traffic volumes than those projected over the design period, then the trial slab thickness must be increased in the next iteration. The process of selecting a slab thickness, determining the flexural stress, and calculating the fatigue life consumption is repeated until the slab thickness which corresponds to an acceptable value for damage (less than 1.00 or 100 percent) is determined.

i. Minimum Thickness. The minimum allowable new concrete pavement thickness is 200 millimeters (8 inches) in primary and secondary traffic areas and 100 millimeters (4 inches) in blast protective areas not subject to aircraft loading. For helicopter and basic training fields the minimum thickness in primary and secondary traffic areas is 150 millimeters (6 inches).

7. DESIGN EXAMPLES FOR NAVY AND MARINE CORPS PLAIN CONCRETE PAVEMENTS.

a. Thickness Design for a Single Aircraft. It is desired to design a plain rigid pavement for the following conditions.

Aircraft = C-141
Design gear load = 70,300 kilograms (155,000 pounds)
Design flexural strength = 4.48 MPa (650 psi)
Effective k value at top of base course = 54 kPa/mm (200 pci)
Total departures over 20-year design life = 25,000
Traffic area = primary taxiway (channelized traffic)

Using Figure 12-22, the required slab thickness is 340 millimeters (13.4 inches). This thickness would then be rounded upward to 350 millimeters (14.0 inches).

b. Thickness Design for Mixed Traffic. A new runway is to be designed to serve frequent operations of C-141, C-130, C-17, and C-5A aircraft. In addition to these aircraft, the new facility will be used by F-14 and P-3 aircraft. The runway is located in a warm climatic region where frost penetration does not need to be considered in the design process. Use the following general design procedure when designing the rigid pavement for this runway.

(1) Subgrade evaluation and testing. A subgrade investigation was performed to evaluate the support of the subgrade soil. Prior to the actual field survey, previous soils investigations, soils maps, climatic data, etc., were collected to provide background information on the soil conditions. Soil borings were then obtained to aid in evaluating the physical properties of the soil. Soil borings were taken at 60-meter (200-foot) intervals along the location of the proposed runway. Soil tests show that the subgrade soil can be classified as CL according to the Unified Soil Classification System. Test results show that there is no significant soil variation in the area for the new runway. Swelling soils are not a problem at the site. Plate load-bearing tests were performed according to ASTM D 1196 to determine the modulus of subgrade reaction (k value). Because of the uniform soils throughout the area, only three plate load tests were taken. The results are summarized below:

Test Number	k Value, kPa/mm (pci)
1	27 (100)
2	41 (150)
3	35 (130)
Average = 34 kPa/mm (127 pci)	

Because of the uniform soil conditions throughout the site, a design k value of the average of the three tests, or 34 kPa/mm (127 pci), is used.

(2) Base course design. Results of a field survey and soil tests indicate that the subgrade soil has a high degree of saturation and low permeability. Thus, very little bottom drainage is likely. Therefore, a base material that is resistant to the detrimental effects of moisture should be used. A free-draining granular base course may be used to increase the subgrade k value to the minimum acceptable k value of 54 kPa/mm (200 pci) on top of the base course. According to Figure 8-1, a 203-millimeter (8-inch) granular base course will raise the k value on top of the base to 54 kPa/mm (200 pci). To prevent intrusion of subgrade fines into the base course, a filter course is included in the design.

(3) Traffic projections. The following tabulations summarize the projected traffic for the new runway over a 20-year design period and the design gear loads.

	Passes	Pass-Coverage Ratio		Coverages, 20 Years	
Aircraft	**20 Years**	**Channelized**	**Nonchannelized**	**Channelized**	**Nonchannelized**
C-141	12,500	3.49	6.23	3,582	2,006
C-130	50,000	4.40	8.54	11,364	5,855
C-5	25,000	1.66	2.11	15,060	11,848
C-17	12,500	1.37	1.90	9,124	6,579
P-3	100,000	3.58	6.66	27,933	15,015
F-14	100,000	7.78	15.34	12,854	6,519

Aircraft	Design Gear Load, kg (lb)
C-141	70,300 (155,000)
C-130	38,100 (84,000)
C-5	86,180 (190,000)
C-17	1,179,360 (260,000)
P-3	30,845 (68,000)
F-14[1]	13,600 (30,000)

[1] The design tire pressure for the F-14 is 1.65 MPa (240 psi).

(4) Slab thickness and joints. The k value of 54 kPa/mm (200 pci) as determined above and a design flexural strength of 4.48 MPa (650 psi) are used to determine the required slab thickness. Results of the mixed traffic analysis for the channelized traffic areas are summarized in Table 12-5. Results for the unchannelized traffic areas are summarized in Table 12-6. This shows that a 345-millimeter (13.6-inch) concrete slab is required in areas of channelized traffic to serve the projected aircraft over a design life of 20 years. This is rounded up to a recommended thickness of 350 millimeters (14.0 inches). A 330-millimeter (13.0-inch) concrete slab is required in areas with unchannelized traffic.

8. JOINT USES. Joints are provided to permit contraction and expansion of the concrete resulting from temperature and moisture changes, to relieve warping and curling stresses due to temperature and moisture differentials, to prevent unsightly irregular breaking of the pavement, and to act as a construction expedient to separate sections or strips of concrete placed at different times. The three general types of joints are contraction, construction, and expansion. A typical jointing layout of the three types is illustrated in Figure 12-29.

9. SELECTION OF JOINT TYPES. Joints are either construction or contraction joints. Construction joints are used because there is a physical limit on the concrete placement such as the beginning or end of a placement lane (transverse construction joint) or at the edges of the placement lane (longitudinal construction joint). Concrete is a dynamic material that changes volume throughout its life as chemical reactions occur and as temperature and moisture fluctuations occur. Either joints must be provided to accommodate these natural volume changes in concrete or the concrete will crack. Such joints are contraction joints and are formed by sawing partial depth into the concrete at early ages before cracking can occur. This sawing must be done as soon as the concrete has hardened sufficiently to allow saw cutting without raveling or damage to the concrete. The exact timing of the saw cutting depends on the characteristics of the concrete mixture and the environmental conditions. This cutting occurs on the same day as placing except under very unusual circumstances. Waiting overnight to cut these joints generally will result in uncontrolled cracking. Contraction joints made by inserts forced into the plastic concrete or by manually grooving the plastic concrete surface are unacceptable for military airfields. The most common contraction joints are the regularly spaced transverse joints (transverse contraction joints) placed down the length of the concrete placement lane. The maximum spacing between joints is a function of the slab thickness and allowable limits are provided in paragraph 10. When the concrete placement lane width exceeds these allowable limits between joints, a longitudinal contraction joint will be placed to bring the joint spacing within the maximum limits. The resulting slabs should be square. If the ratio of length to width falls outside of the range of 0.75 to 1.25 or if the geometry of the pavement dictates an irregular shaped slab (e.g., filet slabs), the slabs will have to be reinforced as required in Chapters 1 and 13. Expansion joints are special construction joints that are used to isolate structures from the concrete pavement movement (e.g., isolate hangar from an apron) or to separate two intersecting pavements (e.g., a taxiway intersecting a runway at right angles). Expansion joints often are

the source of maintenance headaches so they are used only when concrete movement has to be isolated. The old practice of automatically placing expansion joints at prescribed intervals down a pavement feature is unnecessary and has been discontinued since the 1950s. Doweled construction joints and saw-cut contraction joints without dowels will be the default joints used for military airfield pavement construction. Other joints will be used for special circumstances if needed or with the specific approval of the AF MAJCOM pavements engineer, TSMCX, or NAVFAC as appropriate. These other special application joints include:

a. Thickened-edge expansion or doweled expansion joints where isolation from concrete movement is required.

b. Thickened-edge construction joint where load transfer cannot be provided by dowels and aircraft traffic will cross or be adjacent to the joint.

c. Doweled contraction joint where load transfer from aggregate interlock might be lost due to slab movement (e.g., last three contraction joints on a runway are commonly doweled because of possible joint opening from accumulated slab movements or on long reinforced slabs where environmental changes may result in excessive joint opening).

d. Butt longitudinal construction joints but this requires special design for no load transfer for Army and Air Force airfield pavements.

e. Tied joints (Navy only) where relative movement and separation between slabs must be restricted. Such situations are rare on airfield pavements.

f. Doweled construction joints will normally be used at the intersection of new and old concrete, or alternatively the new concrete may have a thickened edge. Note that this latter situation will leave the old concrete slab without load transfer and its premature failure should be anticipated and planned for. Special junctures that require undercutting and placing concrete below the old slab require approval from the AF MAJCOM pavements engineer, TSMCX, or NAVFAC as appropriate before use.

10. JOINTS FOR ARMY AND AIR FORCE PAVEMENTS.

a. Contraction Joints.

(1) General. Weakened-plane contraction joints are provided to control cracking in the concrete and to limit curling or warping stresses resulting from drying shrinkage and contraction and from temperature and moisture gradients in the pavement. Shrinkage and contraction of the concrete causes slight cracking and separation of the pavement at the weakened planes, which will provide some relief from tensile forces resulting from foundation restraint and compressive forces cause by subsequent expansion. Contraction joints will be required transversely and may be required longitudinally depending upon pavement thickness and spacing of construction joints. A typical contraction joint is shown in Figure 12-30. Instructions regarding the use of saw cuts to form the weakened plane are contained in TM 5-822-7/AFM 88-6, Chapter 8.

(2) Width and Depth of Weakened-Plane Groove. The width of the weakened-plane groove will be a +3 millimeters (+1/8 inch) or greater. The depth of the weakened plane groove must be great enough to cause the concrete to crack under the tensile stresses resulting from the shrinkage and contraction of the concrete as it cures. Experience, supported by analyses, indicates that this depth should be at least one-fourth of the slab thickness for pavements less than 300 millimeters (12 inches),

75 millimeters (3 inches) for pavements 300 to 450 millimeters (12 to 18 inches) in thickness, and one-sixth of the slab thickness for pavements greater than 450 millimeters (18 inches) in thickness. In no case will the depth of the groove be less than the maximum nominal size of aggregate used. Concrete placement conditions may influence the fracturing of the concrete and dictate the depth of groove required. For example, concrete placed early in the day, when the air temperature is rising, may experience expansion rather than contraction during the early life of the concrete with subsequent contraction occurring several hours later as the air temperature drops. The concrete may have attained sufficient strength before the contraction occurs so that each successive weakened plane does not result in fracturing of the concrete. As a result, excessive opening may result where fracturing does occur. If this situation occurs, increase the depth of the initial groove by 25 percent to assure the fracturing and proper functioning of each of the scheduled joints.

(3) Width and depth of sealant reservoir. The width and depth of the sealant reservoir for the weakened plane groove will conform to dimensions shown in Figure 12-31. The dimensions of the sealant reservoir are critical to satisfactory performance of the joint sealing materials.

(4) Spacing of transverse contraction joints. Transverse contraction joints will be constructed across each paving lane, perpendicular to the centerline, at intervals of not less than 3.8 meters (12.5 feet) and generally not more than 6 meters (20 feet) for the Navy and 6 meters (20 feet) for the Army and Air Force. The joint spacing will be uniform throughout any major paved area, and each joint will be straight and continuous from edge to edge of the paving lane and across all paving lanes for the full width of the paved area. Staggering of joints in adjacent paving lanes can lead to sympathetic cracking and will not be permitted unless reinforcement is used. The maximum spacing of transverse joints that will effectively control cracking will vary appreciably depending on pavement thickness, thermal coefficient and other characteristics of the aggregate and concrete, climatic conditions, and foundation restraint. It is impractical to establish limits on joint spacing that are suitable for all conditions without making them unduly restrictive. The joint spacings in Table 12-7 have given satisfactory control of transverse cracking in most instances and may be used as a guide, subject to modification based on available information regarding the performance of existing pavements in the vicinity or unusual properties of the concrete. For the best pavement performance, the number of joints should be kept to a minimum by using the greatest allowable joint spacing that will control cracking. Experience has shown, however, that oblong slabs, especially in thin pavements, tend to crack into smaller slabs of nearly equal dimensions under traffic. Therefore, it is desirable, insofar as practicable, to keep the length and width dimensions as nearly equal as possible. In no case should either dimension exceed the other dimension by more than 25 percent. Under certain climatic conditions, joint spacings different from those in Table 12-7 may be satisfactory. Where it is desired to change the joint spacing, a request will be submitted to the Transportation System Mandatory Center of Expertise, TSMCX (CENWO-ED-TX) for Army projects, or the appropriate Air Force Major Command for Air Force projects, regardless of who performs the design.

Table 12-7
Recommended Spacing of Transverse Contraction Joints

Pavement Thickness, millimeters (inches)	Spacing, meters (feet)
Less than 230 (9)	3.8 to 4.6 (12.5 to 15)
230 to 305 (9 to 12)	4.6 to 6 (15 to 20)
Over 305 (12)[1]	6 (20 max)

[1] 6-meter (20-foot) maximum spacing for Army and Air Force pavements.

(5) Spacing of longitudinal contraction joints. Contraction joints will be placed along the centerline of paving lanes that have a width greater than the determined maximum spacing of transverse contraction joints in Table 12-7. Contraction joints may also be required in the longitudinal direction of overlays, regardless of overlay thickness, to match joints existing in the base pavement unless a bond-breaking medium is used between the overlay and base pavement or the overlay pavement is reinforced.

(6) Doweled contraction joints. Dowels will be required in the last three transverse contraction joints back from the ends of all runways to provide positive load transfer in case of excessive joint opening due to cumulative shrinkage of the pavement. Similar dowel requirements may be included in the transverse contraction joints at the end of other long paved areas, such as taxiways or aprons where local experience indicates that excessive joint opening may occur. In rigid overlays in Air Force and Army Type A traffic areas, longitudinal contraction joints that would coincide with an expansion joint in the base pavement will be doweled. Dowel size and spacing will be as specified in Table 12-8.

(7) Aggregate Interlock. Aggregate interlock can provide adequate load transfer across joints when the pavement is originally constructed during hot weather. However, as joint movements due to temperature variation and load applications increase and the joint begins to open, aggregate interlock is lost and load transfer is greatly reduced. The effectiveness of aggregate interlock may be improved by increasing base strength and the angularity of coarse aggregate and shorter spacing of joints.

b. Construction Joints. Centerline longitudinal construction joints should be used on runways and taxiways.

(1) General. Construction joints may be required in both the longitudinal and transverse direction. Longitudinal construction joints (generally spaced 6 meters (20 feet) apart but may be more than one lane wide depending on construction equipment capability) will be required to separate successively placed paving lanes. Transverse construction joints will be installed when it is necessary to stop concrete placement within a paving lane for a length of time that will allow the concrete to start to set. All transverse construction joints will be located in place of other regularly spaced transverse joints (contraction or expansion types) and will normally be doweled butt joints. There are several types of construction joints available for use as shown in Figure 12-32 and as described below. The selection of the type of construction joint will depend on such factors as the concrete placement procedure (formed or slipformed), airfield type, adjacent existing pavement, and foundation conditions.

Table 12-8
Dowel Size and Spacing for Construction, Contraction, and Expansion Joints

Pavement Thickness mm (in.)	Minimum Dowel Length mm (in.)	Maximum Dowel Spacing mm (in.)	Dowel Diameter and Type
Less than 203 (8)	406 (16)	305 (12)	20-mm (3/4-in.) bar
203-292 (8-11.5)	406 (16)	305 (12)	25-mm (1-in.) bar
305-394 (12-15.5)	508 (20)	381 (15)	25- to 30-mm (1- to 1-1/4-in.) bar or 25-mm (1-in.) extra-strength pipe
406-521 (16 - 20.5)	508 (20)	457 (18)	25- to 40-mm (1- to 1-1/2-in.) bar or 25- to 60-mm (1- to 1-1/2-in.) extra-strength pipe
533-648 (21 - 25.5)	610 (24)	457 (18)	50-mm (2-in.) bar or 50-mm (2-in.) extra-strength pipe
660 (26) or more	762 (30)	457 (18)	75-mm (3-in) bar or 75-mm (3-in.) extra-strength pipe

(2) Doweled butt joint. The doweled butt joint is considered to be the best joint for providing load transfer and maintaining slab alignment. Therefore, it is the desirable joint for the most adverse conditions, such as heavy loading, high traffic intensity, and lower strength foundations. However, because the alignment and placement of the dowel bars are critical to satisfactory performance, the dowels must be carefully aligned, especially for slipformed concrete. The doweled butt joint is required for all transverse construction joints.

(3) Thickened-edge joint. Thickened-edge-type joints may be used in lieu of other types of joints employing load-transfer devices. The thickened-edge joint is constructed by increasing the thickness of the concrete at the edge to 125 percent of the design thickness. The thickness is then reduced by tapering from the free-edge thickness to the design thickness at a distance 1.5 meters (5 feet) from the longitudinal edge. The thickened-edge butt joint is considered adequate for the load-induced concrete stresses. The thickened-edge joint may be used at free edges of paved areas to accommodate future expansion of the facility or where aircraft wheel loadings may track the edge of the pavement.

c. Expansion Joints.

(1) General. Expansion joints will be used at all intersections of pavements with structures and may be required within the pavement features. A special expansion joint required at pavement intersections is the slip joint. The types of expansion joints are the thickened-edge, the thickened-edge slip joint, and the doweled type (Figures 12-33 and 12-34). Filler material for the thickened-edge and doweled-type expansion joint will be a nonextruding type. Bituminous filler material will not be used when the sealer is non-bituminous. The type and thickness of filler material and the manner of its installation will depend upon the particular case. Usually a preformed material of 19-millimeter (3/4-inch) thickness will be adequate, but in some instances a greater thickness of filler material may be required. Filler material for slip joints will be either a heavy coating of bituminous material not less than

6 millimeters (1/4 inch) in thickness when joints match or normal nonextruding-type material not less than 6.3 millimeters (1/4 inch) in thickness when joints do not match. Where large expansions may have a detrimental effect on adjoining structures, such as at the juncture of rigid and flexible pavements, expansion joints in successive transverse joints back from the juncture should be considered. The depth, length, and position of each expansion joint will be sufficient to form a complete and uniform separation between the pavements and between the pavement and the structure concerned and, unless doweled, must be completely straight from end to end so translation can occur. The designer should dowel expansion joints only under special conditions. (Use thickened edge expansion joints.) Expansion joint filler must cover the full depth of the joint surface so there is no point-to-point contact of concrete.

(2) Between pavement and structures. Expansion joints will be installed to surround, or to separate from the pavement, any structures that project through, into, or against the pavements, such as at the approaches to buildings or around drainage inlets and hydrant refueling outlets. The thickened-edge-type expansion joint will normally be best suited for these places.

(3) Within pavements.

(a) Expansion joints within pavements must be carefully constructed. Except for protecting abutting structures and taxiways intersecting at an angle, their use will be kept to the absolute minimum necessary to prevent excessive stresses in the pavement from expansion of the concrete or to avoid distortion of a pavement feature through the expansion or translation of an adjoining pavement. The determination of the need for and spacing of expansion joints will be based upon pavement thickness, thermal properties of the concrete, prevailing temperatures in the area, temperatures during the construction period, and the experience with concrete pavements in the area.

(b) Longitudinal expansion joints within pavements will be of the thickened-edge type (Figure 12-33). Dowels are not recommended in longitudinal or most transverse expansion joints because differential expansion and contraction and subgrade movement parallel with the joints may develop undesirable localized strains and possibly failure of the concrete, especially near the corners of slabs at transverse joints.

(c) Transverse expansion joints within pavements will often be the doweled type (Figure 12-33). There may be instances when it will be desirable to allow some slippage in the transverse joints, such as at the angular intersection of pavements to prevent the expansion of one pavement from distorting the other. In some of these instances, instead of a transverse expansion joint, a thickened-edge slip joint may be used (Figure 12-34). When a thickened-edge joint (slip joint) is used at a free edge not perpendicular to a paving lane, a doweled transverse expansion joint will be provided as shown in Figure 12-32.

d. Dowels. The important functions of dowels or any other load-transfer device in concrete pavements are to help maintain the alignment of adjoining slabs and to transmit loads across the joint. Different sizes of dowels will be specified for different thicknesses of pavements (Table 12-8). When extra-strength pipe is used for dowels, the pipe will be filled with either a stiff mixture of sand-asphalt or portland cement mortar, or the ends of the pipe will be plugged. If the ends of the pipe are plugged, the plug must fit inside the pipe and be cut off flush with the end of the pipe so that there will be no protruding material to bond with the concrete and prevent free movement of the dowel. Figures 12-30, 12-32, and 12-33 show the dowel placement. All dowels will be straight, smooth, and free from burrs at the ends. One end of the dowel will be painted and oiled to prevent bonding with the concrete. Dowels used at expansion joints will be capped at one end, in addition to painting and oiling, to permit further penetration of the dowels into the concrete when the joints close.

e. Special Provisions of Slipforming Paving.

(1) Provisions must be made for slipform pavers when there is a change in longitudinal joint configuration. The thickness may be varied without stopping the paving train, but the joint configuration cannot be varied without modifying the side forms, which will normally require stopping the paver and installing a header. The requirements discussed as follows shall apply.

(2) The header may be set on either end of the transition slab with the transverse construction joint doweled as required. As an example, for the transition between the type A and type D areas on a medium-load pavement, the header could be set at the end of either type pavement. The dowel size and location in the transverse construction joint should be commensurate with the thickness of the pavement at the header.

f. Joint Sealing. All joints will be sealed with a suitable sealant to prevent infiltration of surface water and solid substances. The Army and Air Force do not require all joints to be sealed with preformed compression seals. Jet-fuel-resistant (JFR) sealants will be used in the joints of aprons, warm-up holding pads, hardstands, washracks, and other paved areas where fuel may be spilled during the operation, parking, maintenance, and servicing of aircraft. In addition, heat-resistant JFR joint sealant materials will be used for runway ends and other areas where the sealant material may be subject to prolonged heat and blast of aircraft engines. Non-JFR sealants will be used in the joints of all other airfield pavements. JFR sealants will conform to Federal Specification SS-S-200 or ASTM D 3569 and D 3581. Non-JFR sealants will conform to ASTM D 3405, D 3406, D 1190, and CRD-C-525. Silicone sealants meeting ASTM D 5893 may also be used in both JFR and non-JFR areas. When heat- and blast-resistant JFR sealants are required, they will conform to Federal Specification SS-S-200. An optimal sealant, meeting both the heat- and blast-resistant JFR and non-JFR sealant requirements, is a preformed compression seal conforming to ASTM D 2628 and D 2835. As a general rule, compression-type preformed sealants must have an uncompressed width of not less than twice the width of the joint reservoir. However, the maximum and minimum dimensions for the seal width should be based on the joint opening and expected movement. The selection of a pourable or preformed sealant should be based upon the economics involved and the service life desired. Compression seals will remain effective five to seven times as long as liquid sealants.

g. Special Joints and Junctures. Situations will develop where special joints or variations of the more standard-type joints will be needed to accommodate movements that will occur and to provide a satisfactory operational surface. Some of these special joints or junctures as shown in Figure 13-2 are discussed in the following paragraphs and in particular, paragraph 11.

11. JOINTS FOR NAVY AND MARINE CORPS PAVEMENT.

a. Expansion Joints. Expansion joints allow for the expansion of the pavement and the reduction of high compressive stresses at critical locations in the concrete pavement in hot weather. Expansion joints are placed the full depth of the slab. Expansion joints should be used at all intersections of pavements with fixed structures, at nonperpendicular pavement intersections, and between existing and new concrete pavements when the joints in the adjacent slabs are not aligned. Expansion joints are not otherwise required within the nonreinforced concrete pavement. See Figure 12-34 for expansion joint details.

b. Contraction (Weakened Plane) Joints. Contraction joints should be used to control cracking in the pavement due to volume changes resulting from a temperature decrease or a moisture decrease and to limit curling and warping stresses from temperature and moisture gradients in the pavement. Contraction joints are formed in concrete by partial depth sawing or by installing sawable inserts. The saw cut joint or formed groove provides a weakened plane which will crack through the full slab depth during shrinkage and contraction of the concrete as it cures. Contraction joints are required in the transverse direction and also in the longitudinal direction depending upon slab thickness and spacing of the construction joints. See Figure 12-30 for contraction joint details.

c. Construction Joints. Construction joints are used between paving lanes or when abutting slabs are placed at different times. Longitudinal and transverse construction joints may be required. Transverse construction joints will be required when it is necessary to stop concrete placement for a length of time sufficient to allow the concrete to begin to set. Longitudinal construction joints are generally spaced 6 meters (20 feet) apart but may be multiple lane width, depending on the construction equipment.

(1) Transverse construction joints. When possible, locate all transverse construction joints at the same location as regularly spaced transverse joints. Provide for load transfer or a thickened edge.

(2) Longitudinal construction joints. Construct longitudinal construction joints as shown in Figure 12-32 and indicated below.

(a) Keyed joint. Keyways have been used extensively to provide load transfer along longitudinal joints. However, there has been a substantial amount of keyway failure under heavy aircraft loading on thinner slabs. Keyed joints may only be used on slabs 225 mm (9 in.) thick or greater.

(b) Butt joint. A butt joint may be used for longitudinal construction joints on pavements less than 229 mm (9 in.) thick constructed with a stabilized base.

(c) Thickened-edge joint. A thickened-edge joint may be used for longitudinal construction joints. The thickened-edge joint may be used for any pavement thickness and base type.

d. Joint Spacing. The standard slab size for pavements is 3.8 by 4.6 meters (12.5 by 15 feet). Transverse joint spacing is 4.6 meters (15.0 feet) and longitudinal joint spacing is 3.8 meters (12.5 feet). For slabs having a thickness greater than 300 millimeters (12 inches), joint spacing can be increased to a maximum of 6.1 meters (20 feet). The transverse joint spacing shall not vary from the longitudinal joint spacing by more than 25 percent. Figure 12-29 shows standard joint spacings.

e. Load Transfer Design. A properly designed joint must provide adequate load-transfer across the joint. Load transfer efficiency is normally defined as the ratio of deflection of the unloaded side to the deflection of the loaded side of the joint. Good load transfer will aid in preventing deterioration such as corner breaks, transverse and longitudinal cracking, faulting, pumping, and spalling. Different amounts of load transfer can be obtained through the use of aggregate interlock, dowel bars, keyways, a stabilized base, or a combination of these.

(1) Aggregate interlock. Aggregate interlock can provide adequate load transfer across joints when the pavement is originally constructed or during hot weather. However, as joint movements due to temperature variation and load applications increase and the joint begins to open, aggregate interlock is lost and load transfer is greatly reduced. The effectiveness of aggregate interlock may be improved by increasing base strength and the angularity of coarse aggregate and shorter spacing of joints.

(2) Dowel bars. Dowel bars are used to provide load transfer and prevent excessive vertical displacements of adjacent slabs. There are some situations where the use of dowels is appropriate, such as for creating load transfer where tying in to existing pavements.

(3) Stabilized base. A stabilized base can be used to improve load transfer effectiveness by reducing joint deflections through increased support across a joint. Use a stabilized base for all pavements less than 225 millimeters (9 inches) thick to provide improved load transfer and lower deflections and stresses. A stabilized base may also be used for pavements greater than 225 millimeters (9 inches) thick to provide additional load transfer. Where thickened-edge joints are used, the stabilized base is not required.

f. Joint Sealants. Joint sealants are used to provide a seal to reduce infiltration of water and incompressibles. An effective joint seal will help retard and reduce distress related to free water and incompressibles, such as pumping, spalling, faulting, and corrosion of mechanical load transfer devices. Several pavement areas require fuel-resistant or blast-resistant joint sealants. Use jet fuel-resistant sealants for all aprons. Use blast-resistant sealants for the first 305 meters (1,000 feet) of runways and exits at runway ends. Use sealing compounds meeting ASTM D 1190, D 3405, or D 3406 for taxiways and runway interiors.

(1) Types of sealant materials. The three major types of sealant materials are (a) field poured, hot applied; (b) field poured, cold applied; and (c) preformed compression seals. These materials may be jet fuel resistant (tar-based) or nonjet fuel resistant (typically asphalt based).

(a) Field poured, hot applied. This group of sealants includes rubberized asphalt sealant and rubberized tar sealant. Rubberized asphalt joint sealants must meet ASTM D 1190, D 3405, or D 3406. Rubberized tar sealants must meet ASTM D 3569 or D 3581.

(b) Field poured, cold applied. These are two-component, polymer-based, cold-applied heat and jet fuel-resistant joint sealants. These sealants must meet Federal Specification SS-S-200E. The Air Force and Navy recommends the use of silicone sealants that conform to NFGS 02522, 02562, and ASTM 5893 in lieu of sealants that meed Federal Specification SS-S-200E.

(c) Preformed compression seals. The most common type of preformed compression seal is the neoprene compression seal. Neoprene compression seals must satisfy ASTM D 2628. Preformed compression seals may be used in the areas designated in NFGS-02522. Preformed compression seals are designed to be in compression for their entire life. There is little bond between the compression seal and the sidewalls of the joint to sustain tension.

(2) Joint reservoir design. The joint reservoir must be properly designed so that the joint sealant can withstand compressive and tensile strains.

(a) Field poured sealants. The shape factor, which is defined as the ratio of the depth of the sealant to the width of the joint, should be between 1.0 and 1.5. Dimensions of the joint sealant and reservoir are shown in Figure 12-30. A backer rod or bond breaking tape must be used to help obtain a proper shape factor and to prevent the joint sealant from bonding to the bottom of the joint reservoir. Most field poured liquid joint sealants can withstand strains of approximately 25 percent of their original width. Joint reservoir and sealant dimensions shown in Figure 12-30 are based on a slab size of 3.8 by 4.5 meters (12.5 by 15.0 feet).

(b) Preformed compression seals. The reservoir width for preformed compression seals must be designed to keep the sealant in compression at all times. The depth of the reservoir must exceed the depth of the seal but is not related directly to the width of the joint. The width of the compression seal should be approximately twice the width of the joint. The limits on the compression seal are normally 20 percent minimum and 50 percent maximum compression strain of the original sealant width. For example, the working range of a 25-millimeter (1-inch) wide neoprene compression seal is from 13 to 20 millimeters (0.5 to 0.8 inches). If the seal is subjected to compression greater than the 50 percent level for extended periods of time, the seal may take a compression set, and the webs may bond to each other. If this happens, the seal will not open as the joint opens, and the seal will no longer be effective. The joint dimensions for the standard size slab are shown in Figure 12-30. Design sealant dimensions based on the actual joint spacing. Choose preformed neoprene compression seal dimensions so that the working range of the joint is within the working range of the sealant.

12. JOINTING PATTERN FOR RIGID AIRFIELD PAVEMENTS. Proper jointing pattern for rigid airfield pavement is a critical item of design and construction for all services. Not only is it important for a quality product, but it can and should promote efficiency for the construction contractor, and thus cost savings. Criteria for type of joints, their location, and maximum allowable spacing have been given in the previous paragraphs. This paragraph focuses on appropriate and efficient layout of the jointing pattern. Laying out a good jointing pattern depends on experience working at it and is more of an art than a science. The designer must learn to play with it and try various combinations until the optimum layout is reached. Every productive hour spent on this produces appreciable cost savings.

a. General. All project joint layout drawings should have a prominent note on them saying "No changes in the jointing pattern shall be made without the written approval of the design engineer." The design engineer must make every effort to provide an efficient layout for construction, consistent with the limits of criteria. However, once the joint layout is finalized, no change whatever should be made by field personnel unless examined and approved in writing by the designer to be sure that it does not compromise his plan or violate criteria.

b. Layout. Joint layouts should be as simple and as uniform as possible and meet all criteria of the preceding paragraphs. Except for unusual circumstances, all joints should have straight lines with the longitudinal and transverse joints at right angles. Careful study must always be made to ensure that the paving lanes (longitudinal construction joints vs transverse joints) are laid out in the right direction for the contractor's efficient work--particularly where the area has irregular boundaries.

c. Spacing. Longitudinal construction joints should be spaced such that the widths of pioneer (pilot) lanes are all equal and any variability in total distance is taken care of in a few fill-in lanes, where setting the paver width is not such a problem. Except where impractical, the jointing pattern should not require slabs that have one side exceeding the other by more than 25 percent; if any slab exceeds this, it must be reinforced--an extra expense.

d. Longitudinal Construction Joints. Never should longitudinal construction joints be spaced by simply dividing the overall distance into a whole number of lanes of equal width, unless that width comes out to an easily used value for the paving operations. If practical, pioneer lanes should have widths in multiples of 6 inches, or, if metric is used for the project, multiples of 250 millimeters. Extensions to the paver are easily made in these intervals. Other, odd intervals can be used, but they are more expensive for the contractor to adjust. Fill-in lane widths should be reasonably close to the pioneer lanes, and all fill-in lanes can be made the same width as necessary to accommodate the total distance. However, if the take-up distance is small, it is usually better to provide it in just one or two lanes and make the rest of the fill-in lanes uniform in width--simply to reduce the chance of measurement error during construction.

e. Transverse Contraction Joints. For transverse contraction joints, the spacing should be the same as the longitudinal construction joints, or close to the same. Again, it is usually not appropriate to design the transverse joints all with the same spacing, unless this comes out with easily measured spacing. Otherwise, make spacing an easily remembered and an easily measured distance, with any take-up distance provided in one or two spaces. One main objective is to provide spacings that are easy for the joint saw crew (usually working at night) to follow and not get confused (no fractional inches, or odd metric units, and as little variation as possible).

f. Replacements and Additions. Much of the present airfield paving work consists of replacement areas and additions to existing pavement. This often results in odd-shaped areas with irregular boundaries, proving difficult to provide a really good jointing pattern. As much as possible, the guidelines in the previous subparagraphs should be followed, modified as absolutely necessary. Care should be taken to, as much as possible, prevent small slabs and odd-shaped slabs requiring reinforcement. When working with areas having irregular boundaries, it becomes a process of trial and error to provide the best fit to the area, following criteria and minimizing as much as possible the need for odd-shaped reinforced slabs--an expense to be avoided. When abutting existing PCC pavement, an attempt should be made to match the existing joint pattern, where possible. Older pavements will often have 7.6-meters (25-foot) joint spacing, when now we are usually allowed a maximum of 6 meters (20 feet). For jobs of moderate size, if it is possible to match the existing joint pattern, the new joint spacing can be made 7.6 meters (25 feet), provided the existing has shown no distress because of the 7.6-meter (25-foot) spacing. Otherwise, use 3.8-meter (12.5-foot) spacing. Either is acceptable, but the Using Service should be contacted to get their preference--some like one and some the other.

g. Expansion Joints and Slip Joints.

(1) New PCC to New PCC. Where pavements abut buildings and other fixed objects, an expansion joint should be provided. Where two new PCC pavements meet a an angle, an expansion joint is necessary. If they meet at a 90-degree angle, the intersection should be a, thickened-edge expansion joint. If they meet at other than a 90-degree angle, it should be a thickened-edge joint, either expansion joint or slip joint. If the joints on new-to-new construction do not match and no expansion or slip joint is used, 900-millimeter (3-foot) wide strips of reinforcing should be installed along each side of the joint to prevent sympathetic cracks from forming in line with mismatched joints. Normally, expansion joints of any kind should not be doweled if load transfer can be provided in another way. There have been projects where doweled expansion joints have been successfully used, but this should be used only where no translation movements or stresses are expected.

(2) New PCC to Old PCC. Where new PCC pavement meets old (existing) PCC pavement at an angle, an attempt should be made to provide load transfer. At a 90-degree intersection, an ordinary thickened edge (one side) expansion joint can be used if no load transfer is necessary (existing pavement so understrength that it will not match the new pavement). At a 90-degree intersection and at an intersection other than 90 degrees, it usually will be best to put in a doweled construction joint at the intersection, and then install a thickened-edge expansion joint far enough back on the new pavement to totally clear any fillets and give the shortest unobstructed (straight) line across the pavement. .

(3) Slip Joints. Slip joints, 6-millimeter (1/4-inch) minimum thickness, can be used in lieu of expansion joints in places where only translation is expected, and no movement perpendicular to the joint is expected. At 6-millimeter (1/4-inch) thickness, they are sufficient to prevent sympathetic cracking across the joint, and thus eliminate the need for the 900-millimeter (3-foot) strip of reinforcing on each side of new-to-new construction.

h. Special Joint. A "special joint", as shown in Figure 12-32 (Sheet 3 of 3), can be used to provide load transfer on the existing side of a new PCC to old PCC joint. This can be used under the conditions listed below. Although somewhat expensive, this is an excellent joint when constructed properly, but requires close supervision in the field to ensure that the constructor builds it properly. Note that considerable handwork is required in grading the undercut and placing concrete and reinforcement. (Never should the contractor be allowed to attempt to fill the undercut with concrete spread by the paver.) Special joint (undercut) between new and existing pavements. A special joint (undercut) (Figure 12-32 (Sheet 2 of 3)) may be used at the juncture of new and existing pavements for the following conditions:

(1) When load-transfer devices (keyways or dowels) or a thickened edge was not provided at the free edge of the existing pavement.

(2) When load-transfer devices or a thickened edge was provided at the free edge of the existing pavement, but neither met the design requirements for the new pavement.

(3) For any joints, when removing and replacing slabs in an existing pavement if the existing load-transfer devices are damaged during the pavement removal, and if other types of joints are suitable.

The special joint design need not be required if a new pavement joins an existing pavement that is grossly inadequate to carry the design load of the new pavement or if the existing pavement is in poor structural condition. If the existing pavement can only carry a load that is 50 percent or less of the new pavement design load, special efforts to provide edge support for the existing pavement may be omitted. However, if the provisions for edge support are omitted, accelerated failures in the existing pavement may be experienced. Any load-transfer devices in the existing pavement should be used at the juncture to provide as much support as possible to the existing pavement. The new pavement will simply be designed with a thickened edge at the juncture. Drilling and grouting dowels in the existing pavement for edge support may be considered, if structurally suitable, as an alternative to the special joint, but a thickened-edge design will be used for the new pavement at the juncture.

i. Tied Joints (Navy Only). Tied joints are seldom used for airfield pavement. However, two instances occur:

(1) As required and shown in Figure 12-29, "Typical Jointing". (The situation must be evaluated and existing service experience observed to prevent tying two slabs that have conditions (dimensions or aggregate properties) which may cause a crack to form between the tied joint and the next adjacent joint.)

(2) Where half a slab is removed across a paving lane halfway between transverse joints (at least 3 meters (10 feet) must be removed and not less than 3 meters (10 feet) remain). In this instance, the new construction joint of new to existing, at mid-slab, must be tied (with drilled and epoxied reinforcing bars). No joint reservoir should be sawed, or sealant applied.

j. Portland Cement Concrete to Asphalt Concrete Intersections. Figures 12-35, 12-36, 12-37, and 12-38 show various types of joints to use for the juncture of PCC and AC pavements.

(1) Figure 12-35. This joint is to be used for most transverse joints that will receive aircraft traffic at Army installations and for all transverse joints that will receive aircraft traffic at Air Force installations.

(2) Figure 12-36. This detail can be used for transverse joints in areas where high-speed aircraft traffic is expected. It is a more conservative joint, but also more expensive. The Using Service should be contacted to determine which joint they prefer. This joint should no be used for Air Force jobs.

(3) Figures 12-37 and 12-38 show joints that can be used where no appreciable aircraft traffic is expected to cross. (Such as longitudinal joints on the outer edges of PCC keel sections in an AC pavement and similar locations.)

(4) Normally, the joint between PCC pavement and AC shoulder pavement should be a plain butt joint. Depending on local experience, it may be well to saw a reservoir in this joint and apply joint sealer.

k. Sample Joint Layouts. Figures 12-39 through 12-43 are samples of various typical jointing patterns. An explanation of the significance and details of each is in the following subparagraphs.

(1) Figure 12-39. This shows a perfect jointing pattern for a rectangular pavement with easily divided boundary dimensions. Unfortunately such regular dimensions and shapes do not often occur--particularly in all the replacement and repair work being required now.

(2) Figure 12-40. Metric.

(a) This figure shows the same 30.4 meters (100 feet) by 42.7 meters (140 feet) pavement as Figure 12-39, but everything is in metric (SI). It can be seen at the bottom of the page that the longitudinal construction joints have been evenly spaced across the 30.4 meters (100 feet.) This may look nice on paper, but it requires the contractor to set the width of his paver for an odd width--more expensive. If there were a large number of longitudinal lanes, it could be appropriate to make them all the same width, even if this were an odd dimension for all the lanes, since this would require only one odd setting of the paver width. At the top of the page is a layout showing four lanes at 6.0-meter (19.7-foot) width and a single fill-in lane at an odd width. (The width of the fill-in lanes is not so critical.)

(b) At the right-hand side of the figure is shown a spacing for transverse contraction joints--an odd spacing obtained by dividing the total distance into a series of equal width spacing. This is, of course, feasible to construct a series of very odd cumulative spacings. This makes it more likely that the joint sawing crew (usually working at night) may make a mistake in adding the cumulative distance, and thus get a joint out of line. The spacing shown on the left side of the page, with six spaces at 6.0 meters (19.7 feet) and one takeup space of 6.56 meters (21.5 feet), is much easier for the joint sawing crew to work with, and thus much less likely to get out of line. Always make joint layouts as simple as possible, within criteria.

(3) Figure 12-41.

(a) This figure, for a 54-meter (180-foot) wide pavement, shows nice, easy spacing of longitudinal and transverse joints, if everything is in the inch-pound system. See the spacing of 6 meters (20 feet) by 6 meters (20 feet), at the top and right side of the drawing. However, if the same overall width has to be designed in metric, it gets more complicated. Still, there is a variety of spacing that can be feasibly used for transverse contraction joints.

(b) Longitudinal construction joints are a problem, however. At the bottom of the figure are shown three possible solutions. The top one of the three is very pretty and easy to design, but it requires the contractor to adjust his paver to an odd width for the pioneer lanes--an extra expense. The middle line of the three shows a good jointing pattern with nine lanes at 6.0 meters (20 feet) and two fill-in lanes at 6.36 meters (20.9 feet)--well within criteria for shape. The bottom one of the three is also a good jointing pattern with five pioneer lanes at 6.0 meters (20 feet) and four fill-in lanes at 6.18 meters (20.3 feet). Neither of these two last systems requires the contractor to adjust his paver to anything other than an even width or to make any changes in adjustment.

(4) Figure 12-42. This is simply a further explanation of Figure 13-2b, with more details. See also subparagraph 12g.

(a) This figure shows a new PCC pavement intersecting an existing PCC pavement at an angle (90 degrees). Such an intersection requires a joint that can tolerate movement, both at right angles to the joint and along the joint, as well as providing load transfer across the joint.

(b) One approach would be to drill and grout dowels in the existing PCC and put in a doweled expansion joint at the intersection. This is not desirable, because it locks the two pavements together and does not permit any translation movement along the joint. This is particularly significant if the angle of intersection is other than 90 degrees.

(c) Another approach would be to put in a thickened-edge expansion joint at the intersection. But often the existing pavement will not have a thickened edge--and thus no true load transfer across the joint can take place.

(d) The usual approach is to provide joints as shown. A doweled construction joint is installed at the intersection of the two pavements--dowels drilled and grouted into the existing PCC. This provides load transfer but no chance for translation movement. Opportunity for movement is provided by installing a thickened-edge expansion joint at a transverse joint in the new pavement. This should be just far enough back to provide a straight joint from edge to edge of the pavement (primarily to get past the end of the fillet). Note that transverse joints within the fillet area are not straight lines and would prohibit any movement along the joint.

(e) Note that the existing joints and the joints in the new area between the intersection and the expansion joint are at the same spacing. This prevents the need for any other action to prevent sympathetic cracking from any mismatched joints at the intersection. (Not always is it feasible to line up these joints, but an attempt to should be made.) At the expansion joint it is not necessary to line up joints on both sides. This permits making an easy change from the existing joint spacing to a different spacing in the new pavement.

(f) Also note that the 900-millimeter (3-foot) ends of joints intersecting curved fillets must be angled to be perpendicular to the curve at their intersection.

(5) Figure 12-43. This figure illustrates what can happen when a good jointing pattern is messed up by the joint sawing crew. This occurred on a big PCC apron at a military base. What happened was that the crew sawing transverse contraction joints (at night of course) spaced the sawed transverse joints as intended in about 85 percent of the longitudinal paving lanes, with 37 uniformly spaced joints at the left end of the apron, and 3 lesser spaced joints at the right end. But, on the other 15 percent of the longitudinal lanes, they measured the transverse joints backward, with uniform spacing at the right end and lesser spacing at the left end. Outside of the fact that there will be sympathetic cracking at the mismatched joints, structurally the pavement is excellent with a good surface finish.

(6) To reiterate, regardless of the shape and dimensions of the pavement to be constructed, the simplest jointing pattern, conforming to criteria, will be best.

CHAPTER 13

REINFORCED CONCRETE PAVEMENT DESIGN

1. GENERAL. These designs are applicable to Army and Air Force pavements but will not normally be used for Navy and Marine Corps projects. However, reinforced concrete may be considered for special or unusual design conditions on a case-by-case basis and must be approved by the Naval Facilities Engineering Command. The exception to this is in odd-shaped slabs and mismatched joints where reinforcing is required.

2. BASIS FOR DESIGN - NAVY AND MARINE CORPS. Reinforced concrete pavements employ longer joint spacings than plain concrete pavements. The cracks that develop from shrinkage, warping, curling, and traffic load stresses are held together by reinforcement. Steel reinforcing is used to slow the deterioration of cracks that develop in the concrete slab by holding these cracks tightly together to maintain aggregate interlock. When approved for use, design procedures for Navy and Marine Corps reinforced concrete pavements will be the same as for Army and Air Force reinforced pavements.

a. Thickness. The thickness design for reinforced concrete pavement is similar to plain concrete pavement design, modified by the results of accelerated traffic tests. These tests demonstrate that the required pavement thickness may be less than the required thickness of a plain concrete pavement that provides equal performance. However, as thickness is reduced substantially, premature distress may occur. Therefore, because of inconsistent performance of thin reinforced pavements, for new construction, the thickness shall not be reduced from that determined for plain concrete.

b. Reinforcement. Reinforcing steel is usually required in both the transverse and longitudinal directions. The steel may be deformed bars or welded wire fabric. Typical amounts of reinforcing range from 0.05 to 0.25 percent area.

c. Joints. The maximum slab size for reinforced concrete pavements is a function of the slab thickness, yield strength of the reinforcing steel, and the percent of reinforcement. Slab size is commonly 7.6 meters (25 feet) square. All joints in reinforced concrete pavements, with the exception of keyways and thickened-edge joints, are doweled. Dowels are effective in providing load transfer. Alignment of the dowel bars and adequate consolidation around the dowel basket are critical factors.

3. BASIS FOR DESIGN - ARMY AND AIR FORCE. Steel reinforcement in the concrete provides improved continuity across the cracks that develop because of environmental factors or induced loads. The improved crack continuity results in better performance under traffic and less maintenance than an equal thickness of plain concrete pavement. Thus, for equal performance, the thickness of reinforced concrete pavement can be less than the thickness of plain concrete pavements. The design procedure presented herein yields the thickness of reinforced concrete pavement and the percentage of steel reinforcement required to provide the same performance as a predetermined thickness of plain concrete pavement constructed on the same foundation condition. The procedure has been developed from full-scale accelerated traffic testing. Failure is considered to be severe spalling of the concrete along the cracks that develop during traffic.

4. USES FOR REINFORCED CONCRETE. Reinforced concrete pavement may be used as slabs on grade or as overlay pavements for any traffic area of the airfield. Reinforcement may be used to reduce the required thickness and permit greater spacing between joints. Its selection should be based upon

the economics involved. In certain instances, reinforcement will be required to control cracking that may occur in plain concrete pavements without any reduction in thickness requirements.

5. REDUCED THICKNESS DESIGN - ARMY AND AIR FORCE.

a. General. The greatest use of reinforcement to reduce the required plain concrete pavement thickness will probably be to provide a uniform thickness for the various types of traffic areas as different structural conditions of the base pavement. Since these changes in thickness cannot be made at the surface, reinforcement can be used to reduce the required thickness and thereby avoid the necessity for removal and replacement of pavements or overdesigns. There are other instances in which reinforcement to reduce the pavement thickness may be warranted and must be considered, but the economic feasibility for the use of reinforcement must also be considered. The design procedure consists of determining the percentage of steel required, the thickness of the reinforced concrete pavement, and the maximum allowable length of slabs. In addition, a computer program discussed in Chapter 1 may be used for the design of reinforced concrete pavement.

b. Determination of Required Percent Steel and Required Thickness of Reinforced Concrete Pavement. It is first necessary to determine the required thickness of plain concrete pavement using the design loading and physical properties of the pavement and foundation. When the reinforced concrete pavement is to be placed on stabilized or nonstabilized bases or subgrades, the procedure outline in Chapter 12 will be used to determine the thickness of plain concrete. The thickness of plain concrete is then used to enter Figure 13-1 to determine the required percent steel and the required thickness of reinforced concrete pavement. Since the thickness of reinforced concrete and percent steel are interrelated, it will be necessary to establish a desired value of one and determine the other. The resulting values of reinforced concrete thickness and percent steel will represent a reinforced concrete pavement that will provide the same performance as the required thickness of plain concrete pavement. In all cases, when the required thickness of plain concrete pavement is reduced by the addition of reinforcing steel, the design percentage of steel will be placed in each of two directions (transverse and longitudinal) in the slab. For construction purposes, the required thickness of reinforced concrete must be rounded to the nearest full- and half-inch increment. When the indicated thickness is midway between full- and half-inch, the thickness will be rounded upward.

c. Determination of Maximum Reinforced Concrete Pavement Slab Size. The maximum length or width of the reinforced concrete pavement slabs is dependent largely upon the resistance to movement of the slab on the underlying material and the yield strength of the reinforcing steel. The latter factor can be easily determined, but very little reliable information is available regarding the sliding resistance of concrete on the various foundation materials. For this design procedure, the sliding resistance has been assumed to be constant for a reinforced concrete pavement cast directly on the subgrade, on a stabilized or nonstabilized base course, or on an existing flexible pavement. The maximum allowable width W or length L of reinforced concrete pavement slabs will be determined from the following:

$$W \text{ or } L = 0.2224 \sqrt[3]{h_d (y_s S)^2} \quad \text{for SI Units}$$

$$W \text{ or } L = 0.0777 \sqrt[3]{h_d (y_s S)^2} \quad \text{for English Units} \qquad (13\text{-}1)$$

where

h_d = design thickness of reinforced concrete, millimeters (inches)

y_s = yield strength of reinforcing steel, normally 413.7 MPa (60,000 psi)

S = percent reinforcing steel

The formula above has been expressed on the nomograph (Figure 13-1) for a steel yield strength y_s of 413.7 MPa (60,000 psi), and the maximum length or width can be obtained from the intersection of a straight line drawn between the values of design thickness and percent steel that will be used for the reinforced concrete pavement. The width of reinforced concrete pavement will generally be controlled by the concrete paving equipment and will normally be 7.6-12.1 meters (25-40 feet), unless smaller widths are necessary to meet dimensional requirements.

d. Limitations to Reinforced Concrete Pavement Design Procedure. The design procedure for reinforced concrete pavements presented herein has been developed from a limited amount of investigational and performance data. Consequently, the following limitations are imposed:

(1) No reduction in the required thickness of plain concrete will be allowed for percentages of steel reinforcement less than 0.05.

(2) No further reduction in the required thickness of plain concrete pavement will be allowed over that indicated for 0.5 percent steel reinforcement in Figure 13-1 regardless of the percent steel used.

(3) No single dimension of reinforced concrete pavement slabs will exceed 30.5 meters (100 feet) regardless of the percent steel used or slab thickness.

(4) The minimum thickness of a reinforced concrete pavement or overlay will be 152 millimeters (6 inches).

6. REINFORCEMENT TO CONTROL PAVEMENT CRACKING.

a. General. Reinforcement is mandatory in certain pavement areas to control or minimize the effects of cracking. The reinforcing steel holds cracks tightly closed, thereby preventing spalling at the edges of the cracks and progression of the cracks into adjacent slabs. For each of the following conditions, the slabs or portions of the slabs will be reinforced with 0.05 percent steel in two directions normal to each other unless otherwise specified. No reduction in thickness will be allowed for this steel.

b. Odd-shaped Slabs. It is often necessary in the design of pavement facilities to resort to odd-shaped slabs. Unless reinforced, these odd-shaped slabs often crack and eventually spall along the cracks, producing debris that is objectionable from operational and maintenance viewpoints. In addition, the cracks may migrate across joints into adjacent slabs. In general, a slab is considered to be odd-shaped if the longer dimension exceeds the shorter one by more than 25 percent or if the joint pattern does not result in essentially a square or rectangular slab. Figure 13-2 presents typical examples of odd-shaped slabs requiring reinforcement. Where practicable, the number of odd-shaped slabs can be minimized by using a sawtooth fillet and not reinforcing.

c. Mismatched Joints. Steel reinforcement in the slabs is mandatory to prevent migration of cracks into adjacent pavements for the following two conditions of mismatched joints:

(1) Where joint patterns of abutting pavement facilities do not match, partial reinforcement of slabs may be necessary. In such a condition, the mismatch of joints can cause a crack to form in the adjacent pavement unless there is sufficient width of bond-breaking medium installed in the joint. The determination relative to using reinforcement at mismatched joints in such junctures is based upon the type of joint between the two pavement sections. A partial reinforcement of the slab, as described below, is required when the joint between the abutting pavement is one of the following: (a) doweled construction joint, (b) keyed construction joint, (c) thickened-edge butt joint without a bond-breaking medium, (d) doweled expansion joint, and (e) thickened-edge slip joint with less than 6.4-millimeter (1/4-inch) bond-breaking medium. Reinforcement is not required if the joint between the abutting pavement facilities is either a thickened-edge expansion joint or a thickened-edge slip joint with 6.4 millimeters (1/4 inch) or more of bond-breaking medium, except for a mismatch of joints in the center 23-meter (75-foot) width of runway where reinforcement of the slabs of mismatched joints will be required regardless of the type of joint between the facilities. When reinforcement at mismatched joints is required, the slab in the pavement facility directly opposite the mismatched joint will be reinforced with the minimum 0.05 percent steel. The reinforcing steel will be placed in two rectangular directions for a distance 915 millimeters (3 feet) back from the juncture and for the full width or length of the slab in a direction normal to the mismatched joint. When a new pavement is being constructed abutting an existing pavement, the new slabs opposite mismatched joints will be reinforced in the manner described above. When two abutting facilities are being constructed concurrently, the slabs on both sides of the juncture opposite mismatched joints will be reinforced in the manner described above. For this condition shown in Figure 13-2, the slip joint bond-breaking medium can be specified to be a full 6.4 millimeters (1/4 inch) thick, and the reinforcing may be omitted.

(2) The second condition of mismatched joints where reinforcement is required occurs in the construction of a plain concrete overlay on an existing rigid pavement. Joints in the overlay should coincide with joints in the base pavement. Sometimes this is impracticable due to an unusual jointing pattern in the existing pavement. When necessary to mismatch the joints in the overlay and the existing pavement, the overlay pavement will be reinforced with the minimum 0.05 percent steel. The steel will be placed in two rectangular directions for a distance of at least 915 millimeters (3 feet) on each side of the mismatched joint in the existing pavement. The steel will, however, not be carried through any joint in the overlay except as permitted or required to meet joint requirements. If the joint pattern in the existing pavement is highly irregular or runs at an angle to the desired pattern in the overlay, the entire overlay will be reinforced in both the longitudinal and transverse directions. When a bond-breaker course (see Chapter 17) is placed between the existing pavement and overlay, reinforcement of the overlay over mismatched joints is not required, except for mismatched expansion joints.

d. Reinforcement of Pavements Incorporating Heating Pipes. Plain concrete pavements, such as hangar floors that incorporate radiant heating systems within the concrete, are subject to extreme temperature changes. These temperature changes cause thermal gradients in the concrete that result in stresses of sufficient magnitude to cause surface cracking. To control such cracking, these pavement slabs will be reinforced with the minimum 0.05 percent steel placed in the transverse and longitudinal directions.

e. Reinforcement of Slabs Containing Utility Blockouts. The minimum 0.05 percent steel reinforcement is required in plain concrete pavement slabs containing utility blockouts, such as for hydrant refueling outlets, storm drain inlets, and certain types of flush lighting fixtures. The entire slab or slabs containing the blockouts will be reinforced in two rectangular directions.

7. REINFORCED CONCRETE PAVEMENTS IN FROST AREAS. Normally, plain concrete pavements in frost areas will be designed in accordance with Chapter 22, and reinforcement will be unnecessary. There may, however, be special instances when it will be directed that the pavement thickness be less than required by frost design criteria. Two such instances are: the design of new pavements to the strength of existing pavement when the existing pavement does not meet the frost design requirements, and the design of an inlay section of adequate strength pavement in the center portion of an existing runway when the existing pavement does not meet the frost design requirements. In such instances, the new pavements will be reinforced with a minimum of 0.15 percent steel. The minimum 0.15 percent steel will be placed in each of two directions (transverse and longitudinal) in the slab. The reinforcing steel is required primarily to control cracking that may develop because of differential heaving. The pavement thickness may be reduced, and the maximum slab length, consistent with the percent steel, may be used. Longer slabs will help reduce roughness that may result from frost action. Greater percentages of steel reinforcement may be used when it is desired to reduce the pavement thickness more than is allowable for the required minimum percentage of steel.

8. REINFORCING STEEL.

a. Type or Reinforcing Steel. The reinforcing steel may be either deformed bars or welded wire fabric. Deformed bars should conform to the requirements of ASTM A 615, A 616, or A 617. In general, grade 60 deformed bars should be specified, but other grades may be used if warranted. Fabricated steel bar mats should conform to ASTM A 184. Cold drawn wire for fabric reinforcement should conform to the requirements of ASTM A 82, and welded steel wire fabric to ASTM A 185.

b. Placement of Reinforcing Steel. The reinforcing steel will be placed at a depth of $h_d/4$ + 25 millimeters ($h_d/4$ + 1 inch) from the surface of the reinforced slab. This will place the steel above the neutral axis of the slab and will allow clearance for dowel bars. The wire or bar sizes and spacing should be selected to give, as nearly as possible, the required percentage of steel per foot of pavement width or length. In no case should the percent steel used be less than that required by Figure 13-1. Two layers of wire fabric or bar mat, one placed directly on top of the other, may be used to obtain the required percent of steel; however, this should only be done when it is impracticable to provide the required steel in one layer. If two layers of steel are used, the layers must be fastened together (either wired or clipped) to prevent excessive separation during concrete placement. When the reinforcement is installed and concrete is to be placed through the mat or fabric, the minimum clear spacing between bars or wires will be one and one-half times the maximum size of aggregate. If the strike-off method is used to place the reinforcement (layer of concrete placed and struck off at the desired depth, the reinforcement placed on the plastic concrete, and the remaining concrete placed on top of the reinforcement), the minimum spacing of wires or bars will not be less than the maximum size of aggregate. Maximum bar or wire spacing shall not exceed 305 millimeters (12 inches) nor the slab thickness. Figure 13-3 shows the typical details of slab reinforcement with wire fabric or bar mats. The bar mat or wire fabric will be securely anchored to prevent forward creep of the steel mats during concrete placement and finishing operations. The reinforcement shall be fabricated and placed in such a manner that the spacing between the longitudinal wire or bar and the longitudinal joint, or between the transverse wire or bar and the transverse joint, will not exceed 76 millimeters (3 inches) or one-half of the wire or bar spacing in the fabric or mat (Figure 13-3). The wires or bars will be lapped as follows.

(1) Deformed steel bars will be overlapped for a distance of at least 24 bar diameters, measured from the tip of one bar to the tip of the other bar. The lapped bars will be wired or otherwise securely fastened to prevent separation during concrete placement.

(2) Wire fabric will be overlapped for a distance equal to at least one spacing of the wire in the fabric or 32 wire diameters, whichever is greater. The length of lap is measured from the tip of one wire to the tip of the other wire normal to the lap. The wires in the lap will be wired or otherwise securely fastened to prevent separation during concrete placement.

9. JOINTING.

a. Requirements. Figures 13-4 through 13-6 present details of joints in reinforced concrete pavements. Joint requirements and types will be the same as for plain concrete except for the following:

(1) All joints will be doweled with the exception of thickened-edge-type joints and longitudinal construction joints. One end of the dowel will be painted and oiled to permit movement at the joint.

(2) Thickened-edge-type joints (expansion, butt, or slip) will not be doweled. The edge will be thickened to $1.25h_d$.

(3) When a transverse construction joint is required within a reinforced slab unit, the reinforcing steel will be carried through the joint. In addition, dowels meeting the size and spacing requirements of Table 12-8 or the design thickness h_d will be used in the joint.

b. Joint Sealing. Joint sealing for reinforced concrete pavements will be the same as for plain concrete pavements.

10. EXAMPLES OF REINFORCED CONCRETE PAVEMENT DESIGN.

a. A reinforced concrete pavement is to be used for an Air Force heavy-load airfield. Field and laboratory test programs have yielded design values of 4.8 MPa (700 psi) for the concrete flexural strength R and 54 MN/m^3 (200 pci) for the modulus of soil reaction k for the foundation.

b. Assuming that stabilization will not be used, it is first necessary to determine the required thicknesses of plain concrete pavement. By entering Figure 12-8 with the design values of R and k, the required thicknesses of plain concrete are as shown in column 2 of Table 13-1. At this point, it is necessary to decide whether to preselect the percentage of reinforcing steel and determine the required thickness of reinforced pavements, or to select a thickness of reinforced concrete and determine the percent steel. First, let it be assumed that a S = 0.20 percent will be used and that it is desired to determine the required thickness. Figure 13-1 is entered with S = 0.20 percent and the thickness of plain concrete for each traffic area, and values of reinforced concrete pavement thickness determined as shown in column 3 of Table 13-1. These thicknesses are rounded to the nearest 10-millimeter (½-inch) increment for construction (column 4). After the thicknesses are rounded, it is then necessary to reenter Figure 13-1 to determine the percent steel commensurate with the rounded thickness values (column 5). Next, let it be assumed that types A, B, and C traffic areas are to be constructed to the same thickness of 405 millimeters (16 inches) of reinforced concrete pavement, and type D traffic areas are to be 255 millimeters (10 inches). Figure 13-1 is entered with the thickness of plain concrete and selected values of reinforced concrete thickness to determine the required percent steel (column 7). The maximum length or width of a reinforced concrete pavement slab is a function of the yield strength of the steel, thickness of the slab, and percent steel and can be determined either from Figure 13-1 or by Equation 13-1. Columns 6 and 8 of Table 13-1 present the maximum allowable lengths or widths for the examples using a steel with a yield strength of 413 MPa (60,000 psi).

c. Assume that a 152-millimeter (6-inch) lean concrete base course will be used. The compressive strength of the lean concrete is 20.6 MPa (3,000 psi), and the flexural modulus of elasticity is 13,788 MPa (2×10^6 psi). As with the previous example, the required thicknesses of plain concrete pavement on both the nonstabilized and on the lean concrete base are determined and are shown in columns 2 and 3 of Table 13-2. A value may then be selected for the required thickness of reinforced concrete or the percentage of reinforcing steel and determine the other using Figure 13-1. If a percent steel value of 0.20 is selected, the values of reinforced concrete from Figure 13-1 would be shown in column 4 of Table 13-2. These values rounded for construction are listed in column 5. Then, reenter Figure 13-1 with the rounded values of reinforced concrete to obtain the required percent steel shown in column 6. The allowable slab lengths are determined from Equation 13-1 or Figure 13-1 using a reinforcing steel with a yield strength of 413 MPa (60,000 psi) (column 7). If a reinforced concrete thickness of 380 millimeters (15 inches) is selected for the type A, B, and C traffic areas and a thickness of 255 millimeters (10 inches) is selected for the type D traffic area, then the required percent steel determined from Figure 13-1 would be as shown in column 8. Column 9 presents the allowable lengths or widths of slab for the reinforced concrete pavement.

CHAPTER 14

FIBROUS CONCRETE PAVEMENT DESIGN

1. BASIS OF DESIGN. The design of fibrous concrete pavement is based upon limiting the ratio of the concrete flexural strength and the maximum tensile stress at the joint, with the load either parallel or normal to the edge of the slab, to a value found to give satisfactory performance in full-scale accelerated test tracks. Because of the increased flexural strength of the fibrous concrete and the bridging of fibers across cracks that develop in the concrete, the thickness can be significantly reduced; however, this results in a more flexible structure, which causes an increase in vertical deflections and potential for densification and/or shear failures in the foundation, pumping of the subgrade material, and joint deterioration. To protect against these latter factors, a limiting vertical deflection criterion has been applied to the thickness developed from the tensile stress criteria.

2. USES FOR FIBROUS CONCRETE. Although several types of fiber have been studied for concrete reinforcement, most of the experience has been with steel fibers, and the design criteria presented herein are limited to steel fibrous concrete. Fibrous concrete is a relatively new material for pavement construction and lacks a long-time performance history. Experience indicates that with time and number of passes logged on a fibrous concrete pavement, the fiber becomes exposed at the wearing surface and becomes an FOD problem. Because of this, its use will require approval of the Headquarters, U.S. Army Corps of Engineers (HQUSACE) (CEMP), HQ Air Force Command, or the Naval Facilities Engineering Command. The major uses to date have been for thin resurfacing or strengthening overlays where grade problems restrict the thickness of overlay that can be used. The use of fibrous concrete pavement should be based upon the economics involved. Fibrous concrete will not be used in Navy pavements.

3. MIX PROPORTIONING CONSIDERATIONS.

a. The design mix proportioning of fibrous concrete will be determined by a laboratory study. Typical mix proportions are shown on Table 14-1. The following are offered as guides and to establish limits where necessary for the use of the design criteria included herein. Additional details may be found in TM 5-822-7/AFM 88-6, Chapter 8.

Table 14-1
Range of Proportions for Normal-Weight Fibrous Concrete[1]

	9.5-mm (3/8-in.) Maximum Sized Aggregate	19-mm (3/4-in.) Maximum Sized Aggregate
Cement kg/m^3 (lb/yd^3)	355-590 (600-1,000)	295-535 (500-900)
Water-cement ratio	0.35-0.45	0.40-0.50
Percent of fine to coarse aggregate	45-60	45-55
Entrained air content (percent)	4-7	4-6
Fiber content (volume percent)		
Deformed steel fiber	0.4-0.9	0.3-0.8
Smooth steel fiber	0.9-1.8	0.8-1.6

[1] From ACI 544.1R-82, used with permission of the American Concrete Institute.

b. The criteria contained herein are based upon fibrous concrete containing 1 to 2 percent by volume 45 to 113 kilograms (100 to 250 pounds) of steel fibers per cubic yard of concrete, and fiber contents within this range are recommended.

c. Most experience to date has been with fibers 25 to 38 millimeters (1 to 1-½ inches) long, and for use of the criteria contained herein, fiber lengths within this range are recommended.

d. For proper mixing, the maximum aspect ratio (length to diameter or equivalent diameter) of the fibers should be about 100.

e. The large surface-area-to-volume ratio of the steel fibers requires an increase in the paste necessary to ensure that the fibers and aggregates are coated. To accomplish this, cement contents of 445 to 535 kg/m^3 (750 to 900 lb/yd^3) of concrete are common. The cement content may be all portland cement or a combination of portland cement and up to 25 percent by volume of fly ash or other pozzolans.

f. Maximum size coarse aggregates should fall between 9.5 and 19 millimeters (3/8 and 3/4 inches). The percent of fine to coarse aggregate has been between 45 and 60 percent on typical projects using fibrous concrete.

4. THICKNESS DETERMINATION. The required thickness of fibrous concrete will be a function of the design concrete flexural strength, the modulus of soil reaction, the thickness and flexural modulus of elasticity of stabilized material if used, the aircraft gross weight, the volume of traffic, the type of traffic area, and the allowable vertical deflection. When stabilized material is not used, the required thickness of fibrous concrete is determined directly from the appropriate chart (Figures 14-1 through 14-9). If the base or subgrade is stabilized and meets the minimum strength requirements of TM 5-822-14/ AFJMAN 32-1019, the stabilized layer will be treated as a low-strength base and the design will be made using Equation 12-1. The resulting thickness must then be checked for allowable deflection. The minimum thickness for fibrous concrete pavements will be 102 millimeters (4 inches).

5. ALLOWABLE DEFLECTION FOR FIBROUS CONCRETE PAVEMENT. The elastic deflection that fibrous concrete pavements experience must be limited to prevent overstressing of the foundation material and thus premature failure of the pavement. Curves are provided (Figures 14-10 through 14-18) for the determination of the vertical elastic deflection that a pavement will experience when loaded and must be checked for all design aircraft. Use of the curves requires three different inputs: slab thickness, subgrade modulus, and gross weight of the design aircraft. The modulus value to use for stabilized layers is determined from Figure 9-1. The slab thickness is that which is determined from Figures 14-1 to 14-19. The computed vertical elastic deflection is then compared with appropriate allowable deflections determined from Figure 14-19 or, in the case of shoulder design, with an allowable deflection value of 0.15 millimeters (0.06 inches). If the computed deflection is less than the allowable deflection, the thickness meets allowable deflection criteria and is acceptable. If the computed deflection is larger than the allowable deflection, the thickness must be increased or a new design initiated with a modified value for either concrete flexural strength or subgrade modulus. The process must be repeated until a thickness based upon the limiting stress criterion will also have a computed deflection equal to or less than the allowable value. Should the vertical deflection criteria indicate the need for a thickness increase greater than that required by the limiting stress criteria, the thickness increase should be limited to that thickness required for plain concrete with a flexural strength of 6.2 MPa (900 psi).

6. JOINTING. The jointing types and designs discussed for plain concrete pavements generally apply to fibrous concrete pavement. For the mix proportioning in Table 14-1, the maximum spacing of

contraction joints will be the same as for plain concrete, except that for thicknesses of 102 to 152 millimeters (4 to 6 inches), the maximum spacing will be 3.8 meters (12.5 feet). Joints in pavements 152 millimeters (6 inches) or greater in thickness will be cut one-third of the depth of the pavement and joints less than 152 millimeters (6 inches) long will be cut one-half the depth of the pavement. Longitudinal construction joints may be either doweled, keyed, keyed and tied, or thickened-edge with a key, in which case the key dimensions will be based upon the thickened-edge thickness. The keyed and tied construction joint will be limited to a width of 30.5 meters (100 feet). For widths greater than 30.5 meters (100 feet), combinations of keyed and tied, doweled, or thickened-edge-type joints may be used. Sealing of joints in fibrous concrete will follow the criteria presented in Chapter 12.

7. EXAMPLE OF FIBROUS CONCRETE PAVEMENT DESIGN.

a. General. An Air Force medium-load airfield is to be designed using fibrous concrete. On-site and laboratory investigations have yielded the following data required for design: (a) subgrade material is a silty sand; (b) modulus of subgrade reaction is 54 kPa/mm (200 pci); (c) an available source of crushed gravel meets the base course requirements; (d) frost does not enter subgrade; and (e) 90-day flexural strength is 6.9 MPa (1,000 psi) with 0.15 percent steel fibers.

b. Example Design—Slab On Grade. Figure 14-5 is entered with the subgrade k, concrete flexural strength, and the pavement thickness determined for the various traffic areas as follows:

Traffic Area	**Thickness mm (in.)**	**Computed Deflection mm (in.)**	**Allowable Deflection mm (in.)**
A	265 (10.5)	0.13 (0.050)	0.13 (0.050)
B	265 (10.5)	0.13 (0.050)	0.14 (0.053)
C	215 (8.5)	0.12 (0.045)	0.14 (0.053)
D	152 (6.0)	0.16 (0.062)	0.29 (0.114)

Since the medium-load pavement is designed for the F-15, C-141, and B-52, deflections must be determined for each aircraft. Therefore, by entering Figures 14-13, 14-14, and 14-15 with these thicknesses, the computed deflections for all aircraft may be determined and the controlling value is shown in the tabulation. It should be noted that a comparison of the computed deflections with the allowable deflections from Figure 14-19 reveals that the thicknesses determined by the allowable stress criterion are satisfactory, since the allowable deflections are equal to or greater than the computed deflections for all traffic areas.

CHAPTER 15

CONTINUOUSLY REINFORCED CONCRETE PAVEMENT DESIGN

1. BASIS OF DESIGN. A continuously reinforced concrete pavement is one in which the reinforcing steel is carried continuously, in both the longitudinal (direction of paving) and transverse (normal to direction of paving) directions, between terminal points. The terminal points may be either the longitudinal construction joints or ends of the pavement, junctures with other pavements or structures, etc. No joints are required between the terminal points; instead, the pavement is permitted to crack. The crack spacing will vary and be dependent upon the percent of reinforcing steel used, interface conditions between the pavement and foundation, and environmental conditions during the early life of the pavement. A transverse crack spacing ranging from 1.5 to 2.5 meters (5 to 8 feet) is desirable; however, experience has shown that even for the most carefully designed system, the crack spacing will vary from as little as 0.6 meters (2 feet) to as much as 3.5 meters (12 feet). The reinforcing steel provides continuity across the nonload-induced cracks, holding them tightly closed and providing good transfer of load. Considerable trouble has been encountered from underdesigned continuously reinforced concrete highway pavements. Consequently, the current trend and the approach adopted here is to make continuously reinforced concrete pavements the same thickness as plain concrete. The steel is assumed to only handle nonload-related stresses and any structural contribution to resisting loads is ignored. When properly designed and constructed, continuously reinforced concrete pavements provide very smooth, low-maintenance pavements. Experience has shown that continuously reinforced concrete pavements perform satisfactorily until the level of cracking reaches the point where punchout of the concrete between the reinforcing steel bars is imminent. The design procedure has been developed primarily from the results of continuously reinforced concrete pavement performance on highways since there has been only limited experience with airfield pavements.

2. USE FOR CONTINUOUSLY REINFORCED CONCRETE PAVEMENTS. Continuously reinforced concrete pavements are applicable for any airfield pavement, but they have received very limited usage for airfield pavement construction. Therefore, long-time performance history is minimal. Because of this, its use will require approval of the Commander, U.S. Army Corps of Engineers (CEMP-ET), the appropriate Air Force Major Command, or the Naval Facilities Engineering Command. The use of continuously reinforced concrete pavement should be based upon the economics involved.

3. FOUNDATION REQUIREMENTS AND EVALUATION. Subgrade compaction and evaluation for a continuously reinforced concrete pavement shall be as described for plain concrete pavements. If economically feasible, the subgrade and/or base course may be modified or stabilized. Stabilized materials must achieve the strength and durability requirements specified in TM 5-822-14/AFJMAN 32-1019.

4. THICKNESS DESIGN. The required thickness of a continuously reinforced concrete pavement is determined using the same procedures as for plain concrete pavement and will be the same thickness as plain concrete pavement. Although continuously reinforced concrete pavement contains steel in addition to being the same thickness as plain concrete pavement, the advantage of using it is that contraction joints are eliminated.

5.R EINFORCING STEEL DESIGN.

a. Longitudinal Direction. The percent of reinforcing steel required in the longitudinal direction for continuously reinforced concrete pavements will be the maximum calculated by the following three equations with the minimum percent steel being 0.43 percent.

$$P_s = (1.3 - 0.2F)\,\frac{f_t}{f_s} \times 100 \qquad (15\text{-}1)$$

$$P_s = \frac{100 f_t}{2(f_s - \Delta T \epsilon_c E_s)} \qquad (15\text{-}2)$$

$$P_s = \frac{f_t}{f_s} \times 100 \qquad (15\text{-}3)$$

where

P_s = percent of reinforcing steel required in the longitudinal direction

F = friction factor; suggested values are 1.0 for unbound fine-grained soils, 1.5 for unbound coarse-grained soils, and 1.8 for stabilized soils

f_t = 7-day tensile strength of the concrete in MPa (psi) determined using the splitting tensile test (Figure 5-1 may be used to convert 7-day flexural strength into tensile strength.)

f_s = working stress in the steel, MPa (psi) (75 percent of yield tensile strength of steel). This produces a safety factor of 1.33.

ΔT = seasonal temperature differential in degrees Celsius (Fahrenheit)

ϵ_c = thermal coefficient of expansion of concrete in millimeters per millimeter per degree Celsius (inches per inch per degree Fahrenheit)

E_s = modulus of elasticity of the reinforcing steel in tension, MPa (psi)

b. Transverse Direction. Transverse reinforcement is required for all continuously reinforced concrete airfield pavements to control any longitudinal cracking that may develop from load repetitions. The percent steel required in the transverse direction will be determined as follows:

$$P_s = \frac{W_s F}{2 f_s} \times 100 \qquad (15\text{-}4)$$

where

W_s = width of slab, m (ft)

c. Type of Reinforcing Steel. The reinforcing steel may be either deformed bars conforming to ASTM A 615 or welded deformed steel wire fabric conforming to ASTM A 497. Generally, longitudinal reinforcement is provided by deformed billet bars with 413-MPa (60,000-psi) minimum yield strength; however, other grades may be used. A grade 40 deformed bar should be used for the transverse reinforcement or for tie bars if bending is anticipated during construction.

d. Placement of Reinforcing Steel. When the slab thickness is 203 millimeters (8 inches) or less, the longitudinal reinforcement should be placed at the middepth of the slab. For thickness in excess of 200 millimeters (8 inches), the longitudinal steel should be placed slightly above the middepth, but a minimum cover of 75 millimeters (3 inches) of concrete shall be maintained in all cases. Transverse reinforcement is normally placed below and used to support the longitudinal steel; however, it may be placed on top of the longitudinal steel if the minimum of 75 millimeters (3 inches) of concrete cover is maintained. Proper lapping of the longitudinal reinforcement is important from the standpoint of load development and is essential for true continuity in the steel. The deformed bars or welded deformed wire fabric shall be lapped in accordance with Chapter 15. It is particularly important to stagger the laps in the reinforcing steel. Generally, not more than one-third to one-half of the longitudinal steel should be spliced in a single transverse plane across a paving lane. The width of this plane should be 610 millimeters (24 inches) if the one-third figure is used, and 1,220 millimeters (48 inches) if the one-half requirement is used. The latter case shall be interpreted to read that not more than one-half of the longitudinal reinforcing members may be spliced in any 1,220-millimeter (48-inch) length of pavement. The stagger of laps with deformed bars may be on a continuous basis rather than the one-third or one-half detail described above.

6.T ERMINAL DESIGN. When appreciable lengths of continuously reinforced concrete pavement are used, the ends experience large movements if unrestrained and will exert large forces if restrained. To protect abutting pavements or structures from damage, the ends of continuously reinforced concrete pavements must be either isolated or restrained. Experience has shown that it is practically impossible to completely restrain or completely isolate the pavement ends, and a combination of these schemes (that is, partial restrain and limited available expansion space) has proven practical. End anchorage and/or expansion joints must be provided when continuously reinforced concrete pavement is not continuous through intersections or when it abuts a structure. Although numerous terminal treatment systems have been attempted, especially on highway pavements, the most successful system appears to be the wide-flange beam joint. Typical drawings of this terminal system are shown in Figure 15-1. For runways, the continuously reinforced concrete pavement should extend to the runway end, where the wide-flange beam joint would be placed as a part of the overrun area.

7.JO INTING. Continuously reinforced concrete pavements will normally use the same type of joints as used for plain concrete pavements except that contraction joints are not normally required. Longitudinal construction joints will be required with the spacing dictated by the paving equipment. The longitudinal construction joints will be butt joints as shown in Figure 12-32. Transverse construction joints, which are required for construction expediency, will be designed to provide slab continuity by continuing the normal longitudinal steel through the joint. The normal reinforcement will be supplemented by additional steel bars, 1.5 meters (5 feet) long (0.75 meters (2.5 feet) on each side of the joint) and the same diameter as the longitudinal reinforcement. The additional steel will be placed between the normal reinforcement and at the same depth in the slab. Thickened-edge slip joints will be used at intersections of pavements where slippage will occur. Otherwise, doweled expansion joints will be used. Expansion joint design will be in accordance with Chapter 12. It will be necessary to provide for expansion at all barriers located in or adjacent to continuously reinforced concrete pavement.

8.JO INT SEALING. The only joints requiring sealing in continuously reinforced concrete pavements will be longitudinal construction joints and expansion joints. Transverse construction joints need not be sealed since they will behave as conventional volume-change cracks that are present elsewhere in the pavement. Joint sealing membranes will be as specified for plain concrete pavements.

9.EXAMPLE OF CONTINUOUSLY REINFORCED CONCRETE PAVEMENT DESIGN. It is required that a pavement be designed as an Air Force medium-load airfield. Types A and B traffic areas are designed for the F-15 at 23,130 kilograms (81,000 pounds), the C-17 at 263,000 kilograms (580,000 pounds), and the B-52 at 181,440 kilograms (400,000 pounds). Types C and D traffic areas and overruns are designed for the F-15 at 27,555 kilograms (60,750 pounds), the C-17 at 197,280 kilograms (435,000 pounds), and the B-52 at 136,080 kilograms (300,000 pounds). Types A, B, and C traffic areas are designed for 100,000 passes of the F-15, 400,000 passes of the C-17, and 400 passes of the B-52. Type D traffic areas and overruns are designed for 1,000 passes of the F-15, 4,000 passes of the C-17, and 4 passes of the B-52. On-site and laboratory investigations have yielded the following data required for design:

- Subgrade = silty sand (SM)
- Modulus of subgrade reaction = 54 kPa/mm (200 lb/in.^{3})
- Flexural strength = 4.83 MPa (700 psi)

The thickness of the continuously reinforced concrete pavement will be the same as required for plain concrete according to the procedures set forth in Chapter 12. The required thicknesses are therefore as follows:

Traffic Area	Calculated Thickness, mm (in.)	Design Thickness, mm (in.)
A	396 (15.6)	405 (16.0)
B	388 (15.3)	394 (15.5)
C	297 (11.7)	305 (12.0)
D and Overruns	238 (9.4)	241 (9.5)

Additional data required for determining the percent longitudinal steel are as follows:

- Tensile strength of concrete (from Figure 15-2) = 3.45 MPa (500 psi)
- Yield strength of steel = 414 MPa (60,000 psi)
- Coefficient of thermal expansion of concrete = 7.2 × 10^{-6} millimeters per millimeter per degree Celsius (4 × 10^{-6}a inches per inch per degree Fahrenheit)
- Modulus of elasticity of steel = 206 × 820 MPa (30 × 10^6 psi)
- Seasonal temperature differential of pavement = 72 degrees Celsius (130 degrees Fahrenheit)

– Friction factor for fine-grained soils = 1.0

The required percentage of longitudinal reinforcement steel is the maximum from Equations 15-1, 15-2, or 15-3.

$$P_s = (1.3 - 0.2F)\,\frac{f_t}{f_s} \times 100$$

$$= (1.3 - 0.2F)\,\frac{3.45}{310} \times 100 = 1.22 \text{ in SI units} \tag{15-5}$$

$$= [1.3 - 0.2(1.0)]\,\frac{500}{45{,}000} \times 100 = 1.22 \text{ in English units}$$

$$P_s = \frac{100f_t}{2(f_s - \Delta T \epsilon_c E_s)}$$

$$= \frac{100(3.45)}{2(310.2 - 72.2 \times .0000072 \times 206820)} = 0.85 \text{ in SI units} \tag{15-6}$$

$$= \frac{100(500)}{2[45{,}000 - 130(4 \times 10^{-6})(30 \times 10^{6})]}$$

$$= 0.850 \text{ in English units}$$

$$P_s = \frac{f_t}{f_s} \times 100$$

$$= \frac{3.45}{310.2} \times 100 = 1.11 \text{ in SI units} \tag{15-7}$$

$$= \frac{500}{45{,}000} \times 100 = 1.11 \text{ in English units}$$

The design percent of longitudinal steel is therefore 1.222. The cross-sectional area of steel A_s required for the Type A traffic area is:

$$A_s = \frac{P_s \times A_p}{100}$$

$$= \frac{1.22 \times 405 \times 1{,}000}{100} = \begin{array}{l}4{,}941 \text{ mm}^2 \text{ per meter} \\ \text{of pavement (SI units)}\end{array} \qquad (15\text{-}8)$$

$$= \frac{1.22 \times 16.0 \times 12}{100}$$

$$= 2.342 \text{ square inches per foot of pavement (English units)}$$

where

A_p = the cross-sectional area of 1 meter (1 foot) of pavement, square millimeters (square inches)

In determining the percent of steel required in the transverse direction, it is assumed that 6-meter (20-foot) paving lanes will be used along with the following equation:

$$P_s = \frac{W_s F}{2 f_s} \times 100 = \frac{20 \times 1.0}{2(45{,}000)} \times 100 = 0.022 \qquad (15\text{-}9)$$

The design percent steel in the transverse direction is therefore 0.022. The cross-sectional area of steel required per 300 millimeters (12 inches) of pavement for the 405-millimeter (16.0-inch) pavement is therefore

$$A_s = \frac{P_s \times A_p}{100} = \frac{0.022 \times 405 \times 300}{100} = 26.7 \text{ mm}^2 \text{ } (0.0414 \text{ in.}^2) \qquad (15\text{-}10)$$

The percent steel for other traffic areas would be computed in the same manner.

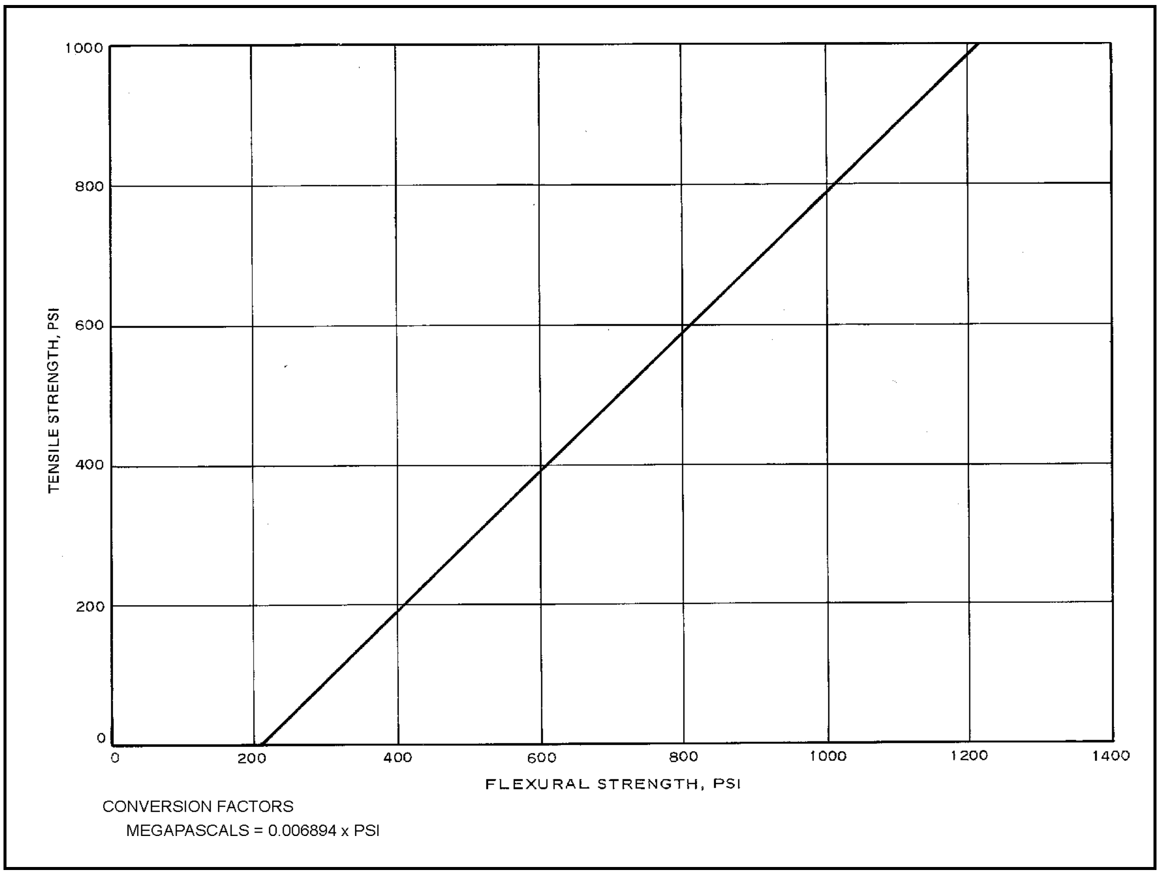

Figure 15-2. Relationship between flexural strength and tensile strength of concrete

CHAPTER 16

PRESTRESSED CONCRETE PAVEMENT DESIGN

1. BASIS OF DESIGN. A prestressed concrete pavement is one in which a significant compressive stress has been induced in both the longitudinal and transverse directions prior to the application of a live load. The induced compressive stress offsets the damaging effects of tensile stresses resulting from applied live loads and permits the formation of momentary, or partial, plastic hinges under passage of wheel loads that change the failure mode from tensile cracking at the bottom of the pavement to tensile cracking in the upper surface of the pavement due to negative moments. These two factors permit the prestressed concrete pavement to carry substantially greater loadings than equal thickness of plain concrete or reinforced concrete pavement and still provide a functionally adequate pavement.

2. UNITS. The design equations and criteria in this chapter are controlled by English units. Therefore, the equations have not been converted to SI units.

3. USES FOR PRESTRESSED CONCRETE PAVEMENT. Although prestressed concrete pavements have been used in Europe, a long-time performance history of prestressed concrete pavements in the United States is not extensive. Therefore, its use will require the approval of HQUSACE (CEMP), the approval Air Force Major Command, or Naval Facilities Engineering Command. Several test or demonstration sections in the United States have shown good performance, but problems have been experienced with joints between long prestressed sections where large movements are experienced. For this reason, complex joints and extreme care are required during construction. The selection of prestressed concrete pavements should be based upon the economics involved.

4. FOUNDATION REQUIREMENTS.

a. Subgrade and base. In general, the subgrade for a prestressed concrete pavement will be treated and evaluated in the same manner as for other types of rigid pavements. The reduced thickness of prestressed concrete pavement will result in a more flexible system and higher vertical stresses in the foundation than for plain concrete pavements. For this reason, the quality and strength of the foundation becomes more important. The foundation should be strengthened through the use of a high-quality (stabilized or nonstabilized) base course and/or stabilized or modified subgrade to provide a minimum modulus of soil reaction or composite modulus of soil reaction of 54 kPa/mm (200 pcl). In addition, because the amount of design prestress is a function of the foundation restraint, the surface of the foundation should be finished as smooth and as free of undulations, holes, etc., as possible.

b. Friction-Reduction Layer. A friction-reducing layer shall be used between the prestressed concrete pavement and the foundation. A satisfactory friction-reducing layer may consist of two polyethylene sheets over a thin 6- to 13-millimeter (1/4- to 1/2-inch) uniform size sand layer. The sand layer is used primarily to smooth out the surface irregularities of the foundation. Other types of friction-reducing material may be considered.

5. METHOD OF PRESTRESSING. Pavements may be prestressed using pretensioning or posttensioning. The method most commonly used for pavements is posttensioning, in which tendons are installed before concrete placement and stressed after concrete placement. The tendons either are placed in conduits or are plastic-encased to prevent bonding with the concrete. The tendons are threaded through bearing plates cast into the face of the concrete at the ends or sides of the concrete slabs. After the concrete has gained sufficient strength, the tendons are stressed, using the bearing

plates and concrete slab as a reaction, to the required total stress level and locked. The total stress level in the tendons is the sum of the stress needed to provide the design prestress level in the concrete plus the stress necessary to offset the various losses that will occur. To help reduce cracking in the concrete during the cure period, a preliminary level of prestress is normally applied at a very early age, and the final level of prestress applied after several days of curing. Both longitudinal and lateral prestressing is needed to obtain the desired structural capacity in the pavement.

6. DESIGN PROCEDURE.

a. General. In the design of prestressed pavements, both thickness and level of prestress will be unknowns; therefore, their determination, in both the longitudinal and transverse directions, becomes an iterative process (that is, one is selected and other computed). A normal practice is to compute the thickness requirements for a range of prestress levels, after which the final selection is made based upon an economic analysis. A maximum value of design prestress of 400 psi is recommended; and based upon experience, a design prestress level falling between 100 and 400 psi has been most economical. The minimum thickness of prestress concrete pavement will be 150 millimeters (6 in.).

b. Design Equation. The design prestress for a given thickness of pavement will be determined as follows:

$$d_s = \frac{6PNB}{wh_p^2} - R + r_s + t_s \qquad (16\text{-}1)$$

where

d_s = design prestress required in concrete, psi

P = aircraft gear load, pounds

N = load-repetition factor

B = load-moment factor

w = ratio of multiple-wheel gear load to single-wheel gear load

h_p = design thickness of prestressed concrete pavement, inches

R = design flexural strength of concrete, psi

r_s = foundation restraint stress, psi

t_s = temperature warping stress, psi

Since both d_s and h_p will be unknown, it is necessary to select values of h_p and compute d_s. For guidance, experience has shown that d_s levels between 100 and 400 psi are generally economical, and at these levels h_p will be about one-third of the required thickness of plain concrete pavement. The design gear load P will depend upon the aircraft for which the pavement is being designed. The load-repetition factor N is a function of the type of design aircraft and the traffic area type. The design aircraft pass level is divided by the aircraft pass per coverage factor to determine the design number of stress repetitions, which are in turn used in Figure 16-1 to obtain N. The load-moment factor B and ratio of multiple-wheel load to single-wheel load w are determined from Figures 16-2 and 16-3, respectively, by entering with a value of A/ℓ^2 (note that for the light-load and Class I airfields, w is 1.0 for all values of A/ℓ^2). A is the contact area in square inches of a tire in the main gear of the design aircraft, and ℓ is computed by

$$\ell = \left[\frac{E h_p^3}{12(1 - \mu^2) k} \right]^{1/4} \tag{16-2}$$

where

ℓ = radius of relative stiffness, inches

E = the modulus of elasticity of concrete (a value of 4,000,000 psi is normally used)

h_p = design thickness of prestressed concrete pavement, inches

μ = Poisson's ratio

k = modulus of subgrade reaction, pci

c. Foundation Restraint Stress. The subgrade restraint stress r_s is a function of the coefficient of sliding friction between the pavement and underlying foundation and the length or width of the prestressed concrete slab and is determined by

$$r_s = \frac{C_f L \rho}{2(144)} \quad or \quad r_s = \frac{C_f W \rho}{2(144)} \tag{16-3}$$

where

r_s = foundation restraint stress, psi

C_f = coefficient of sliding friction

L = length of prestressed concrete slab, feet

W = width of prestressed concrete slab, feet

ρ = density of concrete, lb/ft^3

Experience has shown that for a prestressed concrete pavement constructed with sand and polyethylene sheet bond-breaking medium on the surface of the prepared foundation, a value of C_f of 0.60 is representative. This value can be reduced, with a subsequent reduction in the design prestress level, through the selection of materials with lower coefficients of friction and through careful preparation of the foundation layer.

d. Temperature Warping Stress. The temperature warping stress results from the development of a temperature gradient through the prestressed concrete pavement thickness and can be determined by:

$$t_s = \frac{ET\epsilon_c}{2(1 - v)} \tag{16-4}$$

where

t_s = temperature warping stress, psi

T = difference in temperature in degrees Fahrenheit between the top and bottom of the prestressed concrete pavement

ϵ_c = coefficient of thermal expansion, inches/inch

Values of T should be determined by a test on a pavement in the vicinity of the proposed prestressed concrete pavement; however, without other data, a value of 1 to 3 degrees per inch of pavement has been found to be fairly representative of the maximum temperature gradient.

7. PRESTRESSING TENDON DESIGN.

a. General. The size and spacing of prestressing tendons required will be a function of the required prestress level and the various losses that will occur in the steel tendons during and following construction.

b. Size and Spacing on Tendons. The tendon stress losses occur as a result of elastic shortening and creep of the concrete, concrete shrinkage, tendon relaxation, and slippage in the anchorage system. The determination of these tendon losses is complex because of the many variables, some of which are unknown without extensive field testing. From the experience gained in the few test and demonstration sections and actual pavement sections, the tendon losses can be approximated as 20 percent of the tendon stress needed to achieve the design prestress level in the concrete. With this approximation, the total area of tendon steel required to accomplish the prestress level in the concrete after allowance for tendon losses can be determined by

$$A_s = \frac{1.2d_sA_c}{0.7f_\mu} \tag{16-5}$$

where

A_c = cross-sectional area of concrete being prestressed, square inches

f_μ = ultimate strength of the tendon steel, psi

The equation above is applicable to the determination of A_s based upon a recommended maximum anchorage stress equal to seven-tenths of the ultimate strength of the tendon steel. If the steel is anchored at a stress other than seven-tenths of the ultimate strength, the equation above must be modified accordingly. With the total required A_s determined, the number and size of prestressing tendons can be selected. Spacings of two to four times the prestressed concrete pavement thickness are recommended for the longitudinal tendons, and spacings of three to six times the prestressed concrete pavement thickness are recommended for the transverse tendons.

c. Prestressing Steel Tendons. The tendons used for prestressed concrete pavement will consist of either high-strength wires, strands, or bars.

(1) Wires will conform to the requirements of ASTM A 421.

(2) Seven-wire strands will conform to the requirements of ASTM A 416.

(3) High-strength bars will conform to the requirements of section 405(f) of ACI 318.

d. Prestressing Conduits. Conduits used for enclosing the steel tendons should be either rigid or flexible metal tubing. However, the tendons may be plastic-encased.

(1) Metal conduits must be strong enough to resist damage in transit or during handling. The metal may be bright or galvanized.

(2) When tendons are plastic-encased, the tendons should be permanently protected from rust or corrosion.

e. Placement of Tendons and Conduits. The transverse conduits will be placed on metal chairs at the desired depth and used to support the longitudinal conduits or tendons. Conduits and tendons will be tied firmly in place to maintain proper alignment during placement of the concrete. A preliminary stress applied to the tendons may help maintain the alignment. The inside diameter of metal conduits will be at least 6 millimeters (0.25 inch) larger than the diameter of the stressing tendons. The minimum cover of the conduits will be 75 millimeters (3 inches) at the pavement surface and 50 millimeters (2 inches) at the bottom of the pavement.

f. Tendon Stressing. The prestressed tendons must be stressed to provide a stress in the concrete equal to 1.2 times the design prestress d_s plus sufficient stress to overcome the frictional resistance between the tendon and conduit. After concrete placement and prior to beginning the prestressing operation, any preliminary tension in the tendons must be released. If the tendons are conduit-encased, they should be pulled back and forth several times to reduce and to measure the tendon stress due to friction. This need not be done for plastic-encased tendons. The measured tendon-friction stress must be added to the tendon stress required to produce $1.2d_s$ in the concrete. If the tendons were sized as described in b above, the required tendon stress will be the selected anchorage stress ($0.7f_{\mu}$ or other value if used to size the tendon), plus the stress required to overcome friction. After the maximum tendon stress is reached, it will be held for several minutes and then released to the selected anchorage stress. The longitudinal tendon stressing will be applied in three stages with the amount of prestress at each successive stage being 25, 50, and 100 percent of the anchorage stress. The prestressing will be applied as soon as possible to prevent or minimize the occurrence of contraction cracking in the concrete.

g. Grouting. When the stressing tendons are placed in conduits, the space between the tendons and conduits will be grouted after the final prestressing load is reached. The grout will be made from either cement and water or cement, fine sand, and water. Admixtures to obtain high early strength or to increase workability may be used if they will have no injurious effects on the stressing tendons or conduits. Grouting vents will be provided at each end of the conduits and along the conduits at intervals not to exceed 45 meters (150 feet). A grouting pumping will be used to inject the grout. The grouting will commence at an end vent and continue until grout is forced out of the first interior vent along the conduit. The end vent will then be sealed, and grout will be injected through the first interior vent until it is extruded from the second interior vent. This procedure will be continued until the entire length of conduit has been grouted.

8. JOINTING.

a. Joint Spacing. Experience has shown that from a practical standpoint, the maximum length of prestressed concrete slabs should be 150 meters (500 feet), although lengths of 180 and 215 meters (600 and 700 feet) have been constructed. The width of the slab will vary depending upon the capability of the construction equipment but will generally be a minimum of 7.6 meters (25 feet).

b. Joint Types.

(1) Longitudinal joint. Runway and taxiway pavements will be prestressed for their full width, and the longitudinal joints will be the butt type with the prestressed tendons carried through the joint. The transverse prestressing operation will be carried out after all paving lanes have been completed. For areas wider than 150 meters (500 feet) (such as aprons), the pavement must be constructed in widths not to exceed 150 meters (500 feet); therefore, longitudinal fill-in lanes will be required to permit access for applying the transverse prestressing.

(2) Transverse joint. Because of the length of prestressed slabs and the low subgrade restraint, large movements will occur at the transverse joints. The transverse joint must be designed to accommodate these movements that are a function of the temperature change, slab length, and moisture conditions. The anticipated movements can be determined by

$$\Delta_{LT} = 12L\epsilon_c\Delta T \tag{16-6}$$

and

$$\Delta_{LM} = 12L\epsilon_M \tag{16-7}$$

where

Δ_{LT} = change in length of slab due to temperature change ΔT, inches

L = slab length, feet

ΔT = change in temperature in degrees (either daily or seasonally)

Δ_{LM} = maximum change in length of slab due to seasonable moisture change

ϵ_M = coefficient of moisture expansion of concrete (assumed to be 1×10^{-4} inch per inch seasonally)

The transverse joint must be capable of withstanding the sum of the temperature and moisture change in length. Figure 16-4 shows typical sections of two general methods of construction of the transverse joints. Type A consists of having the transition slab rest directly on the subbase. The transition slab will be constructed to the thickness requirements of either plain or reinforced concrete pavements and connected to the prestressed slabs with dowel bars to provide load transfer through the joint. The size and spacing of the dowel bars will be determined from Chapter 12 based upon the plain or reinforced concrete thickness requirements. Type B consists of a grade slab underlying the ends of the prestressed concrete pavement and transition slab. The transition slab will be reinforced concrete of the same thickness as the prestressed concrete pavement. The grade slab will also be reinforced concrete. The thickness of the grade slab and the percent of reinforcing steel in both the transition slab and grade slab will be determined in accordance with overlay design procedures if the transition slab is a reinforced concrete overlay of the reinforced grade slab.

c. Joint Seals. Longitudinal joints in prestressed concrete pavements, except where longitudinal transition lanes will be required to permit prestressing operations of wide paved areas, need not be sealed since they will be held tightly closed by the prestressing. However, if these joints are sealed, materials meeting the requirements for plain concrete pavements should be used. When longitudinal transition lanes are required, the longitudinal joint should be treated in the same manner as a transverse joint. Several types of sealants have been used for the transverse joints, but no standardized seals have been established. Poured-in-place materials have not been satisfactory to accommodate the large movements that occur. Preformed and mechanical seals, such as shown in Figure 16-5 are recommended. The final selection of a sealant will be a matter of engineering judgment that must be approved by HQUSACE (CEMP-ET), the appropriate Air Force Major Command, or the Naval Facilities Engineering Command.

9. EXAMPLES OF PRESTRESSED CONCRETE PAVEMENT DESIGN.

a. General. A 75-foot-wide by 10,000-foot-long taxiway pavement is to be designed for 100,000 passes of the C-141 aircraft at 320,000 pounds gross weight using prestressed concrete. Laboratory and field test programs have yielded the following pertinent physical property data for the foundation and concrete: modulus of soil reaction, k = 200 pci; 90-day flexural strength of concrete, R = 700 psi; density of concrete = 150 lb/ft^3; modulus of elasticity in flexure of concrete, E = 4×10^6 psi; Poisson's ratio of concrete, v = 0.15; and coefficient of thermal expansion of concrete, $\epsilon_c = 4 \times 10^{-6}$ inch per inch per degree Fahrenheit.

b. Determination of Design Prestress Level. Prestress loads will be determined for preselected thicknesses h_p of 6, 7, and 8 inches. Following the procedures described in paragraph 5, the load-repetition factor N is 2.46 (Figure 16-1) and the load-moment factor B is 0.0523, 0.0544, and 0.0565 for thicknesses of 6, 7, and 8 inches, respectively. The ratio of multiple-wheel gear load to single-wheel gear load, w is 2.22, 2.23, and 2.335 for thickness of 6, 7, and 8 inches, respectively. A polyethylene sheet bond-breaking medium will be used between the foundation and prestressed slab, and the coefficient of sliding friction C_f will be 0.60. A slab length L of 400 feet will be used; therefore, the subgrade restraint stress in the longitudinal direction will be

$$r_s = \frac{C_f L \gamma}{2(144)} = \frac{0.60 \times 400 \times 150}{2(144)} = 125 \text{ psi} \tag{16-8}$$

In the transverse direction, the subgrade restraint stress will be

$$r_s = \frac{C_f W \gamma}{2(144)} = \frac{0.60 \times 75 \times 150}{2(144)} = 23.4 \text{ psi} \tag{16-9}$$

The maximum difference in temperature between the top and bottom of the prestressed concrete pavement is estimated to be about 6, 7, and 8 degrees for the 6-, 7-, and 8-inch pavements, respectively, with resulting temperature warping stresses of 46, 65, and 75 psi, respectively. The design prestressing required in the concrete is then determined by the following equation:

$$d_s = \frac{6PNB}{wh_p^2} - R + r_s + t_s \tag{16-10}$$

For h_p values of 6, 7, and 8 inches, the design prestress d_s in the longitudinal direction will be 853, 492, and 253 psi, respectively, and in the transverse direction the values of d_s will be 761, 391, and 151 psi, respectively. Plotting these values, as shown in Figure 16-6, permits the selection of various thicknesses and prestressing levels that will support the design loading condition. Experience has shown that d_s levels between 100 and 400 psi are most practicable; therefore, from Figure 16-6, a 7.5-inch pavement with longitudinal prestress of 360 psi and transverse prestress of 250 psi would provide a satisfactory pavement. With a slab length of 400 feet, 25 slabs and thus 24 joints will be required for the 10,000-foot-long taxiway. In actual design, several combinations of k, h_p, slab length, etc., should be considered, and the final selection should be based on an economic study considering all aspects of material and construction costs.

c. Prestressed Tendon Design. Plastic-encased stranded wire having an ultimate strength f_μ of 240,000 psi is selected for the prestressed tendons. The stranded wire tendon will be finally anchored at a stress not to exceed $0.7f_\mu$ or 168,000 psi. The required area of steel in the longitudinal and transverse directions to achieve the design prestressing level in the concrete and allowing for the various tendon stress losses will be

Longitudinal Direction

$$A_s = \frac{1.2 \times 360 \times 7.5 \times 75 \times 12}{0.7 \times 240{,}000} = 17.4 \text{ square inches} \tag{16-11}$$

Transverse Direction

$$A_s = \frac{1.2 \times 250 \times 7.5 \times 400 \times 12}{0.7 \times 240{,}000} = 64.3 \text{ square inches} \tag{16-12}$$

Several combinations of wire diameter and spacing will yield the required cross-sectional area of steel for the stressing tendons. For example, if in the longitudinal direction, a spacing of four times the prestressed concrete pavement thickness (30 inches) is selected, then 30 tendons will be required, each having a cross-sectional area of 0.58 square inch and diameter of 0.86 inch. Therefore, a 7/8-inch-diameter tendon could be selected. Selection of a tendon that is greater or less than that required may require the final anchor stress to be revised. If, in the transverse direction, a spacing of five times the prestressed concrete pavement thickness (37.5 inches) is selected, then 128 tendons would be needed and the required cross-sectional area of the tendons would be 0.50 square inch. Therefore, a 13/16-inch-diameter tendon would provide the required prestressing.

CHAPTER 17

OVERLAY PAVEMENT DESIGN

1. GENERAL. Overlay pavements are designed to increase the load-carrying capacity (strength) of the existing pavement. The basis for design is to provide a layer or layers of material on the existing pavement that will result in a layered system which will yield the predicted performance of a new rigid pavement if constructed on the same foundation as the existing pavement. Two general types of overlay pavement are considered: rigid and nonrigid. Procedures are presented for the design of plain concrete, reinforced concrete, continuously reinforced concrete, fibrous concrete, prestressed concrete, and nonrigid overlays. Nonrigid overlays include both flexible (nonstabilized base and bituminous concrete wearing course) and all-bituminous concrete for strengthening existing plain concrete, reinforced concrete, and flexible pavements. Continuously reinforced, fibrous, and prestressed concrete overlays will not be permitted unless it is technically and economically justified and approved by HQUSACE (CEMP), Air Force Major Command, or Naval Facilities Engineering Command. Overlays will be used when the nonstabilized aggregate base course can be positively drained. When the overlay includes a nonstabilized aggregate base course layer, the unbound base course must be positively drained.

2. CONVENTIONAL OVERLAY DESIGN EQUATION BACKGROUND AND LIMITATIONS. The overlay design equations for rigid and flexible overlays of rigid pavements presented in this chapter are based on full-scale accelerated traffic tests conducted in the 1950's modified with experience and performance observations in succeeding years. The equations were developed to support a program of strengthening Air Force airfield pavements to accommodate the introduction of the large B-47 and B-52 aircraft into the inventory. Because of theoretical limitations of the time, the overlay equations are empirical. They have the advantage of simplicity for use, but their empirical basis means that they are valid only for conditions consistent with their original development. To use these equations effectively, one must be aware of their limitations and their proper application as discussed in this chapter. For more complex situations, a more comprehensive overlay analysis as presented in the layered elastic design chapter may be necessary.

a. The overlay equations for rigid and flexible overlays of rigid pavements recognize four basic conditions:

(1) Fully bonded overlay where the rigid overlay and rigid base pavement are fully bonded and behave monolithically. Because of problems with providing load transfer, these overlays are generally limited to correcting surface deficiencies of a structurally adequate pavement in good condition other than the surface problems.

(2) Partially bonded overlay where no particular attempt is made to achieve or prevent bond between the rigid overlay and the base pavement. This equation is a best fit to empirical data and therefore can give either conservative or nonconservative thicknesses. Partially bonded overlays are particularly well suited for structurally upgrading an essentially sound pavement to accommodate larger loads as might happen when a mission change brings new heavier aircraft to a base.

(3) Unbonded overlay where a thin separation layer asphalt concrete or other material is interposed between the rigid overlay and the base pavement to avoid direct bonding between the

two. This equation gives generally conservative results. Unbonded overlays are best suited for restoring a deteriorated pavement to structural and functional capacity.

(4) Flexible overlay where an asphaltic concrete is placed directly on a rigid base pavement to restore surface and structural quality. For very thick overlays, a combination of granular base and asphalt concrete surface can be used provided the granular base is positively drained so that no water can be trapped in the overlay. When compared to more powerful layered elastic based overlay analysis, the flexible overlay equation tends to be somewhat unconservative for thin overlay thicknesses and conservative for relatively thick overlay designs. Because of reflective cracking problems, flexible overlays are probably best suited as an interim rehabilitation technique that postpones more comprehensive restoration of a deteriorated pavement.

b. Because of concerns over FOD damage to jet aircraft engines, the empirical rigid and flexible overlay equations were developed for entirely different failure conditions in the accelerated traffic field tests upon which they were based. The rigid overlay sections were considered failed when initial structural cracks appeared, since such cracking was considered the precursor of spalling and potential FOD problems. Failure for the flexible overlays was taken to be when the underlying slab was shattered into 35 or more pieces and the subgrade was on the verge of failing. Because these equations represent two vastly different pavement conditions at the end of the pavement design life, it is not appropriate to try to make comparative cost comparisons between flexible overlays and rigid overlays designed using these equations. Also, this extreme terminal design condition for the flexible overlay equation is empirical and can give anomalous results such as negative numbers. This simply means the design case is outside the valid conditions, and the minimum thickness flexible overlay of 100 millimeters (4 inches) should be used.

3. SITE INVESTIGATIONS. Explorations and tests of the existing pavement will be made to determine the structural condition of the existing pavement prior to overlay, assess the required physical properties of the existing pavement and foundation materials, and locate and analyze all existing areas of defective pavement and subgrade that will require special treatment. The determination of the structural condition and required physical properties of the existing pavement will depend upon the type of overlay used as described in subsequent paragraphs. An investigation will be conducted to determine whether there are voids under the existing rigid pavement. This investigation is especially important if there has been, or is, any evidence of pumping or bleeding of water at cracks, joints, or edges of the existing rigid pavement. Nondestructive pavement test equipment has application for this type of investigation. If voids are found under the existing rigid pavements, fill the voids with grout before the overlay is placed. The results of the investigation, especially the nondestructive tests, may show rather large variations in the strength of the existing pavement and may lead to a requirement for more extensive testing to determine the cause of the variation. It will then be necessary to determine the feasibility and economics of using a variable thickness overlay, basing the design on the lower-strength pavement section, or removing and replacing the low-strength pavement areas.

4. PREPARATION OF EXISTING PAVEMENT.

a. General. The preparation of the existing pavement prior to overlay will vary, depending upon whether the overlay is rigid or nonrigid.

b. Rigid Overlay. Overlay thickness criteria are presented for three conditions of bond between the rigid overlay and existing rigid pavement: fully bonded, partially bonded, and nonbonded. The fully bonded condition is obtained when the concrete is cast directly on concrete and special efforts are made to obtain bond. The partially bonded condition is obtained when the concrete is cast directly on concrete with no special efforts to achieve or destroy bond. The nonbonded condition is obtained when the bond is prevented by an intervening layer of material. When a fully bonded or partially bonded rigid overlay is to be used, the existing rigid pavement will be cleaned of all foreign matter (such as oil and paint), spalled concrete, extruded joint seal, bituminous patches, or anything else that would act as a bond-breaker between the overlay and existing rigid pavement.

(1) In addition, fully bonded overlays use careful surface preparation to ensure the overlay and underlying base slab are fully bonded and behave monolithically. To reliably achieve this full bond, the base slab is cold milled or shotblasted to remove all deteriorated or defective concrete and all surface contamination. This roughened surface must be thoroughly cleaned by sandblasting followed by airblasting, waterblasting, or both. Achieving and maintaining the surface cleanliness concrete placement is critical for achieving good bond. A portland-cement grout is then pneumatically applied immediately ahead of the concrete placement to help achieve a high degree of bond between the new and old concrete. This grout must not dry prior to placement of the concrete so usually it is only applied about 3 to 4 m ahead of the concrete placement. If the grout dries out prior to the concrete placement, the grout should be removed by sandblasting or other similarly reliable method and reapplied prior to continuing concrete placement. Older requirements for acid etching the base concrete surface are unnecessary and are not environmentally sound. Portland-cement grouts have proven adequate, and more expensive epoxy or polymer grouts are not normally needed. Some bonded overlays have reportedly been successfully placed with no bonding grout, but the military has no experience with such at present. For military airfield work where debonding poses such a serious FOD hazard, the intense surface preparation, surface cleaning, and use of a portland-cement grout are considered to be the minimum allowable effort for fully bonded overlays.

Past tests and studies have failed to identify adequate methods of providing satisfactory load transfer in fully bonded overlays. Consequently, fully bonded overlays will only be used on military airfields to correct surface deficiencies, and they are not suitable for structural upgrades unless the pavement is redesigned assuming no load transfer exists. The minimum thickness for a fully bonded overlay is 50 millimeters (2 inches), and most military airfield bonded overlays have been 75 to 125 millimeters (3 to 5 inches) thick. Typical past uses have included correction of surface smoothness or skid resistance problems, providing a sound operational surface over underlying pavements that are scaling, posing an FOD hazard from popouts or spalling and raveling, or to cover pavement surfaces that pose an FOD hazard from D-cracking, excess surface grout, or alkali-aggregate reaction deterioration.

All joints and cracks in the base pavement will reflect through a fully bonded overlay. Therefore, the overlay joints must match the base slab joints. Cracked slabs in the pavement to be overlaid should be removed and replaced, or the bonded overlay slab above the cracked slab should be reinforced.

(2) When a nonbonded rigid overlay is being used, the existing rigid pavement will be cleaned of all loose particles and covered with a leveling or bond-breaking course of bituminous concrete, sand-asphalt, heavy building paper, polyethylene, or other similar stable material. The bond-breaking medium generally should not exceed a thickness of about 25 millimeters (1 inch), except in the case of leveling courses where greater thicknesses may be necessary. When a rigid overlay is being applied to an existing flexible pavement, the surface of the existing pavement will be cleaned of loose materials and any potholing or unevenness, exceeding about 25 millimeters

(1 inch), will be repaired by cold planing, localized patching, or the application of a leveling course using bituminous concrete, sand-asphalt, or a similar material.

c. Nonrigid Overlay. When a flexible overlay is used, no special treatment of the surface of the existing pavement will be required other than the removal of loose material. When an all-bituminous concrete overlay is used, the surface of the existing pavement will be cleaned of all foreign matter. Spalled concrete, fat spots in bituminous patches, and extruded soft or spongy joint seal material on rigid pavements will be removed. Joints or cracks less than 25 millimeters (1 inch) wide in an existing rigid pavement will be filled with joint sealant. Joints or cracks that are 25 millimeters (1 inch) or greater in width will be cleaned and filled with an acceptable bituminous mixture (such as sand-asphalt) which is compatible with the overlay. Leveling courses of bituminous concrete will be used to bring the existing pavement to the proper grade when required. Prior to placing the all-bituminous concrete overlay, a tack coat will be applied to the surface of the existing pavement.

5. CONDITION OF EXISTING CONCRETE PAVEMENT.

a. General. The support that the existing rigid pavement will provide to an overlay is a function of its structural condition just prior to the overlay. In the overlay design equations, the structural condition of the existing concrete pavement is assessed by a condition factor, C. The value of C should be selected based upon a condition survey (ASTM D 5340) of the existing rigid pavement. Interpolation of C values between those shown below may be used if it is considered necessary to more accurately define the existing structural condition. As an alternative, Figure 17-1 may be used to select the C value for plain concrete or nonrigid overlays. This figure relates a structural condition index (SCI) and C. The SCI is that part of the pavement condition index (PCI) related to structural distress types as deduct values. To determine SCI values, a condition survey is conducted according to ASTM D 5340. However, rather than calculating the PCI, an SCI is calculated by subtracting the deduct values for corner breaks, longitudinal, transverse and diagonal cracking, shattered slabs, spalling along joints, and spalling corners from 100.

b. Rigid Overlay. The following values of C are assigned for the following conditions of plain and reinforced concrete pavements.

(1) Condition of existing plain concrete pavement:

C = 1.00 - Pavements in the trafficked areas are in good condition with little or no structural cracking because of load

C = 0.75 - Pavements in the trafficked areas exhibit initial cracking because of load but no progressive cracking or faulting of joints or cracks

C = 0.35 - Pavements in the trafficked areas exhibit progressive cracking because of load accompanied by spalling, raveling, or faulting of cracks and joints

(2) Condition of existing reinforced concrete pavement.

C = 1.00 - Pavements in the trafficked areas are in good condition with little or no short-spaced transverse (305- to 610-millimeter (1- to 2-foot)) cracks, no longitudinal cracking, and little spalling or raveling along cracks

C = 0.75 - Pavements in the trafficked areas exhibit short-spaced transverse cracking but little or no interconnecting longitudinal cracking because of load and only moderate spalling or raveling along cracks

C = 0.35 - Pavements in the trafficked areas exhibit severe short-spaced transverse cracking and interconnecting longitudinal cracking because of load, severe spalling along cracks, and initial punchout-type failures

c. Nonrigid Overlay. The following values of C are assigned for the following conditions of plain and reinforced concrete pavement.

(1) Condition of existing plain concrete pavements.

C = 1.00 - Pavements in the trafficked areas are in good condition with some cracking because of load but little or no progressive-type cracking

C = 0.75 - Pavements in the trafficked areas exhibit progressive cracking because of load and spalling, raveling, and minor faulting at joints and cracks

C = 0.50 - Pavements in the trafficked areas exhibit multiple cracking along with raveling, spalling, and faulting at joints and cracks

(2) Condition of existing reinforced concrete pavement.

C = 1.00 - Pavements in the trafficked areas are in good condition but exhibit some closely spaced load-induced transverse cracking, initial interconnecting longitudinal cracks, and moderate spalling or raveling of joints and cracks

C = 0.75 - Pavements in trafficked areas exhibit numerous closely spaced load-induced transverse and longitudinal cracks, rather severe spalling or raveling or initial evidence of punchout failures

6. RIGID OVERLAY OF EXISTING RIGID PAVEMENT.

a. General. There are three basic equations for the design of rigid overlays which depend upon the degree of bond that develops between the overlay and existing pavement: fully bonded, partially bonded, and nonbonded. The fully bonded overlay equation is used when special care is taken to provide bond between the overlay and the existing pavement. The partially bonded equation will be used when the rigid overlay is to be placed directly on the existing pavement and no special care is taken to provide bond. A bond-breaking medium and the nonbonded equation will be used when (a) a plain concrete overlay is used to overlay an existing reinforced concrete pavement, (b) when a continuously reinforced or prestressed concrete overlay is used to overlay an existing plain concrete or reinforced concrete pavement, (c) when a plain concrete overlay is being used to overlay an existing plain concrete pavement that has a condition factor $C \leq 0.35$, and

(d) when matching joints in a plain concrete overlay with those in the existing plain concrete pavement cause undue construction difficulties or result in odd-shaped slabs.

b. Plain Concrete Overlay.

(1) Thickness Determination. The required thickness h_o of plain concrete overlay will be determined from the following applicable equations:

Fully bonded

$$h_o = h_d - h_E \tag{17-1}$$

Partially bonded

$$h_o = \sqrt[1.4]{h_d^{1.4} - C\left(\frac{h_d}{h_e} \times h_E\right)^{1.4}} \tag{17-2}$$

Nonbonded

$$h_o = \sqrt{h_d^2 - C\left(\frac{h_d}{h_e} \times h_E\right)^2} \tag{17-3}$$

where

h_E = existing plain concrete pavement thickness

h_d and h_e = design thicknesses of rigid pavement determined using the design flexural strength of the overlay and measured flexural strength of the existing rigid pavement, respectively; the modulus of soil reaction k of the existing rigid pavement foundation; and the design loading, traffic area, and pass level needed for overlay design.

Use of fully bonded overlay is limited to existing pavements having a condition index of 1.0, and to overlay thickness of 50 to 120 millimeters (2.0 to 5.0 inches). The fully bonded overlay is used only to correct a surface problem such as scaling rather than as a structural upgrade. The factor h_E represents the thickness of the existing plain concrete pavement or the equivalent thickness of plain concrete pavement having the same load-carrying capacity as the existing pavement. If the existing pavement is reinforced concrete, h_E is determined from Figure 13-1 using the percent reinforcing steel S and design thickness h_e. The minimum thickness of plain concrete overlay will be 50 millimeters (2 inches) for a fully bonded overlay and 150 millimeters (6 inches) for a partially bonded or nonbonded overlay. The required thickness of overlay must be rounded to the nearest full- or half-inch increment. When the indicated thickness falls midway between a full and half-inch, the thickness will be rounded upward.

(2) Jointing. For all partially bonded and fully bonded plain concrete overlays, joints will be provided in the overlay to coincide with all joints in the existing rigid pavement. It is not necessary for joints in the overlay to be of the same type as joints in the existing pavement. When it is

impractical to match the joints in the overlay to joints in the existing rigid pavement, either a bond-breaking medium will be used and the overlay designed as a nonbonded overlay, or the overlay will be reinforced over the mismatched joints. Should the mismatch of joints become severe, a reinforced concrete overlay design should be considered as an economic alternative to the use of nonbonded plain concrete overlay. For nonbonded plain concrete overlays, the design and spacing of transverse contraction joints will be in accordance with requirements for plain concrete pavements on grade. For both partially bonded and nonbonded plain concrete overlays, the longitudinal construction joints will be doweled using the dowel size and spacing given in Table 12-8. Any contraction joint in the overlay that coincides with an expansion joint in the existing rigid pavement within the prescribed limits of a type A traffic area will be doweled. Dowels and load-transfer devices will not be used in fully bonded overlays. Joint sealing for plain concrete overlays will conform to the requirements for plain concrete pavements on grade.

(3) Example of Plain Concrete Overlay Design. An existing plain concrete pavement will be strengthened to serve as a type A traffic area for an Air Force medium-load pavement using a plain concrete overlay. The pertinent physical properties of the existing rigid pavement are: h_E = 200 millimeters (8 inches), R = 4.83 MPa (700 psi), and k = 27 MN/m^3 (100 pci). The design (90-day) flexural strength of the concrete for the overlay is 5.17 MPa (750 psi).

(a) The existing pavement is showing some initial cracking due to load so that the condition factor C is 0.75. The condition of the existing pavement is such that there is no reason to use a leveling course or other bond-breaking medium. The required thickness h_o of the plain concrete overlay is then determined using the partially bonded overlay equation (Equation 17-2). The design thickness h_d of plain concrete pavement, using the design flexural strength of 5.17 MPa (750 psi) for the overlay concrete and k = 27 MN/m^3 (100 pci) for the existing foundation, from Figure 12-7 (medium-load design curve) and type A traffic area, is 457 millimeters (18.0 inches). The design thickness h_e of plain concrete pavement, using the 4.82 MPa (700 psi) flexural strength of the existing pavement, a k value of 27 MN/m^3 (100 pci), and Figure 12-7 is 488 millimeters (19.2 inches). Since the existing rigid pavement is plain concrete, h_E = 200 millimeters (8 inches). Substituting these values in Equation 17-2,

$$h_o = \sqrt[1.4]{457^{1.4} - 0.75\left(\frac{457}{488} \times 200\right)^{1.4}}$$

$$= 384 \text{ mm (SI units)}$$

$$h_o = \sqrt[1.4]{18.0^{1.4} - 0.75\left(\frac{18.0}{19.2} \times 8\right)^{1.4}}$$

$$= 15.1 \text{ inches (use 15.0 inches) (English units)}$$

(b) The existing rigid pavement is 200 millimeters (8 inches) of reinforced concrete with 0.15 percent of reinforcing steel S and a condition factor C of 0.75. All properties of the existing pavement and proposed plain concrete overlay are the same as above. Since the existing pavement is reinforced concrete, it will be necessary to use a bond-breaking medium and determine the required thickness of plain concrete overlay using the nonbonded overlay equation

(Equation 17-3). The design thickness h_d of plain concrete is 457 millimeters (18.0 inches), and the design thickness h_e is 488 millimeters (19.2 inches). The value of h_E, the thickness of plain concrete pavement equivalent to the existing thickness of reinforced concrete pavement, determined from Figure 13-1 using the existing thickness of reinforced concrete pavement of 200 millimeters (8 inches) and S = 0.15 percent, is 241 millimeters (9.5 inches). Substituting these values in the equation above,

$$h_o = \sqrt{457^2 - 0.75\left(\frac{457}{488} \times 241\right)^2}$$

$$= 413 \text{ millimeters (SI units)}$$

$$h_o = \sqrt{18.0^2 - 0.75\left(\frac{18.0}{19.2} \times 9.5\right)^2}$$

$$= 16.3 \text{ inches (use 16.5 inches) (English units)}$$

c. Reinforced Concrete Overlay. A reinforced concrete overlay may be used to strengthen either an existing plain concrete or reinforced concrete pavement. Generally, the overlay will be designed as a partially bonded overlay. The nonbonded overlay design will be used only when a leveling course is required over the existing pavement. The reinforcement steel for reinforced concrete overlays will be designed and placed in accordance with reinforced concrete slabs on grade.

(1) Thickness determination. The required thickness of reinforced concrete overlay will be determined using Figure 13-1 after the thickness of plain concrete overlay has been determined using the appropriate overlay equation. Then, using the value for the thickness of plain concrete overlay, either the thickness of reinforced concrete overlay can be selected and the required percent steel determined, or the percent steel can be selected and the thickness of reinforced concrete overlay determined from Figure 13-1. The minimum thickness of reinforced concrete overlay will be 152 millimeters (6 inches).

(2) Jointing. Whenever possible, the longitudinal construction joints in the overlay should match the longitudinal joints in the existing pavement. All longitudinal joints will be of the butt-doweled type with dowel size and spacing designated in accordance with Chapter 12 using the thickness of reinforced concrete overlay. It is not necessary for transverse joints in the overlay to match joints in the existing pavement; however, when practical, the joints should be matched. The maximum spacing of transverse contraction joints will be determined in accordance with Figure 13-1, but it will not exceed 30 meters (100 feet) regardless of the thickness of the pavement or the percent steel used. Joint sealing for reinforced concrete pavements will conform to the requirements for plain concrete pavements.

(3) Example of reinforced concrete overlay design. An existing rigid pavement will be strengthened to serve as a type B traffic area for a heavy-load pavement using a reinforced concrete overlay. The pertinent physical properties of the existing plain concrete pavement are: h_E = 250 millimeters (10 inches), R = 4.48 MPa (650 psi), and k = 54 MN/m^3 (200 pci). The design (90-day) flexural strength of the overlay is 5.17 MPa (750 psi).

(a) The existing rigid pavement is plain concrete with a structural condition C of 0.35; however, there is no significant faulting of the slabs and a leveling course is not needed. The required thickness of plain concrete overlay is determined using the partially bonded overlay equation (Equation 17-2). The required thickness h_d of plain concrete pavement for the overlay design flexural strength of 5.17 MPa (750 psi) and the k value of 54 MN/m^3 (200 pci) for the foundation under the existing pavement determined from Figure 12-8 (heavy-load design curve) type B traffic area is 521 millimeters (20.5 inches). The design thickness h_e of plain concrete pavement for the flexural strength of 4.48 MPa (650 psi) of the existing pavement and the k value of 54 MN/m^3 (200 pci) from Figure 12-8 is 574 millimeters (22.6 inches). Since the existing pavement is plain concrete, the equivalent thickness h_E is equal to the 250-millimeter (10-inch) thickness of the existing slab. Substituting these values in Equation 17-2,

$$h_o = \sqrt[1.4]{521^{1.4} - 0.35\left(\frac{521}{574} \times 250\right)^{1.4}}$$

$$= 478 \text{ millimeters (SI units)}$$

$$h_o = \sqrt[1.4]{20.5^{1.4} - 0.35\left(\frac{20.5}{22.6} \times 10\right)^{1.4}}$$

$$= 18.8 \text{ inches (English units) (Use 19.0 inches)}$$

This is the thickness of the plain concrete overlay required to strengthen the existing plain concrete pavement for the design loading condition. The thickness of reinforced concrete overlay is then dependent upon the percent of reinforcing steel S that will be used. Let it be assumed that because of grade problems, the overlay thickness must be limited to 380 millimeters (15 inches). Then, the value of S required, determined from Figure 13-1 using the plain concrete overlay thickness of 478 millimeters (19.0 inches) and the reinforced concrete overlay thickness of 380 millimeters (15 inches), is 0.25 percent. It is also noted from Figure 13-1 that a maximum joint spacing of 30 meters (100 feet) may be used with a reinforcing steel having a yield strength y_s of 413 MPa (60,000 psi).

(b) The existing pavement in the example above consists of 250 millimeters (10 inches) of reinforced concrete with 0.10 percent of reinforcing steel and all other properties and design requirements remain the same. The thickness of plain concrete pavement h_E equivalent to the 250 millimeters (10 inches) of existing reinforced concrete pavement, determined from Figure 13-1 using the existing thickness of 250 millimeters (10 inches) and S = 0.10, is 287 millimeters (11.3 inches). Substituting these values in the partially bonded overlay equation yields a required overlay thickness h_o of plain concrete equal to:

$$h_o = \sqrt[1.4]{521^{1.4} - 0.35\left(\frac{521}{574} \times 287\right)^{1.4}}$$

$$= 470 \text{ millimeters (SI units)}$$

$$h_o = \sqrt[1.4]{20.5^{1.4} - 0.35\left(\frac{20.5}{22.6} \times 11.0\right)^{1.4}}$$

$$= 18.5 \text{ inches (English units)}$$

From Figure 13-1, the thickness of reinforced concrete overlay using the thickness of plain concrete of 470 millimeters (18.5 inches) and a percent steel of 0.20 is 380 millimeters (15 inches).

d. Continuously Reinforced Concrete Overlay. A continuously reinforced concrete overlay may be used to strengthen either an existing plain concrete or reinforced concrete pavement. For both conditions, a bond-breaking medium is required between the overlay and the existing pavement. The required thickness of a continuously reinforced concrete pavement is determined in the same manner and will be equal in thickness to a plain concrete overlay. Jointing and sealing of joints in a continuously reinforced concrete pavement will be the same as for continuously reinforced concrete pavements on grade.

e. Fibrous Concrete Overlay. A fibrous concrete overlay may be used to strengthen either an existing plain or reinforced concrete pavement. The mix proportioning of the fibrous concrete overlay will follow the considerations presented for fibrous concrete pavements on grade.

(1) Thickness determination. The required thickness of fibrous concrete overlay will be determined using the partially bonded or nonbonded overlay equations. Normally, the partially bonded equation will be used, but in cases of extremely faulted or uneven existing pavement surfaces, a leveling course may be required and the design of the overlay will be made using the nonbonded overlay equation. If the existing rigid pavement is plain concrete, then the equivalent thickness is equal to the existing slab thickness. If the existing rigid pavement is reinforced concrete, however, then the equivalent thickness must be determined from Figure 13-1 using the thickness of the existing slab and the percent of reinforcing steel. The minimum thickness of fibrous concrete overlay will be 100 millimeters (4 inches).

(2) Jointing. In general, the joint types, spacing, and designs discussed for plain concrete pavements apply to fibrous concrete overlays, except that for thicknesses from 100 millimeters (4 inches) to 150 millimeters (6 inches), the maximum spacing will be 3.8 meters (12.5 feet). Joints in the fibrous overlay should coincide with joints in the existing rigid pavement. Longitudinal construction joints will be the butt-doweled type, and dowels will be required in transverse contraction joints exceeding 15-meter (50-foot) spacings. For pavement thickness less than 150 millimeters (6 inches), it will be necessary to obtain guidance on joint construction from HQUSACE (CEMP-ET), the appropriate Air Force Major Command, or the Naval Facilities Engineering Command. Sealing of joints in fibrous overlays will be in accordance with sealing of joints in fibrous concrete pavements on grade.

(3) Example of fibrous concrete overlay design. An existing rigid pavement will be strengthened to serve as a type B traffic area for an Air Force light-load pavement using a fibrous concrete overlay. The pertinent physical properties of the existing rigid pavement are: existing thickness is 150 millimeters (6 inches), R = 4.8 MPa (700 psi), and k = 27 MN/m^3 (100 pci). The design (90-day) flexural strength of the fibrous concrete overlay is 6.2 MPa (900 psi). The existing rigid pavement is plain concrete with a structural condition, C, of 1.0. A leveling course will not be required; therefore, the required thickness of fibrous concrete overlay will be determined using the

partially bonded overlay equation (Equation 17-2). Use of this equation requires that h_d be the thickness of fibrous concrete from the appropriate fibrous concrete design curve. The design thickness of fibrous concrete pavement is determined from Figure 14-4 to be 228 millimeters (9 inches) using the design flexural strength of the fibrous concrete overlay (6.2 MPa (900 psi)) and k value of (27 MN/m^3 (100 pci)) for the existing rigid pavement foundation. The design thickness of plain concrete, using the flexural strength of the existing pavement (4.8 MPa (700 psi)) and k of 27 MN/m^3 (100 pci) for the existing foundation strength, is 310 millimeters (12.2 inches). Since the existing rigid pavement is plain concrete, h_E = 150 millimeters (6 inches); substituting these values in the partially bonded overlay equation yields a required thickness of fibrous concrete overlay of:

$$h_o = \sqrt[1.4]{228^{1.4} - 1.0\left(\frac{228}{310} \times 150\right)^{1.4}}$$

$$= 165 \text{ millimeters (SI units)}$$

$$h_o = \sqrt[1.4]{8.99^{1.4} - 1.0\left(\frac{9.00}{12.2} \times 6\right)^{1.4}}$$

$$= 6.5 \text{ inches (English units)}$$

7. PRESTRESSED CONCRETE OVERLAY OF RIGID PAVEMENT. A prestressed concrete overlay may be used above any rigid pavement. The procedure for designing the prestressed concrete overlay is to consider the base pavement to have a k value of 135 MN/m^3 (500 pci) and design the overlay as a prestressed concrete pavement on grade.

8. RIGID OVERLAY OF EXISTING FLEXIBLE OR COMPOSITE PAVEMENT. Any type of rigid overlay may be used to strengthen an existing flexible or composite pavement. The existing pavement is considered to be a composite pavement when it is composed of a rigid base pavement that has been strengthened with 100 millimeters (4 inches) or more of nonrigid (flexible or all-bituminous) overlay. If the nonrigid overlay is less than 100 millimeters (4 inches), the rigid overlay is designed using the nonbonded overlay equation. The design of the rigid overlay will follow the procedures outlined in Chapters 12 through 16 of this document. The strength afforded by the existing pavement will be characterized by the modulus of soil reaction k determined using the plate bearing test, or Figure 8-1. The following modifications or limitations apply: (a) The plate bearing test will be performed when the pavement temperature equals or exceeds the maximum ambient temperature for the hottest period of the year, and (b) in no case will a k value greater than 135 MN/m^3 (500 pci) be used for design. When Figure 8-1 is used to estimate the k value at the surface of the existing flexible pavement, the bituminous concrete portion will be assumed to be unbound base material since its performance will be similar to a base course.

9. NONRIGID OVERLAY OF EXISTING RIGID PAVEMENT.

a. General. Two types of nonrigid overlay, all-bituminous concrete overlay, and flexible overlay, may be used with certain reservations to strengthen an existing rigid pavement.

b. All-Bituminous Overlay. The all-bituminous overlay will be composed of hot-mix bituminous concrete meeting the requirements of TM 5-822-8/AFM 88-6, Chapter 9. A tack coat is required between the existing rigid pavement and the overlay. The all-bituminous overlay is the preferred nonrigid type overlay to lessen the danger of entrapped moisture in the overlay.

c. Flexible Overlay. The flexible overlay will be composed of hot-mix bituminous concrete and high-quality crushed aggregate base with a CBR of 100, provided positive drainage of the base course is achieved. The bituminous concrete will meet the requirements of TM 5-822-8/AFM 88-6, Chapter 9 and the minimum thickness requirements of Chapter 8. If the design thickness of nonrigid overlay is less than that required by the minimum thickness of bituminous concrete and base course, the overlay will be designed as an all-bituminous overlay.

d. Thickness Determination. Regardless of the type of nonrigid overlay, the required thickness t_o will be determined by

$$t_o = 3.0(Fh_d - Ch_E) \qquad (17\text{-}4)$$

where

h_d = design thickness of plain concrete pavement using the flexural strength R of the concrete in the existing rigid pavement and the modulus of soil reaction k of the existing pavement.

The factor h_E represents the thickness of plain concrete pavement equivalent in load-carrying ability to the thickness of existing rigid pavement. If the existing rigid pavement is plain concrete, then the equivalent thickness equals the existing thickness; however, if the existing rigid pavement is reinforced concrete, the equivalent thickness must be determined from Figure 13-1. F is a factor, determined from Figure 17-2, that projects the cracking expected to occur in the base pavement during the design life of the overlay. Use of Figure 17-2 requires converting passes to coverages using values shown in Table 17-1. C is a coefficient based upon the structural condition of the existing rigid pavement. The minimum thickness of overlay used for strengthening purposes will be 50 millimeters (2 inches) for Air Force type D traffic areas and all overruns, 75 millimeters (3 inches) for Army Class I, II, and III pavements, 75 millimeters (3 inches) for Air Force types B and C traffic areas on light-load pavements, 75 millimeters (3 inches) for Navy and Marine Corps secondary pavements designed for fighter aircraft, and 100 millimeters (4 inches) for all other Army, Air Force, Navy and Marine Corps pavements. In certain instances, the nonrigid overlay design equation will indicate thickness requirements less (sometimes negative values) than the minimum values. In such cases the minimum thickness requirement will be used. When strengthening existing rigid pavements that exhibit flexural strength less than 3.5 MPa (500 psi) or that are constructed on foundations with k values exceeding 54 MN/m^3 (200 pci), it may be found that the flexible pavement design procedure in Chapter 10 or 11 may indicate a lesser required overlay thickness than the overlay design formula. For these conditions, the overlay thickness will be determined by both methods, and the lesser thickness used for design. For the flexible pavement design procedure, the existing rigid pavement will be considered to be either an equivalent thickness of high-quality crushed aggregate base with a CBR = 100 or an equivalent thickness of all-bituminous concrete (equivalency factor of 1.15 for base and 2.3 for subbase), and the total pavement thickness determined based upon the subgrade CBR. Any existing base or subbase layers will be considered as corresponding layers in the flexible pavement. The thickness of required overlay will then be the difference between the required flexible pavement thickness and the combined thicknesses of existing rigid pavement and any base or subbase layers above the subgrade.

e. Reflective Cracking. If a flexible overlay is placed over a rigid pavement, the underlying joints will reflect through the overlay, and these cracks will progressively deteriorate by raveling. This reflective cracking is primarily caused by seasonal and diurnal environmental changes occurring in the overlaid rigid pavement, and reflective cracking will often appear during the first winter after the placement of the overlay. At present there is no completely reliable method of preventing reflective cracking. Consequently, in many cases, the designer should probably consider a flexible overlay as a maintenance tool to upgrade the serviceability and to a more limited extent, the structural capacity of a rigid pavement for a relatively limited time while more comprehensive rehabilitation is postponed to the future. Some methods of ameliorating the adverse effects of reflective cracking include:

(1) Overlay Thickness: The thicker the overlay, the longer the cracking will be postponed and the slower it will deteriorate. Hence, abiding by minimum flexible overlay thicknesses is an important issue.

(2) Saw and Seal: Since there is no way to reliably avoid reflective cracking, another approach is to saw the flexible overlay directly above the rigid pavement joints and seal this with an appropriate sealer. These sealed cuts are then more easily and effectively maintained than the reflective cracks would be. The Air Force has found this to be an effective approach, and it is generally their preferred approach to dealing with flexible overlays over rigid pavements.

(3) Geotextiles: Geotextiles have shown a limited ability to slow the development and severity of reflective cracking in warm climates. Field trials found that in Area I of Figure 17-3, geotextiles were usually helpful, in Area II they gave mixed results, and in Area III, they were ineffective in dealing with reflective cracking. The minumum overlay thickness is 100 millimeters (4 inches).

(4) Crack & Seat and Rubblizing: An alternative approach is to break the existing rigid pavement slabs into smaller individual segments (crack and seat) or to pulverize them into shattered small fragments (essentially rubblize to aggregate) before overlaying . Concetually, the shattered slabs or rubblized concrete fragments are then too small to develop movements to generate reflective cracks. This technique has proven successful on highways, but experience on thicker pavements such as found on airfields is very limited at present.

(5) Bond Breakers: Open graded materials, aggregate bases as part of the flexible overlay, and specially designed stress/strain absorbing membranes have all been tried to provide a layer capable of absorbing the movement of the underlying rigid pavement without transmitting it to the asphalt concrete overlay surface. These have given mixed results, and some systems are proprietary.

(6) Reinforcing: Besides geotextiles, other proprietary reinforcing systems using steel wire and fiberglass grids to combat reflective cracking are available. These have not been evaluated by the military.

Military experience has found thicker overlays and in some warm climates geotextiles may help mitigate but not prevent reflective cracking in flexible overlays. Sawing and sealing above the rigid pavement joints has also been found to be a pragmatic way of minimizing the problems with

Table 17-1
Pass per Coverage Ratios

reflective cracking. The other techniques discussed above have given mixed results or have not been independently evaluated by the military.

f. Example of Nonrigid Overlay Design. An existing rigid pavement will be strengthened to support 75,000 operations of the C-130 aircraft using a nonrigid overlay. It is a type B traffic area. The existing rigid pavement is 229 millimeters (9 inches) of plain concrete on a 152-millimeter (6-inch) crushed aggregate base and has the following properties: R = 4.8 MPa (700 psi), k of subgrade = 41 MN/m^3 (150 pci), and C = 0.75. The k value on top of the base course is determined to be 54 MN/m^3 (200 pci) from Figure 8-1 using the subgrade k of 41 MN/m^3 (150 pci) and 152 millimeters (6 inches) of base course. The required thickness of nonrigid overlay is determined by

$$t_o = 3.0\ (Fh_d - Ch_E) \tag{17-5}$$

To determine F, convert passes of the C-130 into coverages using the pass per coverages ratio of 8.54 from Table 17-1. The 75,000 passes convert to 1,171 coverages. Therefore, for a k of 54 MN/m^3 (200 pci) and 1,171 coverages, the F factor from Figure 19-2 is 0.78. Values of h_d, determined from Figure 12-5 with the design gross aircraft weight of 79,380 kilograms (155 kips), flexural strength of 4.8 MPa (700 psi), and k value of 54 MN/m^3 (200 pci) is 256 millimeters (10 inches). Since the existing pavement is concrete, then the equivalent thickness h_E is equal to the existing thickness of 229 millimeters (9.0 inches). Therefore, the required overlay thickness t_o is:

$$(3)(0.78 \times 256 - 0.75 \times 229) = 84 \text{ mm (SI units)}$$

$$(3)(0.78 \times 10 - 0.75 \times 9) = 3.15 \text{ in. (English units)}$$

Use the minimum thickness of 102 millimeters (4 inches).

10. NONRIGID OVERLAY ON FLEXIBLE PAVEMENT. After a determination has been made that strengthening of a flexible pavement is required, design the overlay thickness as follows:

a. Determine the total thickness of the section, and the thickness of the base and surface courses from the criteria in Chapter 12 or 13 for the design aircraft. Compare the new design requirements with the existing section to determine the thickness of overlay required.

b. Where the in-place density of the existing material is less than required, the overlay thickness should be increased or the low-density material recompacted. In some instances this is possible by using heavy rollers on the surface to compact the underlying layers. However, if the moisture content of these layers, particularly if cohesive, is above optimum, their shear strength may be decreased by heavy rolling. Heavy rolling, also, will frequently damage the surface layer if brittle. The decision to excavate and recompact low density layers or to increase the overlay thickness should be examined very carefully in each case. Factors to be considered in this examination are depth of water table, subgrade soil properties, and the performance of the existing pavement.

c. Overlaid asphalt courses must meet the quality requirements for their position in the strengthened pavement.

d. As an example of the overlay design procedure, it is assumed that an existing pavement (type B traffic area) is to be upgraded to an Air Force medium-load pavement. The existing pavement consists of 75 millimeters (3 inches) of AC, 150 millimeters (6 inches) of base (100 CBR), and 533 millimeters (21 inches) of subbase (50 CBR). The subgrade is a lean clay with a CBR of 6, and has a density of 95 percent in the top 150 millimeters (6 inches) and 90 percent below 150 millimeters (6 inches). From Figure 10-18, the total thickness of new pavement required is 1,143 millimeters (45 inches) and the thickness of base and surface required over the 50 CBR subbase is 178 millimeters (7 inches). However, from Table 8-5, the minimum surface and aggregate base course required for medium load and traffic area B is 25 millimeters (10 inches). From Table 6-2, it is noted that the in-place subgrade density is adequate. Based on above information, the following analysis is made:

(1) New design criteria requires a 1,143-millimeter (45-inch) pavement section above the subgrade and, from Table 8-5, 254 millimeters (10 inches) above the subbase.

(2) Existing pavement section is 758 millimeters (30 inches) with 225 millimeters (9 inches) above the subbase.

(3) In this example, the existing thickness would require an additional inch of pavement to meet the minimum thickness asphalt and the thickness required above the subbase. A 1-inch overlay however is not sufficient to protect the subgrade which requires 1,143 millimeters (45 inches) (or equivalent) of pavement above it. Any thickness of asphalt exceeding the minimum of 100 millimeters (4 inches) can be converted to an equivalent thickness of subbase. This excessive thickness of asphalt is equal to the thickness of overlay plus any existing thickness of asphalt minus the minimum thickness. The required thickness of overlay (t_o) is then determined as follows:

$$t_m + (t_o + t_e - t_m)E_f + t_b + t_{Sb} = T_p \qquad (17\text{-}6)$$

where

t_m = minimum thickness of asphalt

t_o = thickness of overlay

t_e = thickness of existing asphalt

E_f = equivalency factor for converting asphalt to an equivalent thickness of subbase

t_{Sb} = thickness of existing base course

t_b = thickness of existing subbase

T_p = total thickness of pavement required above the subgrade

For this example, the equation is

$$4 + (t_o + 3 - 4)2.3 + 6 + 21 = 45 \text{ (English units)}$$

The thickness of overlay to use would then be 178 millimeters (7 inches).

11. OVERLAYS IN FROST REGIONS. Whenever the subgrade is subject to frost action, the design will meet the requirements for frost action stated in Chapter 22. The design will conform to frost requirements for rigid pavements. If subgrade conditions will produce detrimental nonuniform frost heaving, overlay pavement design will not be considered unless the combined thickness of overlay and existing pavement is sufficient to prevent substantial freezing of the subgrade.

CHAPTER 18

RIGID PAVEMENT INLAY DESIGN

1. GENERAL. Many existing airfield pavement facilities have developed severe distress because the design life or the load-carrying capacity of the facilities has been exceeded. The distress normally occurs first in the center lanes of the runways and taxiways because of the concentration of traffic. A method commonly used to rehabilitate these distressed facilities is to construct an adequately designed rigid pavement inlay section in the center of the facility. These inlays are generally 15 meters (50 feet) wide for taxiways and 23 meters (75 feet) wide for runways; however, the widths will be influenced by the lateral traffic distribution and, in existing rigid pavements, by the joint configuration. The inlay pavement may consist of plain concrete or reinforced concrete. The thickness design of the rigid inlay will be the same as outlined in Chapters 12 through 16 or 19, except for the special requirements presented herein.

2. RIGID INLAYS IN EXISTING FLEXIBLE PAVEMENT.

a. Figure 18-1 shows a section of a typical rigid pavement inlay in an existing flexible pavement.

b. Removal of the existing flexible pavement will be held to the absolute minimum. The depth of the excavation will not exceed the design thickness of rigid inlay pavement. The width of excavation of the existing pavement will not exceed the required width of the inlay section plus the minimum necessary, approximately 1 meter (3 feet), for forming or slipforming the edges of the concrete pavement (Figure 18-1).

c. Subdrains and drainage layers will be considered only when they are essential to the construction of the inlay section or necessary for proper drainage. When required, the subdrains will be placed outside of the edge of the rigid inlay and at least 100 millimeters (4 inches) below the bottom of the inlay pavement to permit construction of the stabilized layer required in the following paragraph.

d. Unless the material in the bottom of the excavation is granular and free-draining or the airfield is located in a arid climate, the bottom full width of the excavation will be scarified to a minimum depth of 150 millimeters (6 inches), and recompacted to the density requirements for the top 150 millimeters (6 inches) of base course or subgrade as specified previously. This type of overlay may trap water, and satisfactory drainage must be provided. Reference should be made to TM 5-822-14/AFJMAN 32-1019 for selection of stabilizing agent and minimum strength requirements.

e. The modulus of soil reaction k used for the design of the rigid pavement inlay will be determined on the surface of the material at the bottom of the excavation prior to stabilization. If stabilization is used and if the strength of the stabilized material does not meet the requirements in TM 5-822-14/AFJMAN 32-1019 for pavement thickness reduction, no structural credit will be given to the stabilized material in the design of the rigid pavement inlay. If the strength of the stabilized layer meets the minimum strength requirement for pavement thickness reduction in TM 5-822-14/AFJMAN 32-1019, the rigid pavement inlay will be designed in accordance with applicable sections of Chapters 12 through 16 pertaining to the use of stabilized soil layers.

f. If the existing pavement is not composed of nonfrost-susceptible materials sufficient to eliminate substantial frost penetration into an underlying frost-susceptible material, an appropriate reduction in the k value will be made in accordance with Chapter 20.

g. After the construction of the rigid pavement inlay, the working areas used for forming or slipforming the sides of the concrete will be backfilled to within 100 millimeters (4 inches) of the pavement surface with either lean-mix concrete or normal paving concrete.

h. The existing bituminous concrete will be sawed parallel to and at a distance of 3 meters (10 feet) from each edge of the inlay. The bituminous concrete surface and binder courses and, if necessary, the base course will be removed to provide a depth of 100 millimeters (4 inches). The exposed surface of the base course will be recompacted, and a 3-meter (10-foot) wide paving lane of bituminous concrete, 100 millimeters (4 inches) thick, will be used to fill the gap (Figure 18-1). The bituminous concrete mix will be designed in accordance with Chapter 9.

I. In cases where the 3-meter (10-foot) width of new bituminous concrete at either side of the inlay section does not permit a reasonably smooth transition from the inlay to the existing pavement, additional leveling work outside of the 3-meter (10-foot) lane will be accomplished by removal and replacement, planer operation, or both.

3. RIGID INLAYS IN EXISTING RIGID PAVEMENT.

a. Figure 18-2 shows a section of a typical rigid pavement inlay in an existing rigid pavement.

b. The existing rigid pavement will be removed to the nearest longitudinal joints that will provide the design width of the rigid pavement inlay. Care will be exercised in the removal of the existing rigid pavement to preserve the load-transfer device (key, keyway, or dowel) in the longitudinal joint at the edge of the new inlay pavement. If the existing load-transfer devices can be kept intact, they will be used to provide load transfer between the rigid pavement inlay and the existing pavement except that a male key will be removed. If the load-transfer devices are damaged or destroyed, a thickened-edge joint shall be used to protect against edge loading of the existing pavement or the face shall be sawed vertically and dowels installed. In addition to the removal of the existing pavement, the existing base and/or subgrade will be removed to the depth required for the design thickness of the rigid pavement inlay.

c. The criteria for subdrains, stabilization, soil strength and frost also pertain to rigid pavement inlays in existing rigid pavements.

d. The design of the rigid pavement inlay, including joint types and spacing, will be in accordance with the chapter pertaining to the type of rigid pavement selected.

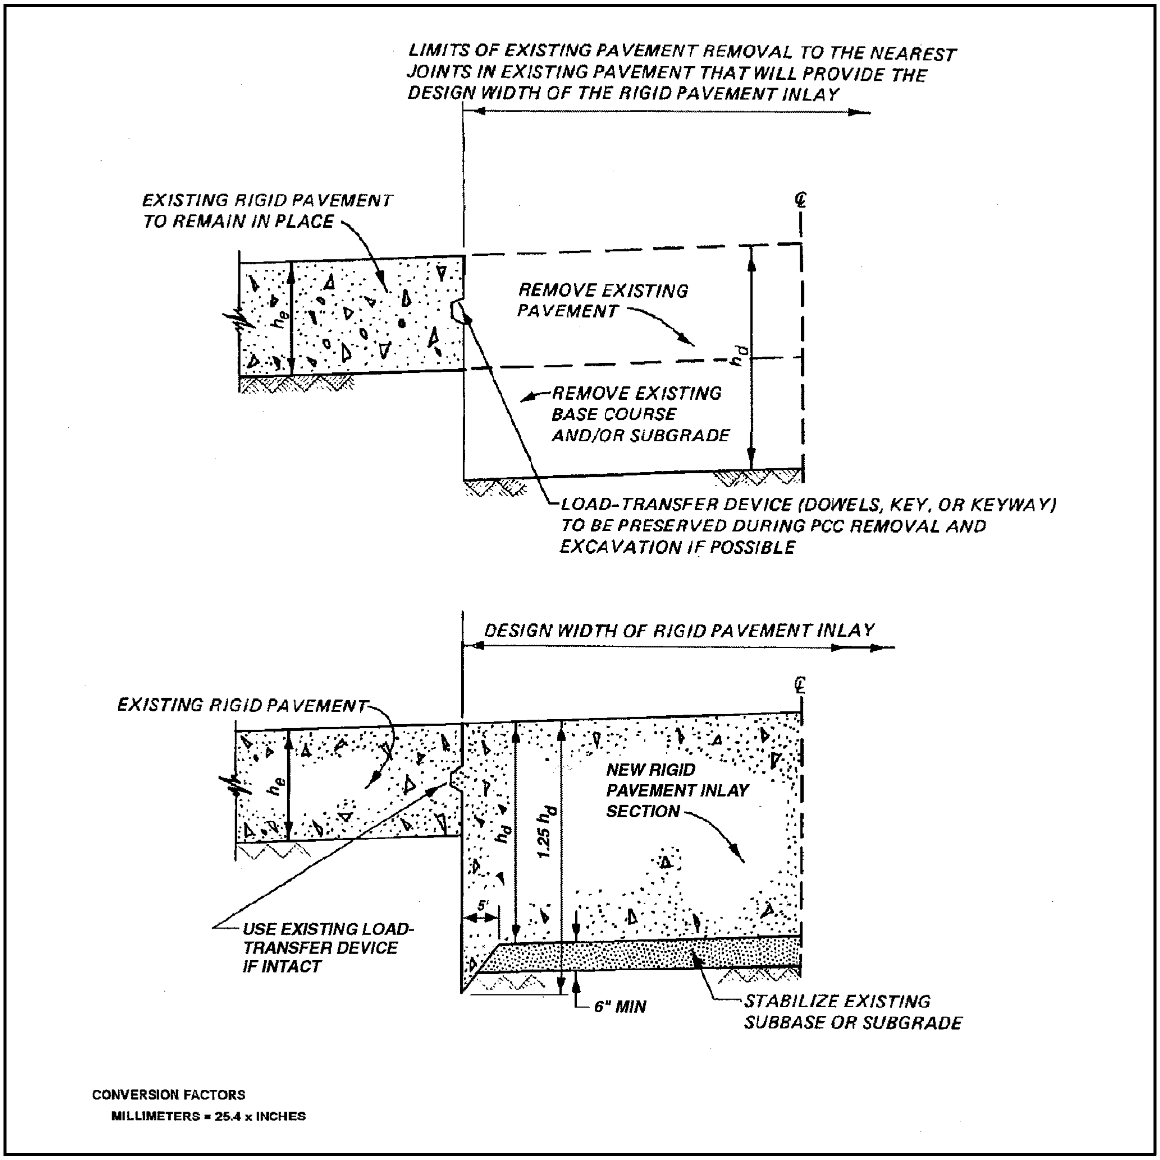

Figure 18-2. Typical rigid pavement inlay in existing rigid pavement

CHAPTER 19

LAYER ELASTIC DESIGN OF RIGID PAVEMENTS

1.RIGID PAVEMENT DESIGN PRINCIPLES. The basic design principle for this design procedure is to limit the tensile stresses in the Portland Cement Concrete (PCC) to levels that are sufficiently below the flexural strength of the concrete such that failure occurs only after the pavement has sustained a number of load repetitions. The tensile stress is modeled by the use of Burmister's solution for elastic multilayered continua and calculated using the JULEA computer program. The computed tensile stress divided by the concrete strength is the design parameter and is referred to as the design factor. This parameter has been related to pavement performance through a study of test section data. To account for mixed traffic, i.e., traffic producing stresses of varying magnitudes, the cumulative damage concept based on Miner's hypothesis is employed. This procedure may be used as an option to the empirical procedure for the design of new Navy pavements. The design procedure is illustrated in Figure 19-1 and summarized as follows:

a. Select three or four concrete slab thicknesses and compute the maximum tensile stresses in the slabs under the design aircraft load.

b. Based on the computed stresses, determine the allowable coverages N_i ($N_i = C_o$ for initial cracking criteria or $N_i = C_f$ for complete failure criteria) using Equations 19-1, 19-2, and 19-3 for each thickness design.

c. Compute the damage for each design which is equal to the ratio of the design coverage n_i to the allowable coverage N_i, where i varies from 1 to the number of aircraft.

d. Select the proper slab thickness at a damage value of 1.0 from the relationship between damage and slab thicknesses.

e. The selection of an unbound granular base or a stabilized base under the concrete slab is a matter of engineering judgment depending on many factors such as cost, material availability, frost penetration requirement, and subgrade swell potential. Subgrade soil may be stabilized to gain strength or modified to increase its workability and reduce swell potential.

2.R IGID PAVEMENT RESPONSE MODEL. The pavement is assumed to be a multilayered continuum with each layer being elastic, isotropic, and homogeneous. Each layer is to extend to infinity in the horizontal direction and to have, except for the bottom layer, a finite thickness. The applied loads to the pavement are considered as static circular and uniform over the contact area. The program chosen for the analysis is JULEA computer code. This program was chosen because it provided accurate computations and provisions for different degrees of bond between interfaces. Investigations into modeling rigid pavements with this code have resulted in the performance criteria being developed with the assumptions that the interface between the PCC slab and the supporting subgrade is considered smooth with no bond; i.e., there is no frictional resistance at the interface and all other interfaces are considered to be completely bonded. At a depth of 6 meters (20 feet), a very stiff bottom layer is used to mitigate the assumption that the bottom layer extends to infinity. Figure 21-1 presents a diagram for the design of pavements using the layered elastic analysis.

3.DESI GN PROCEDURE. Design of rigid pavements using the elastic layered procedure is initiated by assuming a pavement section. The assumptions are the number of layers, type of materials, and layer thicknesses. For each material in the assumed section, the modulus of elasticity (E) and Poisson's ratio (μ) are determined. The design flexural strength (R) of the concrete is also determined. The aircraft parameters are defined beginning with the first aircraft (AC_1) in the list of aircraft. The parameters required for the response model are tire contact area, tire loading, number of tires, and tire spacing. Traffic volume is expressed in terms of coverages. The elastic parameters for the materials, the layer thicknesses, and the aircraft parameters for the first aircraft are input into the response model (JULEA computer code) to calculate the tensile stress (σ_1) in the concrete resulting from loading the first aircraft. The computed stress is used along with the concrete design strength to compute a design factor for the first aircraft (DF_1). The design factor is input into the performance model to determine the allowable traffic (N_1) in terms of coverages for the first aircraft on the assumed pavement section. The damage caused by the first aircraft is computed by dividing the applied traffic by the allowable traffic, i.e., n_1/N_1 . The damage caused by the first aircraft is then added to the damage caused by subsequent aircraft. After computing the damage for the first aircraft, the procedure is repeated for other aircraft. After completing the damage computations for all aircraft, the computed cumulative damage is compared with unity. If the assumed section gives a computed cumulative damage substantially different from unity, then a new section is assumed and the procedure repeated for all aircraft. After computing the damage for two sections, a plot of log damage as a function of pavement thickness can be used to estimate the required thickness and used as the assumed section for the next iteration. By updating the plot, the thickness yielding a cumulative damage approximately equal to unity can quickly be established.

4.MAT ERIAL CHARACTERIZATION.

a. Portland-Cement Concrete (PCC).

(1) General. The effects of repeated load on PCC modulus of elasticity are not considered because of the complexity of the relationship between modulus of elasticity and repeated loads and the apparently small magnitude of change caused by traffic. There may be some decrease in modulus because of repeated loads or exposure, but conversely, there should be some increase because of the effects of long-term hydration. The net result is that the computation of the modulus of elasticity from the stress-strain relationship obtained from the initial loading of a PCC specimen is considered adequate for characterizing the material for the life of a pavement.

(a) Poisson's ratio for PCC normally receives very little attention. The range of statically determined Poisson's ratio is only about 0.11 to 0.21, and the average of dynamically determined values was about 0.24. Added factors are the difficulty of measurement and relatively small influence that varying Poisson's ratio within a reasonable range has on the computed response. No procedures are recommended for determining Poisson's ratio for PCC. It is recommended that a value of 0.15 be used for all PCC.

(b) The magnitude of stress that can be sustained by PCC before cracking is a function of the number of repetitions of the stress. This stress magnitude decreases as the number of stress repetitions increases. The number of stress repetitions of a given magnitude that a material can sustain is dependent on numerous factors, such as age, mix proportions, type of aggregate, rate of loading, range of loading, etc. The most important, however, is the static strength of the material. The stress in the slabs is due primarily to bending, and a flexural test is considered the most appropriate for characterizing PCC.

(2) Modulus of elasticity and flexural strength. The modulus of elasticity E_f and flexural strength R of PCC will be determined from static flexural tests of beams having a cross-sectional area

of 152 by 152 millimeters (6 by 6 inches) with a length long enough to permit testing over a span of 457 millimeters (18 inches). The recommended procedures are widely accepted and extensively used for determining the properties of PCC. The test procedure for determining flexural strength and modulus of elasticity will be determined in accordance with ASTM C 78 and CRD-C 21, respectively. When aggregate larger than the 51-millimeter (2-inch) nominal size is used in the concrete, the mix will be wet-screened over a 51-millimeter (2-inch) square mesh sieve before it is used for casting the beam specimen.

(3) Mix proportioning and control. Proportioning of the concrete mix and control of the concrete for pavement construction will be in accordance with TM 5-822-7/AFM 88-6, Chapter 8. Normally, a design flexural strength at 90-days will be used for pavement thickness determination. Should it be necessary to use the pavements at an earlier age, consideration should be given to the use of a design flexural strength at the earlier age or to the use of high early-strength cement, whichever is more economical.

b. Bound Bases (Subbases).

(1) General. Chemically stabilized materials (portland cement, lime, fly ash, etc.) and bituminous-stabilized materials need to be discussed separately, even though the conclusions regarding inclusion of effects of repeated loading are the same. Due to the viscous and temperature-dependent behavior of the bituminous binder, bituminous-stabilized materials are affected by temperature and rate of loading to a much greater extent than any other component in a pavement structure.

(2) Requirements. Bituminous base materials are designed in accordance with TM 5-822-8/ AFM 88-6, Chapter 9. The design for frost consideration will be in accordance with Chapter 20, herein. Chemically stabilized materials should meet requirements set forth in TM 5-822-14/AFM 32-1019. Among these are requirements for durability and the requirement that strength increase with age. These requirements are intended to ensure that the materials continue to function with age and that no adverse chemical reactions occur. However, in terms of ensuring that the material functions as a bound material (sustains flexural loading), it is required that the material attain an unconfined compressive strength of 1.7 MPa (250 psi) at 28 days. This requirement should be used in lieu of strength requirements in the above references. Chemically treated soils in which no substantial increase in strength is considered are modified soils and should be characterized using the methods presented herein for unbound base, subbase, and subgrade materials. Chemically treated soils having unconfined compressive strengths greater than 1.7 MPa (250 psi) should be tested in accordance with the methods specified for stabilized materials. Pavement designs that result in a nonstabilized (pervious) layer sandwiched between a stabilized or modified soil (impervious) layer and the pavement present the danger of entrapped water with subsequent instability in the nonstabilized layer. These designs will not be used unless the nonstabilized layer is positively drained, and its use on Air Force bases will require the approval of the appropriate Air Force Major Command.

(3) Modulus and Poisson's ratio. The modulus of elasticity E_f of bound base material will be determined from cyclic flexural tests of beams. The recommended test procedures have not been standardized but are described in Appendix J. There are differences in the procedures for chemically stabilized materials and those stabilized with bituminous binders. These differences are necessary because of the sensitivity of bituminous-stabilized bases to rates of loading and temperature.

(a) A simply supported unconfined beam loaded at the third point with essentially point loads will be used for bound bases (subbases). For chemically stabilized bound bases, the ultimate load is first determined. Loads of 0.4, 0.6, and 0.8 times the ultimate load are applied repetitively, and the modulus is computed from the load-deflection curves. The modulus used should be the average obtained for the three loadings. For bituminous-stabilized materials, the definition of an ultimate load will be dependent on the rate of application of load and the temperature. Several loads should be selected that will result in stresses in the outer fibers of the beam, which are less than the values shown in Table 19-1. One test should be conducted at about 0.34 MPa (50 psi).

Table 19-1
Recommended Maximum Stress Levels to Test Bituminous-Stabilized Materials

Temperature Range, °C(°F)	Maximum Stress Level in Extreme Fibers, MPa (psi)
4.4-15.5 (40-60)	3.1 (450)
15.5-27 (60-80)	2.1 (300)
27-38 (80-100)	1.4 (200)

(b) An indirect method of obtaining an estimated modulus value for bituminous concrete is presented in detail in Appendix C. The use of this method requires that the ring-and-ball softening point and the penetration of the bitumen as well as the volume concentration of the aggregate and percent air voids of the compacted mixture be determined.

(c) No procedures are provided for determining Poisson's ratio of bound base material. It is recommended that the values in Table 19-2 be used.

Table 19-2
Poisson's Ratio Values for Bound Base Material

Material	Poisson's Ratio
Bituminous-stabilized	0.5 for E < 3,447 MPa (500,000 psi)
	0.3 for E > 3,447 MPa (500,000 psi)
Chemically stabilized	0.2

c. Unbound (Granular) Bases (Subbases).

(1) General. Unbound granular materials are extremely difficult to characterize. The state of stress, particularly the confining stress, is the dominating factor in determining load-deformation properties. Repeated loadings also affect the modulus of granular materials. The general pattern noted was that repeated loadings increased the stiffness provided shear failure was not progressing. This implies that the modulus of elasticity is increased.

(2) Material requirement. A complete investigation will be made to determine the source, quantity, and characteristics of available materials. A study should be made to determine the most economical thickness of material for a base course that will meet requirements. The base course may consist of natural materials or processed materials, well-graded and high-stability, as referred to in Chapter 8. All base courses to be placed beneath airfield rigid pavements will conform to the following requirements:

(a) Well-graded course to fine.

(b) Not more than 85 percent passing the 2-millimeter (No. 10) sieve.

(c) Not more than 15 percent passing the 0.075-millimeter (No. 200) sieve.

(d) PI not more than 8 percent.

However, when it is necessary that the base course provide drainage, the requirements set forth in TM 5-820-2/AFM 88-5, Chapter 2, will be followed. When frost penetration is a factor, the requirements set forth in Chapter 20, herein, will be followed.

(3) Compaction requirements. High densities are essential to keep future consolidation to a minimum; however, thin base courses placed on yielding subgrades are difficult to compact to high densities. Therefore, the design density in the base course materials should be as required in Chapters 7 and 8.

(4) Modulus and Poisson's ratio. The modulus values of unbound granular bases (subbases) will be determined from cyclic triaxial tests on prepared samples. The recommended test procedure is outlined in Appendix O. The outputs from the test procedure are measures of modulus of elasticity and Poisson's ratio. Triaxial compression tests should be conducted at confining pressures of 13.8, 34.5, 41.4, and 68.9 KPa (2, 5, 6, and 10 psi). Axial stresses should be applied that result in ratios with confining stresses (σ_1/σ_3) of 13.8, 20.7, 27.6, and 34.5 KPa (2, 3, 4, and 5 psi). Plots of resilient modulus versus first stress invariant ($\sigma_1 + \sigma_2 + \sigma_3$ or $\sigma_x + \sigma_y + \sigma_z$) should be prepared and an average relationship established. From this relationship, a value of resilient modulus at a first-stress invariant of 68.9 KPa (10 psi) should be selected. No well-defined relationships exist for Poisson's ratio. However, plots of Poisson's ratio versus ratio of axial to confining stress (σ_1/σ_3) may be made and representative values selected. The modulus value of granular material may also be estimated from the relationship in a chart in which the modulus is a function of the underlying layer and the layer thickness. The chart and the procedure for use of the chart are given in Appendix I. However, it is recommended that the chart be used in conjunction with test results to determine a representative modulus rather than as the sole method. A Poisson's ratio of 0.3 will be used unless there is a reason to believe that it is significantly different for the material in question.

d. Subgrade Soils.

(1) General. Subgrades may be divided into the general classes of cohesive and cohesionless soils. Repeated loadings affect both cohesive and cohesionless soils. Cohesionless sands, gravels, or sand-gravel combinations will respond much like granular bases or subbase. Cohesive soils are more sensitive to repeated loadings. The resilient modulus of cohesive subgrades generally increases with load repetitions provided the level of stress is lower than that required to initiate shear failure. However, the number of stress repetitions required before a stable condition is reached may be greater than for bound bases, granular bases, or cohesionless subgrades.

(2) Exploration. In all instances, field and laboratory tests will be conducted to determine the classification, moisture-density relations, expansion characteristics, and strength of the subgrade. If stabilization of the subgrade is to be considered, other tests as required by TM 5-822-14/AFM 32-1019, will be made, as well as chemical analysis and clay mineralogy determination. When a subgrade soil that has a chemical stabilizing agent added but does not meet the 1.72-MPa (250-psi) compressive strength requirement, the soil should be characterized with procedures for subgrades and be considered simply as part of the subgrade. The engineer is cautioned that although the elastic layered method requires only the modulus of elasticity and Poisson's ratio of the subgrade, such factors as groundwater, surface water infiltration, soil capillarity, topography, drainage, rainfall, and frost conditions may affect the future support rendered by the prepared subgrade or base course. Experience has shown that the subgrade will reach near saturation, even in semiarid and arid regions, after a pavement has been constructed. If conditions exist that will cause the subgrade soil to be affected adversely by frost action, the subgrade will be treated in accordance with the requirements in Chapter 20. Subgrades and base courses are grouped into three types with respect to behavior during saturation: low plastic soils exhibiting little or no swell, swelling soils, and cohesionless sands and gravels. Special cases of subgrade soil are discussed in Chapter 6.

(3) Modulus and Poisson's ratio. The modulus of elasticity and Poisson's ratio of subgrade soils will be determined from repetitive triaxial tests on undisturbed samples when possible or on samples prepared as close as possible to field conditions when fill is involved. The samples considered should represent the worst anticipated condition in the field. The recommended test procedures are outlined in Appendix K. The procedures are similar to those used for granular base (subbase) materials. There are differences in details of the test procedures and presentation of results for cohesive and cohesionless materials. These differences are necessary because of the sensitivity of cohesive soils to moisture and the differences in the behavior as a function of the state of stress.

(a) For characterizing cohesive materials, the triaxial tests should be conducted at a range of stress conditions. Tests should be conducted at confining stresses of 13.8, 27.6, and 41.4 KPa (2, 4, and 6 psi), and at axial stresses applied that will result in a range of deviator stress from about 13.8 to 110 KPa (2 to 16 psi). From the composite curve, the resilient modulus used to represent the material should be selected at a deviator stress of 34.5 KPa (5 psi). No well-defined relationships exist for Poisson's ratio, but similar plots may be made and a representative value selected.

(b) For cohesionless soils, the confining stress in the triaxial tests should approximate conditions in the subgrade. The minor principal stress in the subgrade is a measure of the confinement. For cohesionless subgrade soils, it is considered appropriate to select properties at minimum values of the first stress invariant and confining stress, since the general trends are applicable for cohesionless subgrade soils, i.e., as the confining stress and the first stress invariant decreases, the resilient modulus decreases.

(c) Basically, the same stresses should be used in the triaxial tests for characterizing cohesionless material as are used for granular bases. Confining pressures of 13.8, 27.6, 41.4, and 68.9 KPa (2, 4, 6, and 10 psi) and axial stresses that result in principal stress ratios (σ_1/σ_3) of 2, 3, 4, and 5 should be applied. From the average relationship of resilient modulus versus first stress invariant, a representative modulus value should be selected at a first stress invariant of 68.9 KPa (10 psi). A representative value of Poisson's ratio should be selected from a composite plot of Poisson's ratio versus principal stress ratio. If test results prove unreliable or are not available, the values of 0.4 for cohesive and 0.3 for cohesionless materials may be used.

(4) Modulus of soil reaction. In Westergaard-type solutions, the modulus of soil reaction k characterizes the foundation support under a rigid pavement. Consequently, the modulus of soil reaction k has been used extensively to define the supporting value of all unbound subgrade and base-course materials and all soils that have been additive-modified (TM 5-822-14/AFM 32-1019). The k value has been determined by the field plate bearing test as described in CRD-C 655. When elastic-layered procedures are used for pavements in which only information on modulus of soil reaction k is available, a correlation between the modulus of elasticity E and modulus of soil reaction k may be employed. Figure 19-2 shows such a correlation for subgrade soils. Figure 19-2 should be used with caution as the correlation was developed based on very limited data.

5.DESI GN CRITERIA.

a. The limiting stress (fatigue) criteria form the backbone of the design of rigid airfield pavements. The criteria provide for a prediction of pavement deterioration in terms of a structural condition index (SCI). The SCI is derived from a pavement condition index (PCI) as presented in ASTM D 5340. The SCI is defined as

$$\text{SCI} = \text{PCI} - \text{All nonload-related deducts}$$

The SCI prediction is based on a relationship between design factor and stress repetitions for initial cracking (SCI = 100) and for complete failure (SCI = 0). It is assumed to be linearly related to the logarithm of coverages between initial cracking and complete failure, which results in the relationship illustrated in Figure 19-3.

b. The thickness of the PCC is so selected that the maximum tensile stress at the bottom of the slab does not exceed the allowable value. The criteria are presented as a relationship between design factor, the SCI, and the logarithm (to the base ten) of coverages by the equations:

$$DF = 0.5234 + 0.3920 \log_{10} (C_o) \tag{19-1}$$

and

$$DF = 0.2967 + 0.3881 \log_{10} (C_f) \tag{19-2}$$

and the design factor is defined as

$$DF = R/\sigma \tag{19-3}$$

where

DF = design factor computed with elastic-layered method

R = concrete slab flexural strength, MPa (psi)

σ = maximum computed tensile stress with elastic-layered model such as JULEA computer program, MPa (psi)

C_o = coverage level at which the SCI begins to decrease from 100

C_f = coverage level at which the SCI becomes 0

SCI = the structural condition index desired at the end of the pavement design life

c. When aircraft passes are given, then the pass-per-coverage ratio for the particular design aircraft will be used to convert passes to coverages. The engineer is cautioned that Equations 19-1 and 19-2 were formulated based on accelerated traffic tests with volumes less than 10,000 coverages. The use of the relationship to design for traffic volume greater than 10,000 coverages, which will frequently be the case for current traffic volumes, will require extrapolation of the linear relationship. The pass-per-coverage ratios for some aircraft are shown in Table 17-1.

6.F ROST CONSIDERATION. Two methods have been developed for determining the thickness design of a pavement in frost areas. One method is to limit subgrade frost penetration and the other is to design the pavement for reduced subgrade strength. The first method is directed specifically to the control of pavement distortion caused by frost heave. It requires a sufficient thickness of pavement, base, and subbase to limit the penetration of frost into the frost-susceptible subgrade to an acceptable amount. Complete frost penetration prevention is nearly always uneconomical and unnecessary except in regions with a low design freezing index or where the pavement is designed for heavy-load aircraft. When the rigid airfield pavement is designed by the reduced subgrade strength method, a minimum thickness of 102 millimeters (4 inches) of granular unbound base will be used. A mechanistic procedure for seasonal frost is being developed. Until it is available, the method in Chapter 20 should be used.

7.ALT ERNATE OVERLAY DESIGN PROCEDURE. A methodology for the design of rigid overlays of rigid pavements has been developed that predicts pavement structural deterioration from load induced stresses. The performance of the pavement is expressed in terms of an SCI which relates the type, degree, and severity of pavement cracking and spalling on a scale from 0 to 100. The design methodology for rigid overlays uses the layered-elastic analytical model and the analysis of fatigue cracking in the base slab to predict rigid overlay deterioration in terms of an SCI. Because the methodology predicts performance, an accurate characterization of the materials, structural pavement condition, and fatigue are required. The steps for designing rigid overlays of rigid pavements are illustrated in Figure 19-1 and are implemented in the LEDRRO group of programs.

a. Material Properties. Each layer of the pavement must be described by a modulus of elasticity and a Poisson's ratio.

(1) The modulus value for the concrete can be determined in the laboratory or conservatively estimated as 27,576 MPa (4,000,000 psi).

(2) Modulus values for subgrade soils are often estimated from correlations with existing tests.

(3) Flexural strength of concrete overlays should be determined as part of the mixture proportioning studies. The flexural strength of the base slab may be determined from historical data, flexural beams cut from the base pavement, or approximate correlations between flexural strength and tests run on cores taken from the base pavement.

(4) The interface condition between layers also needs to be determined. The condition of the base slab at the time of the overlay determines the bonding condition used for the overlay. In general, the interface between concrete and other materials is considered to be frictionless. A frictionless interface may be attained by providing a bond breaker course between the overlay and the base pavement. If special effort is taken to prepare the surface for complete bonding, then the interface is considered to be fully bonded.

b. Base Slab Pavement Fatigue and Structural Condition. Traffic applied on the base slab before the overlay is placed consumes some of its fatigue life. If it has begun to deteriorate from traffic, an SCI can be determined from a pavement condition survey. The ratio between the effective modulus of elasticity (E_e) and the initial undamaged modulus of elasticity (E_i) is determined by the relationship:

$$R_E = \frac{E_e}{E_i} = 0.02 + 0.0064 * SCI + (0.00584 * SCI)^2 \quad (19\text{-}4)$$

This equation is used to account for the deterioration of the base pavement with the application of traffic. If the SCI of the base pavement is equal to 100, the amount of past traffic must be determined to estimate the remaining fatigue life of the base slab.

c. Selection of Trial Thickness. The rigid overlay design procedure is an iterative process. A trial overlay thickness is assumed, and its condition assessed in terms of the overlay life predicted for the design SCI. If the predicted life is unacceptably low, then a thicker overlay thickness is assumed. If the initial trial overlay thickness predicts a pavement life that is too high, then a thinner overlay is tried.

d. Base Slab Performance. The base pavement performance curve is determined by calculating the damage rate at the time of initial cracking (DR_o) and the damage rate at the time of complete failure (DR_f). Equations 19-1, 19-2, and 19-3 in conjunction with the following equations are used to compute the damage rates.

$$DR_o = \sum_{i=1}^{nac} \frac{(C_r)_i}{C_o} \quad \text{and} \quad DR_f = \sum_{i=1}^{nac} \frac{(C_r)_i}{C_f} \quad (19\text{-}5)$$

$$t_o = \frac{B_o}{DR_o} \quad \text{and} \quad t_f = \frac{B_f}{DR_f} \quad (19\text{-}6)$$

where

C_r = design traffic rate, coverages per year

C_o = allowable coverage level at the time of initial cracking (SCI begins to decrease from 100)

C_f = allowable coverage level at the time of complete failure (SCI = 0)

nac = number of aircraft

t_o, t_f = time to initial cracking and time to complete failure, respectively

B_o, B_f = remaining life of base pavement to initial cracking and complete failure, respectively. The remaining life may be estimated from PCI surveys or by computing the damage caused by applied traffic before overlay. ($B_o = 1 - \sum C_i/C_o$ and $B_f = 1 - \sum C_i/C_f$)
C_i = applied past traffic, coverages

e. Time Periods. The base pavement performance curve (with the overlay in place) is divided into time periods so that the variation of the base slab support with time can be determined. The first time period is up to the base slab t_o. The last time period is the time past the t_f. If some traffic has been applied before overlay, the fatigue life consumed must be subtracted from t_o and t_f because this damage has already occurred. To calculate the stresses in the overlay, Equation 19-4 is used to determine the varying base slab support for each of the time periods. If the base slab has begun to deteriorate before the overlay is placed (SCI is less than 100), the base SCI value at the time of the overlay determines the initial support condition. If the time to initial cracking computed exceeds t_o, the time to initial cracking can be set to t_o. Doing so is equivalent to assuming that the base pavement will start to deteriorate with the first coverage of traffic on the overlay. Figure 19-4 illustrates the performance curve for the base slab subdivided into five time periods.

f. Overlay Performance Curve. Once the base pavement performance curve is established, the damage is computed and accumulated for each time period. The damage for a time period is computed as:

$$(d_o)_j = \Delta T_j * \sum_{i=1}^{nac} \frac{C_{ij}}{(C_o)_j} \quad and \quad (d_f)_j = \Delta T_j * \sum_{i=1}^{nac} \frac{C_{ij}}{(C_f)_j} \tag{19-7}$$

where

$(d_o)_j$ = damage to initial cracking for time period j

$(d_f)_j$ = damage to complete failure for time period j

$(C_o)_j$ and $(C_f)_j$ = a function of the changing modulus of elasticity of the base slab in each time period whereas $j\Delta T_j$ is the magnitude of the time interval in years.

By plotting the cumulative damage versus time in years, the time to initial cracking and complete failure for the overlay can be established. These times correspond to the times when the cumulative damage reaches a value of one. From these time values, a plot of SCI versus logarithm of time (performance curve) then indicates how long the trial thickness will last for the selected design aircraft, traffic rate, and design SCI at the end of the composite overlay pavement design life. Figure 19-5 illustrates the composite overlay performance. If the life of the overlay for the trial overlay thickness is not adequate, a new overlay thickness is assumed and the process is repeated. If several overlay thicknesses are assumed, then a plot of thickness versus logarithm of time, like the one shown in Figure 19-6, can be generated for the selected design SCI, and the design overlay thickness can be chosen.

8.REI NFORCED CONCRETE. Limited full-scale accelerated traffic test data are available for the design of reinforced concrete pavements. The test tracks contained reinforced test sections of varying thickness and percentages of reinforcement. Comparisons were made between the performance of plain and reinforced pavements. The improvements in performance were related to the amount of steel in the concrete slabs. The basis for the comparison was the thickness of unreinforced pavement. The established criteria for the design of reinforced pavements is shown in Figure 19-7. Assuming that the proposed elastic layer design procedure can result in adequate thicknesses of unreinforced pavement, application of the criterion illustrated in Figure 19-7 will result in adequate thicknesses of reinforced pavements.

9.DESI GN EXAMPLES. Design examples are given illustrating various layer elastic design procedures. The first example illustrates the procedure for selecting a concrete thickness for an airfield designed for a single aircraft. This design example considers the cases of unreinforced concrete slabs. The second example is for an airfield subject to mixed traffic. Overlay designs are given in the last example. The designed concrete pavements are for a type A or primary traffic area. The steps in designing a rigid pavement using the elastic layered method are to establish input data, compute critical stresses, and complete final design.

a. Input Data Required for the Design.

(1) Modulus values and Poisson's ratios of the PCC, bonded and nonbonded granular materials, and subgrade soil. For the purpose of this design example, the following values are assumed in the computation.

E_{PCC} and μ_{PCC} = 27,580 MPa (4,000,000 psi) and 0.2, respectively

E_{bound} and μ_{bound} = 1,034 MPa (150,000 psi) and 0.2, respectively (stabilized base)

$E_{unbound}$ and $\mu_{unbound}$ = 207 MPa (30,000 psi) and 0.3, respectively (granular base)

$E_{subgrade}$ and $\mu_{subgrade}$ = 42 MPa (6,000 psi) and 0.4, respectively

(2) Flexural strength of the PCC. A value of 4.48 MPa (650 psi) is assumed.

(3) Aircraft parameters. The characteristics of the design aircraft and other traffic data required in design are wheel load, number and spacing of wheels in an assembly, tire contact pressure, design life, design traffic, design coverage level, and pass-to-coverage ratio for the particular aircraft.

(4) Limiting stress criteria. Equation 19-1 and 19-2 are used to determine the allowable coverages based on the computed critical stresses induced by the design aircraft.

b. Computation of Critical Stresses. The critical tensile stress in the trial concrete section is computed using the JULEA elastic layered model based on the design aircraft loading and the material properties of each component layer. The interface conditions between layers are such that frictional constraints do not exist between the PCC slab and the base layer and that frictional constraint is developed between the base layer and subgrade soil. Several concrete trial sections are needed for each design. A nearly optimum concrete slab thickness should first be selected, and concrete thicknesses less and greater than the optimum value are then selected. Computations should also be made for different thickness of base-course materials.

c. Final Design. The accumulated damage for each trial concrete section is computed based on the design and the allowable coverages. The final concrete slab thickness is selected as that thickness having an accumulated damage of 1.

10.DESI GN EXAMPLE 1, SINGLE AIRCRAFT.

a. Plain Concrete. This design example is for an airfield taxiway supporting the C-130 aircraft. The design loading for the C-130 on the taxiway is 70,300 kilograms (155,000 pounds). The design is for the C-130 aircraft having a single tandem gear with a tire spacing of 1.5 meters (60 inches) c-c, a tire load of 15,820 kilograms (34,875 pounds), a tire contact area of 0.258 m^2 (400 $in.^2$), a design traffic of 200,000 passes and a pass to coverage ratio of 4.40. For this example an SCI of 80 is desired at the end of the design life.

(1) Computations of critical stresses and damages. Several trial concrete slab thicknesses, i.e., 330, 356, 380, and 405 millimeters (13, 14, 15, and 16 inches) and two thicknesses of granular base and stabilized base, i.e., 15 and 457 millimeters (6 and 18 inches), were selected for design. The maximum tensile stresses in each concrete slab were computed using the elastic layered model JULEA. Equations 19-1, 19-2, and 19-3 were then used to calculate the allowable coverages based on the calculated stresses and the 4.48-MPa (650-psi) flexural strength of the PCC. The amount of damage is the ratio of the design passes to the allowable passes. The computed values, together with other pertinent pavement information, are presented in Tables 19-3 and 19-4 for different base materials. As an illustration, the determination of values shown in the first line of Table 19-3 is explained. For a pavement with 330-millimeter (13-inch) PCC and a 15-millimeter (6-inch) base, the maximum stress under the C-130 aircraft using the computer program JULEA is 2.36 MPa (343 psi). Since an SCI = 80 is desired at the end of the design life, the allowable pass level should be determined from the linear variation between initial cracking (C_o) and complete failure (C_f) (Figure 19-3). From Equation 19-1, the log C_o = 3.50, and from Equation 19-2, the log C_f = 4.12. Interpolating for an SCI = 80, a coverage level of 4,248 is obtained. The allowable pass level is computed as 4,248 * 4.40 = 18,691. The damage is calculated as the ratio of 200,000 and 18,691, i.e., 200,000/18,691 = 10.7.

(2) Selection of Concrete Thickness. The results between PCC thickness and damage presented in Table 19-3 for granular bases and in Table 19-4 for stabilized bases are plotted in Figure 19-8. The required PCC thicknesses are determined at a damage of 1. The required concrete thicknesses are 373 millimeters (14.7 inches) and 378 millimeters (14.9 inches) for granular bases of 457 millimeters (18 inches) and 152 millimeters (6 inches), respectively, and are 358 millimeters (14.1 inches) and 373 millimeters (14.7 inches) for stabilized bases of 457 millimeters (18 inches) and 152 millimeters (6 inches), respectively (thicknesses will be rounded to the nearest 10 millimeters (½ inches) for construction). Figure 19-8 shows that in the case of granular base, the increase of the base thickness from 152 to 457 millimeters (6 to 18 inches) reduces the PCC only 5 millimeters (2/10 inch). In the case of the stabilized base, the increase of the base thickness from 152 to 457 millimeters (6 to 18 inches) can reduce 13 millimeters (½ inch) of PCC. However, an economical comparison should be made between the 13-millimeter (½-inch) reduction in PCC and the 305-millimeter (12-inch) additional stabilized base to determine the final design.

b. Reinforced Concrete. For reinforced concrete pavements, the increase in effective slab thickness due to the presence of the steel in the pavement can be determined from the relationship shown in Figure 19-7. For example, if 0.10 percent reinforcing steel is used for the particular concrete thickness of 381 millimeters (15.0 inches), which was computed in the previous example (see Figure 19-8 for the case of a 152-millimeter (6-inch) base), the relationship shown in Figure 19-7 indicates that the slab thickness can be reduced to 381 millimeters × 0.9 = 343 millimeters (15 inches × 0.9 = 13.5 inches).

c. Frost Action. When frost action needs to be considered in the design, it should first be determined if the subgrade soil is frost susceptible. A description of frost susceptible soils is given in Chapter 20. The depth of frost penetration in the region shall be determined to check if the frost action is deep enough to weaken the subgrade soil. When this is the case, the reduced subgrade strength method shall be used for design. The procedures to determine the PCC thickness using the elastic layered model are then applied in the same manner as in the first part of this example; the only input parameter change is the (reduced) subgrade elastic modulus. To check for a lesser thickness requirement with limited frost penetration procedures, the criteria in Chapter 20 should be used.

11. DESIGN EXAMPLE 2, MIXED AIRCRAFT TRAFFIC. This design example is for type A traffic areas. The airfield has traffic of 12,500 passes of C-141 (156,500 kilograms (345,000 pounds)), 100 passes of B-52 (181,450 kilograms (400,000 pounds)), and 25,000 passes of F-15 (30,850 kilograms (68,000 pounds)), and 12,500 passes of C-17 (1,179,400 kilograms (260,000 pounds)). The characteristics of the design aircraft are presented in Table 19-5. A 250-millimeter (10-inch) thick stabilized base layer is used in this example. An SCI = 80 is desired at the end of the design life.

a. Computations of Critical Stresses and Damage. A number of trial concrete slab thicknesses were selected for design. The maximum tensile stress in each concrete slab under each aircraft loading was computed using the elastic layered model. Equations 19-1, 19-2, and 19-3 were used to calculate the allowable coverages based on the calculated stresses and the flexural strength of 4.48 MPa (650 psi) for the PCC following the same procedure outlined in example 1. The amount of damage is the ratio of the design or applied passes to the allowable passes. The computed damage for different PCC

thicknesses under each of the four different aircraft are presented in Table 19-6. The total damage induced by the mixed traffic for different PCC thicknesses are tabulated in Table 19-7. The total damage is the sum of the damage caused by all the design aircraft.

b. Selection of Concrete Thickness. The results between the PCC thickness and damage presented in Table 19-7 are plotted in Figure 19-9, and the required slab thickness corresponding to a damage of 1 is determined as 470 millimeters (18.5 inches). Results in Table 19-7 indicate that for

Note: Allowable passes are computed using equations 19-1, 19-2, and 19-3 based on the computed maximum stress shown in column 3 based on a selected value of k and the pass-to-coverage ratio for the specific aircraft.
Conversion Factors: Millimeters = 25.4 × inches, Megapascals = 0.006894 × psi

Table 19-7
Relationship Between Cumulative Damage and PCC Thickness for Mixed Traffic

PCC Thickness mm (in.)	Damage				
	C-141	B-52	F-15	C-17	Cumulative
406 (16)	1.37	0.37	0.00	4.02	5.76
457 (18)	0.27	0.11	0.00	1.02	1.40
508 (20)	0.05	0.03	0.00	0.25	0.33
558 (22)	0.00	0.01	0.00	0.06	0.07
610 (24)	0.00	0.00	0.00	0.01	0.01

this mix of traffic, most pavement damage is caused by the 12,500 passes of the C-17 aircraft. Although the B-52 is a very heavy bomber aircraft, the 100 passes used for design at a reduced load cause minor damage to the pavement. Because the F-15 aircraft is very light, its 25,000 passes cause practically no damage to the pavement.

12.D ESIGN EXAMPLE 3, OVERLAY DESIGN. The overlay design example presented is for the airfield pavement illustrated in design example 1. The airfield had a 380-millimeter (15-inch) PCC originally designed for the C-130 aircraft. After several years of service, the airfield is to be upgraded to the mixed traffic presented in example 2. Based on the results of subgrade evaluation and following the design procedures in design example 2, the required PCC thickness without a base layer is computed as 470 millimeters (18.5 inches). The existing pavement is in good condition structurally, and the C factor for Equations 17-2 and 17-3 is equal to 0.75. Also, the flexural strength of the concrete in the existing slab is very close to that of the overlay (therefore, $h_d = h_c$), and the required overlay thicknesses h_o can be computed from Equations 17-2 and 17-3 as follows:

a. Computation for Nonbonded Concrete:

$$h_o = \sqrt{470^2 - 0.75(380)^2} = 335 \text{ millimeters}$$

$$h_o = \sqrt{18.5^2 - 0.75(15)^2} = 13.2 \text{ inches}$$

b. Computation for Partially Bonded Concrete:

$$h_o = \sqrt[1.4]{470^{1.4} - 0.75(380)^{1.4}} = 262 \text{ millimeters in SI units}$$

$$h_o = \sqrt[1.4]{18.5^{1.4} - 0.75(15)^{1.4}} = 10.3 \text{ in English units}$$

13.DESI GN EXAMPLE 4, ALTERNATE OVERLAY DESIGN PROCEDURE. This example is based on predicting structural deterioration from load-induced stresses. A concrete overlay must be designed to support the traffic mix from example 2. The pavement consisted of a 381-millimeter (15-inch) PCC pavement originally designed for the C-130 aircraft. It was considered that the concrete flexural strength of the overlay will be approximately equal to that of the base slab which is 4.48 MPa (650 psi). Only minor cracking of the base slab was observed; therefore, a SCI of 100 was assumed. It was also estimated from pavement condition surveys that 90 percent of the pavement life to reach initial cracking has been consumed. A bond breaker layer will be placed between the base slab and the overlay (unbonded case). The overlay will be designed for a 20-year operating life and an SCI = 80 at the end of its life.

a. Establish Base Slab Performance Curve. The first step in designing concrete overlays using the alternate methodology is to determine the performance of the base slab under the new traffic when the overlay is placed. For this example, overlay trial thicknesses of 305, 356, and 406 mm (12, 14, and 16 in.) are used. For each trial overlay, the tensile stress caused by each aircraft is computed at the bottom of the base slab. From these computed stresses the coverages to initial cracking and complete failure are computed. Table 19-8 presents in detail the necessary data and equations to perform the calculations. Column 1 of Table 19-8 contains the overlay trial thicknesses, column 2 contains the design aircraft, and column 3 contains design traffic data for each aircraft. Since the design is for a 20-year life, the traffic rate for the B-52 would be 100 passes (from example 2) divided by 20 years, or 5 passes per year. Column 4 contains the factor to convert passes to coverages. Column 5 contains the calculated tensile stresses at the bottom of the base slab using the elastic layer computer program JULEA. The coverages for initial cracking and complete failure of the base slab were computed using Equations 19-1 and 19-2. The damage rate (DR_o) is then computed and accumulated in column 7. The sum of the damage rates is used to calculate the time for initial cracking (T_o) in column 8. Similar calculations are performed in columns 9, 10, and 11 to calculate the damage rate for complete failure (DR_f) and the time for complete failure (T_f) of the base slab. These two time values establish the base slab rate of deterioration between the SCI=100 and an SCI=0. Figure 19-10 shows the base slab performance curve for the 356-millimeter (14-inch) overlay. Similar plots are generated for the 305- and the 406-millimeter (12- and the 16-inch) overlay trials. Finally, the time from the placement of the overlay (m_o) to initial cracking of the base slab is computed in column 12. Since 90 percent of the base slab life has been consumed, the remaining life is then 10 percent (B_o = 0.10). For the 356-millimeter (14-inch) overlay, m_o = 0.10/0.0158 = 6.33 years.

b. Subdivide Base Slab Performance Curve. The next step is to subdivide the base slab performance curve for a trial overlay thickness into time intervals. For the 356-millimeter (14-inch) overlay (Figure 19-10), the curve is divided into six intervals. The first interval will be from the time when the overlay is placed (m_o) to initial cracking of the base slab (T_o). This first interval then corresponds to 6.33 years. Between T_o and T_f, the performance curve is then divided into time intervals to account for the deterioration of the base slab with time (the base slab modulus of elasticity decreases). The slope between T_o and T_f represents the rate of deterioration of the base slab when the SCI decreases from 100. To illustrate this, the time between T_o and T_f in Figure 19-10 is divided in four equal time intervals (on a logarithm scale) and the magnitude of each time interval recorded. The last time period corresponds to the time T_f and beyond (SCI=0). Table 19-9 summarizes this procedure and Figure 19-11 illustrates the actual base slab performance curve when the 356-millimeter (14-inch) overlay is in place. The magnitude of these time intervals will be used in the calculation of the cumulative damage in the overlay within a time interval.

DEFINITIONS:

Traffic Rate = Number of design aircraft passes per year.
P/C = Pass to Coverage Ratio at offset where the maximum damage occurs.
C_o = Coverage level at which the SCI begins to decrease from 100 (initial cracking).
C_f = Coverage level at which the SCI becomes 0 (complete failure).
DR_o = Damage rate to initial cracking.
DR_f = Damage rate to complete failure.
T_o = Time in years to initial cracking.
T_f = Time in years to completed failure.
m_o = Time from the placement of overlay to initial cracking of the base slab.

B_o = Remaining life of base slab.
(5) = Computed tensile stress at the bottom of the base slab.
(6) = Coverages to initial cracking (C_o) calculated using stress in (5).
(7) = (3)/(6)/(4).
(8) = 1.0/(7) = 1.0/Sum DR_o.
(9) = Coverage to complete failure (C_f) calculated using stress in (5).
(10) = (3)/(9)/(4).
(11) = 1.0/(10) = 1.0/Sum DR_f.
(12) = Bo/(7) = Bo/Sum DR_o.

5	130.92	57.15
6	213.05	82.13

c. Compute the Cumulative Damage in the Overlay. Once the base slab performance curve is established, the damage in the trial overlay can be assessed. The procedure basically consists of computing the tensile stresses at the bottom of the overlay, calculating the number of coverages to initial cracking and complete failure, and calculating and cumulating the damage in the overlay for each time period. This process is demonstrated in Table 19-10. Columns 1 and 2 contain the interval number and the magnitude of the interval in years, respectively. Column 3 contains the average SCI's within each interval that is used to compute the reduced modulus of elasticity (Equation 19-4). Columns 4, 5, and 6 contain the design aircraft, traffic rate, and pass-to-coverage ratio. Column 7 contains the computed tensile stresses at the bottom of the overlay. These stresses are computed with the elastic layer computer program JULEA assuming the interface between the overlay and the slab is unbonded since a bond-breaker layer is used. Column 8 contains the number of coverages to initial cracking (Co) of the overlay for each aircraft. The damage (Do) is computed in column 9 and accumulated in column 10 (DAMo). In a similar fashion the damage to complete failure (DAMf) is calculated and accumulated in columns 11, 12, and 13. This process is repeated for each time interval as is shown in the table.

d. Determine Required Overlay Thickness. The cumulative damage for initial cracking (DAMo) and complete failure (DAMf) of the trial overlay for each time interval can now be plotted. Figure 19-12 shows the plot for the 356-millimeter (14-inch) overlay. From this plot, the years to initial cracking and complete failure of the overlay can be obtained by reading the years at which the DAMo and DAMf curves cross a cumulative damage of 1.0. For the 356-millimeter (14-inch) overlay shown in Figure 19-12, these values correspond approximately to 26 years to initial overlay cracking and 50 years to complete failure of the overlay. Similar curves can be generated for the 406-millimeter (16-inch) and 457-millimeter (18-inch) overlay trials. Figure 19-13 summarizes the analysis performed on the 305-, 356-, and 406-millimeter (12-, 14-, and 16-inch) overlay trials. The values obtained from Figure 19-12 are used to generate the composite overlay performance curve. From Figure 19.13, for the case of the 356-millimeter (14-inch) overlay, the overlay performs at an SCI of 100 for 4.0 years before it starts to deteriorate. It then deteriorates linearly with the logarithm of time until it reaches a complete failure condition (SCI=0.0) after 50 years. Finally from Figure 19-13, the life of each overlay trial can be obtained for the design overlay SCI of 80. These values are 4.2 years, 29.6 years, and 81.7 years for the 305-, 356-, 406-millimeter (12-, 14-, and 16-inch) overlays, respectively. To obtain the required thickness for the design life of 20 years, a plot of the overlay thicknesses versus the life of each overlay is generated as illustrated in Figure 19-14. From this figure, a 426-millimeter (16.8-inch) overlay would be required for a design life of 20 years and a SCI of 80.

CHAPTER 20

SEASONAL FROST CONDITIONS

1. GENERAL. This chapter presents criteria and procedures required for the design and construction of pavements placed on subgrade materials subject to seasonal frost action. If frost does not penetrate into the subgrade using thicknesses necessary for nonfrost design, pavement design need not consider effects of frost action unless the base, subbase courses contain other than NFS, PFS, S1, or S2 materials. The designer must select subbase materials which do not allow pumping of subbase course or subgrade fines during periods of saturated or nearly saturated conditions. The detrimental effects of frost action in frost susceptible subsurface materials are manifested by nonuniform heave of pavements during the winter and/or loss of strength of affected soils during the ensuing thaw periods. Studies have shown that the modulus of subgrade reaction is reduced substantially during the thaw period. Application of load on thaw-weakened pavements can lead to premature failure. Other effects of frost on pavements are possible loss of compaction, pumping, increased pavement roughness, restriction of drainage by frozen layers, and cracking of asphalt concrete pavements. In extreme conditions, these problems can cause hazardous operating conditions, or Foreign Object Damage (FOD) to aircraft, and can lead to extensive maintenance of the pavement surface. Except in cases where other criteria are specifically established, pavements should be designed so that there will be no interruptions of traffic at any time due to differential heave or to reduction in load-supporting capacity. Pavements should also be designed so that the rate of deterioration during critical periods of thaw weakening and thermally induced cracking will not be so high that the useful life of the pavement is less than that assumed as the design objectives. For interior pavements which fall within a geographical area subject to subgrade frost action, the “reduced subgrade strength” or the “limited subgrade frost penetration” pavement design criteria should be used for all aircraft hangar pavements in heated or unheated areas.

2. FROST-SUSCEPTIBILITY CLASSIFICATION. For frost design purposes, soils are divided into eight groups as shown in Table 20-1. Soils are listed in approximate order of increasing frost susceptibility and decreasing bearing capacity during periods of thaw.

a. The frost susceptibility of the soils classified in Table 20-1, based on laboratory tests, are shown in Table 20-2. The NFS, S1, and S2 groups are negligible to very low frost susceptible soils. Based on laboratory tests, the heave rates range between 1 and 4 mm/day and the thawed CBR ranges between 12 to 20 percent. These soils are considered to be suitable as base and subbase course material. Soils categorized as F1, F2, F3, and F4 are unsuitable as base or subbase materials.

b. Under special conditions the frost group classifications adopted for design may be permitted to differ from that obtained by application of the above frost group definitions provided a written waiver is obtained and a valid justification is presented in the design analysis. Such justification may take into account special conditions of subgrade moisture or soil uniformity, in addition to soil gradation and plasticity, and should include data on performance of existing pavements near those proposed to be constructed. This will require the approval of HQUSACE (CEMP-ET), the appropriate Air Force Major Command or the Naval Facilities Engineering Command.

3. METHODS OF THICKNESS DESIGN. Three methods are prescribed for determining the thickness of a pavement that will have adequate resistance to distortion by frost heave, cracking from differential frost heave and distortion under traffic load as affected by seasonal variation of

Table 20-1
Frost Design Classification

Frost Group	Kind of Soil	Percentage Finer than 0.02 mm by Weight	Typical Soil Types Under Unified Soil Classification System

[1] Nonfrost susceptible.
[2] Possibly frost susceptible, requires laboratory test to determine frost design soil classification.

supporting capacity, including severe weakening during frost melting periods. The three methods are (a) complete frost penetration method, (b) reduced subgrade strength method, and (c) limited subgrade frost penetration method.

a. Complete Frost Penetration Method. In the complete frost penetration method, frost is not allowed to penetrate into frost susceptible subgrade soils. This method completely prevents affects of frost action, i.e., frost heave and thaw weakening in the subgrade, subbase, or base course. The total pavement thickness from this method is seldom used in the final design since prevention of frost penetration into the subgrade is nearly always uneconomical and unnecessary.

Table 20-2
Frost Susceptibility Classification

Heave Rate (mm/day)	Thawed CBR	Frost Susceptibility Classification	Frost Group
<1	>20	Negligible	NFS, PFS
<2	>15	Very Low	S1, PFS
<4	>12	Very Low	S2, PFS
<6	>10	Low	F1
<8	>6	Medium	F2
<16	>3	High	F3
No Limit	<3	Very High	F4

It will not be used to design pavements to serve conventional traffic, except when approved by appropriate written waiver.

b. Reduced Subgrade Strength Method. The reduced subgrade strength method does not seek to limit the penetration of frost into the subgrade. It determines the thickness of pavement, base, and subbase that will adequately carry traffic. This approach relies on uniform subgrade conditions, adequate subgrade preparation, and transitions for adequate control of pavement roughness resulting from differential frost heave.

c. Limited Subgrade Frost Penetration Method. The limited subgrade frost penetration method requires a sufficient thickness of pavement, base, and subbase to limit the penetration of frost into the frost susceptible subgrade.

4. SELECTION OF DESIGN METHOD. In most cases the choice of the pavement design method will be made in favor of the one that gives the lower cost. The limited subgrade frost penetration method will be used, even at higher costs, in areas where the subgrade soils are extremely variable (e.g., in some glaciated areas) and the required subgrade preparation could not be expected to sufficiently restrict differential frost heave, and when special operational demands on the pavement might dictate unusually severe restrictions on pavement roughness, requiring that subgrade frost penetration be severely restricted or even prevented. If the use of limited subgrade frost penetration method is not required, tentative designs must be prepared using both methods for comparison of costs.

5. REDUCED SUBGRADE STRENGTH METHOD. The thickness design is based on the seasonally varying subgrade bearing capacity that includes sharply reduced values during frost melting periods. This design procedure usually requires less thickness of pavement and base than that needed for limited subgrade frost penetration. The method may be used for pavements where the subgrade is reasonably uniform or can be made reasonably uniform horizontally by the required subgrade preparation techniques discussed later in this chapter. This will prevent or minimize significant or objectionable differential heaving and resultant cracking of pavements. When the reduced

subgrade strength method is used with an F3 or F4 subgrade soil, rigorous control of subgrade preparation is required. In situations, based on previous experience, where use of the reduced subgrade strength procedure has resulted in pavement thicknesses allowing objectionable frost heave, but use of the greater base-course thickness obtained from the limited subgrade frost penetration method is considered over conservative, intermediate design base-course thickness may be used. However, these must be justified on the basis of frost heaving experience developed from existing pavements where climatic and soil conditions are comparable.

a. Thickness of Flexible Pavements. The thickness design procedure is identical to the thickness design for nonfrost conditions, with the exception that instead of using the subgrade CBR, Frost Areas Soil Support Index (FASSI) values are used. The flexible pavement design curves are used in connection with the reduced subgrade strength procedure. In place of the estimated or determined subgrade CBR, use the applicable FASSI values outlined in Table 20-3 with the design curves. The FASSI values for the F1 to F4 subgrade soils were backcalculated from performance data of in-service pavements, and are the weighted average CBR valued for an annual cycle. These values cannot be determined by CBR tests. The FASSI values for S1 and S2 materials meeting current specifications for base and subbase will be determined by conventional CBR procedures. The reduced subgrade strength design procedure is included in the design computer program PDSF discussed in Chapter 1.

Table 20-3
Frost Area Soil Support Indexes (FASSI) for Subgrade Soils

Frost Group of Subgrade Soil	FASSI Values
F1 and S1	9.0
F2 and S2	6.5
F3 and F4	3.5

Once the overall thickness of the pavement structure has been determined, criteria for nonfrost design should be used to determine the thickness of individual layers. It should also be ascertained whether it will be advantageous to incorporate bound base layer(s) in the system. Although the use of bound bases will reduce the thickness of the base and subbase layers, it is possible that deeper frost penetration may occur leading to increased frost heave. The base-course requirements set forth in this chapter must be followed rigorously.

(1) Design of overrun pavements. The runway overrun pavement thicknesses for providing adequate strength during frost melting periods are determined from the appropriate flexible pavement design curves and the applicable FASSI values outlined in Table 20-3. The thickness established by this procedure shall have the following limitations:

(a) It shall not be less than required for nonfrost condition design.

(b) It shall not exceed the thickness required under the limited subgrade frost penetration design method.

(c) It shall not be less than that required for normal operation of snowplows and other support vehicles.

The subgrade preparation techniques and transition details outlined in this chapter are required for overrun pavements.

(2) Control of surface roughness in overruns. For a frost group F3 and F4 subgrade, differential heave can generally be controlled to 75 millimeters (3 inches) in 15.2 meters (50 feet) by providing a thickness of base and subbase equal to 60 percent of the base-course thickness required by the limited subgrade frost penetration design method. For well drained F1 and F2 subgrade soils, the minimum thickness of pavement and base course in overruns should not be less than 40 percent of the total thickness required for limited subgrade frost penetration design.

(3) Design of shoulder pavements. When paved shoulders are required, the paved shoulder pavement, base, and subbase, shall have the combined thickness obtained from the flexible pavement design curve and the appropriate FASSI value in Table 20-3. The subgrade preparation techniques and transition details outlined in this chapter are required. If the subgrade is highly susceptible to frost heave, local experience may indicate a need for a shoulder section that incorporates an insulating layer or an additional granular unbound material to moderate the frost heave. The base-course requirements set forth in this chapter must be followed.

(4) Control of differential frost heave at small structures located within shoulder pavements. To prevent objectionable heave of small structures inserted in shoulder pavements, such as drain inlets and bases for airfield lights, the shoulder base and subbase courses extending at least 1.5 meters (5 feet) radially from the structures should be designed and constructed entirely with nonfrost susceptible material to a depth to prevent subgrade freezing. Gradual transitions are required. Alternatively, synthetic insulation could be placed below a base of the minimum prescribed thickness to prevent the advance of freezing temperatures into the subgrade; suitable transitions to the adjoining uninsulated pavement would be needed.

(5) Drainage. Subsurface drainage must be provided in flexible pavements in accordance with EI 02C202/AFJMAN 32-1016.

b. Rigid Pavement Thickness Design. The thickness design procedure is identical to the thickness design for nonfrost conditions, with the exception that instead of using the modulus of subgrade reaction k, Frost Area Index of Reaction (FAIR) values are used. The design curves for plain concrete and for fibrous concrete are used in connection with the reduced subgrade strength procedure. In place of the estimated or determined subgrade k in the design curves, use the applicable FAIR values from Figure 20-1. The FAIR values can also be estimated from the following equations:

S1 or F1 material:

$$\text{FAIR (pci)} = 6.7 + 10.7 \times \text{base-course thickness (in.)}$$

or (20-1)

$$\text{FAIR}\left(\frac{\text{MN}}{\text{m}^3}\right) = 1.8 + 114 \times \text{base-course thickness (m)}$$

S2 or F2 material:

$$\text{FAIR (pci)} = 4.5 + 8.0 \times \text{base-course thickness (in.)}$$

or (20-2)

$$\text{FAIR}\left(\frac{\text{MN}}{\text{m}^3}\right) = 1.2 + 83.8 \times \text{base-course thickness (m)}$$

F3 or F4 material:

$$\text{FAIR (pci)} = 5.4 + 5.7 \times \text{base-course thickness (in.)}$$

or (20-3)

$$\text{FAIR}\left(\frac{\text{MN}}{\text{m}^3}\right) = 1.5 + 60.8 \times \text{base-course thickness (m)}$$

The FAIR values for the S1, and F1 to F4 subgrade soils were determined from field measurements and are the weighted average k values for an annual cycle. These values cannot be determined from plate bearing tests.

(1) It is good practice to use a combined base thickness equal in thickness to the slab. The design procedure is as follows:

(a) Determine frost group soil classification of subgrade, Table 20-1.

(b) Assume three combined base thicknesses, enter Figure 20-1 or use appropriate equations, determine the FAIR value for each thickness.

(c) Use the FAIR values with appropriate design curves to determine pavement thickness.

(d) Plot combined base thickness and pavement thickness. From the figure, pick out base-course and pavement thickness of similar values.

(e) If unable to converge to a solution, repeat steps b to d with new base-course thickness.

(f) A minimum of 203 millimeters (8 inches) of combined base (100-millimeter (4-inch) drainage layer plus 100-millimeter (4-inch) separation layer) is required for rigid pavements in frost areas.

(2) The combined base must meet the drainage and filter requirements outlined in EI 02C202/AFJMAN 32-1016. A 100-millimeter (4-inch) separation layer meeting the filter requirements must be placed between the subgrade and base or subbase course. A geotextile separator can also be used in lieu of the granular filter. No structural advantage will be attained in the design when a geotextile is used. Guidance for selection of geotextile fabric materials

proposed for a specific project is provided in EI 02C202/AFJMAN 32-1016 and TM 5-818-8/ AFJMAN 32-1030.

(3) Bound base also has significant structural value and is considered to be a low-strength concrete for design purposes. A minimum 200-millimeter (8-inch) drainage plus separation layers must be placed between the bound base and the subgrade.

(4) If sufficient high-quality base material is not locally available, the nonfrost design base layer thickness can be used. The appropriate FAIR value will be used for the base to determine the PCC thickness.

(5) The subgrade preparation techniques and transition details outlined in this chapter are also required for the design of overrun pavements.

(6) The control of differential frost heave at small structures is located within shoulder pavements. To prevent objectionable heave of small structures inserted in shoulder pavements, such as drain inlets and bases for airfield lights, the shoulder base and subbase courses extending at least 1.5 meters (5 feet) radially from the structures should be designed and constructed entirely with nonfrost susceptible material to a depth to prevent subgrade freezing. Gradual transitions are required. Alternatively, synthetic insulation could be placed below a base to prevent the advance of freezing temperatures into the subgrade; suitable transitions to the adjoining uninsulated pavement would be needed.

6. LIMITED SUBGRADE FROST PENETRATION METHOD. This design method permits a small amount of frost penetration into frost susceptible subgrades. The procedure uses a design freezing index (DFI) as illustrated in Figure 20-2. Typical DFI values are shown in Figures 20-3 and 20-4. The procedure is described in the following subparagraphs. A computer program (PDSF) for providing the limited subgrade frost penetration design thickness is discussed in Chapter 1.

a. Step One. Determine frost penetration depths. The maximum frost penetration depths with respect to the design freezing index shown in Figure 20-5 are calculated from the Modified Berggren formula and computational procedures outlined in TM 5-852-6/AFM 88-19, Chap. 6. Frost penetration depths presented in Figure 20-5 are measured from the pavement surface. The pavement is considered free of snow and ice. Computations also assume that all soil beneath the pavement within the depth of frost penetration are granular and nonfrost susceptible. It was assumed in the computations that all soil moisture freezes at 0 degrees Celsius (32 degrees Fahrenheit). Use straight-line interpolation where necessary. The frost penetration depth a in meters for SI units and inches for English units can also be estimated from the following equations:

(1) For $\gamma = 2{,}160$ kg/m^3 (135 lb/ft^3) and $\omega = 3$ percent,

$$a = 0.157 + 9E{-}5(DFI) - 4E{-}10(DFI)^2 \text{ in SI units} \tag{20-4}$$

$$a = 6.183 + 0.047(DFI) - 2.91E{-}6(DFI)^2 \text{ in English units} \tag{20-5}$$

(2) For $\gamma = 2{,}160$ kg/m^3 (135 lb/ft^3) and $\omega = 7$ percent,

$$a = 0.1852 + 8E\text{-}5(DFI) - 4E\text{-}10(DFI)^2 \text{ in SI units} \tag{20-6}$$

$$a = 7.291 + 0.044(DFI) - 2.58E\text{-}6(DFI)^2 \text{ in English units} \tag{20-7}$$

(3) For γ = 2,400 kg/m^3 (150 lb/ft^3) and ω = 3 percent,

$$a = 0.1725 + 0.0001(DFI) - 5E\text{-}10(DFI)^2 \text{ in SI units} \tag{20-8}$$

$$a = 6.793 + 0.055(DFI) - 3.41E\text{-}6(DFI)^2 \text{ in English units} \tag{20-9}$$

(4) For γ = 2,400 kg/m^3 (150 lb/ft^3) and ω = 7 percent,

$$a = 0.1583 + 9E\text{-}5(DFI) - 4E\text{-}10(DFI)^2 \text{ in SI units} \tag{20-10}$$

$$a = 6.231 + 0.049(DFI) - 2.98E\text{-}6(DFI)^2 \text{ in English units} \tag{20-11}$$

where

DFI = °C-hours in SI units or °F-days in English units.

γ = soil density

ω = soil moisture content

In Figure 20-5, the frost penetration curves for γ = 2,160 kg/m^3 (135 lb/ft^3) and ω = 3 and 7 percent are combined because the curves were very close together. Also, note that these densities and moisture contents represent an approximation of a weighted average value of combined base.

b. Step Two. Estimate the moisture content and dry density of the nonfrost susceptible base-course material. For a conservative design, the 3 percent moisture content, 2,400 kg/m^3 (150 lb/ft^3) base material should be selected. Determine frost penetration depth for complete frost penetration from Figure 20-5.

c. Step Three. Compute thickness of combined base (combined thickness of base, subbase, drainage layer and separation layer) required for zero frost penetration into the subgrade (Figure 20-6) as follows:

$$c = a - p \tag{20-12}$$

where

c = thickness of unbound base, millimeters (inches)

a = thickness for complete frost protection, millimeters (inches)

p = thickness of asphalt or concrete for nonfrost design

d. Step Four. For limited frost penetration into the subgrade, determine the average moisture content of the subgrade prior to freezing. Compute water content ratio r.

$$r = \frac{\text{moisture content of subgrade}}{\text{moisture content of base}} \tag{20-13}$$

where

moisture content of the base = same as that assumed for nonfrost base material in step 2.

If the computed r exceeds 2.0, use 2.0 for types A, B, and primary traffic areas. If r exceeds 3.0, use 3.0 for all pavements other than those in types A, B, or primary traffic areas.

e. Step Five. Enter Figure 20-6, with c (from step 3) as the abscissa and, at the applicable value of r, find the design combined base thickness b on the left scale and the allowable frost penetration into the subgrade s on the right scale or use Equations 20-10 and 20-11. This procedure will result in a sufficient thickness of material between the frost susceptible subgrade and the pavement so that for average field conditions subgrade frost penetration of the amount s should not cause excessive differential heave of the pavement surface during the design freezing index year.

$$b = c \times f \tag{20-14}$$

$$s = c \times g \tag{20-15}$$

where

b = design combined base thickness

c = combined base thickness for zero penetration

s = limited subgrade frost penetration depth

f and g = factors from the following tabulation

Water Content Ratio (*r*)	***f***	***g***
0.6	0.881	0.216
0.8	0.850	0.209
1.0	0.806	0.200
1.2	0.781	0.197
1.4	0.756	0.188
1.6	0.725	0.181
1.8	0.706	0.178
2.0	0.644	0.175
2.5	0.613	0.156
3.0	0.550	0.144

g. Step Six. When the maximum combined thickness of pavement layers required by this design procedure exceeds 1.5 meters (60 inches), a total combined thickness to 1.5 meters (60 inches) will be used. Limiting the combined thickness of pavement and base to 1.5 meters (60 inches) may result in a greater surface roughness because of the greater subgrade frost penetration. To minimize pavement damage and roughness, steel reinforcements can be used in the concrete slabs to prevent large cracks. Smaller unreinforced slabs can also be considered. Alternatively, the design could incorporate subbase layers of uniform fine sand with a high moisture content to reduce frost penetration into the subgrade. These materials would be allowed only in the lower 500 millimeters (20 inches) of the subbase. When using this alternative the designer must be certain that materials of Frost Groups S2 or better are used as subbase layers. If either the high moisture retention subbase course or a combined thickness over 1.5 meters (60 inches) is selected for frost design purposes, specific approval of HQUSACE (CEMP-ET), the appropriate Air Force Major Command, or Naval Facilities Engineering Command shall be obtained.

h. Step Seven. The combined thickness of pavement layers required for limited subgrade frost penetration is then compared with that obtained for nonfrost conditions, and the thicker of the two cross sections will be adopted as the design thickness.

7. GRANULAR BASE- AND SUBBASE-COURSE REQUIREMENTS. The base-course material used in pavements in seasonal frost areas will meet the requirements for base course outlined in Chapter 8. In addition, the following requirements must be met:

(1) The top 50 percent of the combined base thickness must be nonfrost susceptible.

(2) The lower 50 percent thickness of combined base may be either nonfrost susceptible material, partially frost susceptible material, S1 or S2 material. If the separation layer meets the minimum S1 or S2 frost susceptibility criterion, then it can be considered to be part of the combined base. If not, then an additional 100-millimeter (4-inch) separation layer is required.

(3) Base- and subbase-course materials of borderline quality should be tested frequently after compaction to ensure that the compacted material meets requirement (1). For material expected to exhibit serious degradation during placement and compaction (>3 percent finer than 0.02 millimeters by weight), a test embankment may be needed to study the formation of fines by the proposed compaction method. If the test embankment shows serious degradation, the material gradation should be changed to account for the fines obtained during compaction. If experience indicates that the base- or subbase-course materials degrade rapidly under traffic loads or due to environmental effects, consideration should be given to stabilizing the material with asphalt or Portland cement.

(4) Mixing of base or subbase course material with frost susceptible subgrade soils should be avoided. The subgrade should be properly graded and compacted prior to the placement of the base or subbase course. Separation layer requirements must be met.

8. DRAINAGE LAYER REQUIREMENTS. A minimum 100-millimeter (4-inch) thick nonfrost susceptible drainage layer must be placed at the bottom of the asphalt concrete layer, the PCC layer or below the bound base for all pavements constructed in frost areas. The rapid draining nonfrost susceptible material must meet the gradation requirements shown in EI 02C202/AFJMAN 32-1016. The drainage layer will be designed in accordance with the requirements in EI 02C202/AFJMAN 32-1016. The layer is considered as a structural component of the pavement and will serve as part of the base course. In seasonal frost areas, as frost penetrates into the frost susceptible subgrades, water is drawn to the cold front and ice lenses form. During the frost melting period, the ice lenses will melt and the water will have to be removed. In extremely wet conditions or with F3 and F4 subgrade soils, a drainage layer should be considered between the subbase and the subgrade in lieu of a drainage layer under the surfacing as illustrated in Figure 20-7.

9. SEPARATION LAYER. If subgrade freezing will occur, a minimum of a 100-millimeter (4-inch) granular separation layer as specified in EI 02C202/AFJMAN 32-1016 will be placed between the subgrade and the overlying base course. Over weak subgrades, a 152-millimeter (6-inch) or greater thickness may be necessary to support construction equipment and to provide a working platform for placement and compaction of the base course. This layer is not intended to be a drainage layer. The gradation of this separation layer should meet the requirements in EI 02C202/AFJMAN 32-1016. An additional requirement is that the separation layers must be nonfrost susceptible or of frost group S1 or S2. Alternatively, where stable foundation already exists, geotextile fabrics meeting the requirements of EI 02C202/AFJMAN 32-1016 can be used in lieu of a granular material as a separation layer. No structural advantage will be attained in the design when a geotextile fabric is used. The fabrics must meet the requirements of EI 02C202/AFJMAN 32-1016.

10. SUBGRADE REQUIREMENTS. In addition to the requirement outlined for subgrades in nonfrost areas in Chapter 6, the following additional requirements shall be required for subgrades in frost areas. It is a basic requirement for all pavements constructed in frost areas that subgrades in which freezing will occur be as uniform as possible. This will be done by mixing nonhomogeneous soils, eliminating isolated pockets of soil of higher or lower frost susceptibility, and blending the various types of soils into a single, relatively homogeneous mass. This attempts to produce a subgrade of uniform frost susceptibility and thus create conditions tending to make both surface heave and subgrade thaw weakening as uniform as possible over the paved area. To achieve uniformity in some cases, it will be necessary to remove high frost-susceptible soils or soils of low frost susceptibility. In that case, the pockets of soil to be removed should be excavated to the full

depth of frost penetration and replaced with material similar to the material left in place. This replacement should be completed before any required mixing and blending of the subgrade. This will minimize the potential for large variations in frost heave and subgrade support. In fill sections, the least frost susceptible soils shall be placed in the upper portion of the subgrade by temporarily stockpiling, cross hauling, and selective grading. If the upper layers of fill contain frost susceptible soils, the completed fill section shall be subjected to the subgrade preparation procedures, outlined below for cut sections. In cut sections, no matter the type of frost susceptible subgrade soil, the subgrade shall be scarified and excavated to a prescribed depth, and the excavated material windrowed and bladed successively until thoroughly blended, and relaid and compacted. Alternatively, a soil mixing and pulverizing machine may be used to blend the material in place. Multiple passes of the machine will be required for proper blending.

a. Depth of Subgrade Preparation. The depth of subgrade preparation is applicable for limited subgrade penetration and reduced subgrade strength design. The depth of subgrade preparation measured downward from the top of the subgrade shall be lesser of:

(1) 0.6 meter (24 inches).

(2) Two-thirds of the frost penetration less the actual combined thickness of pavement, base course, drainage layers, and subbase course under types A, B, or primary traffic areas.

(3) Under type C, D, and secondary traffic areas and under overruns and shoulder pavements, it will be one-half the frost penetration less the actual combined thickness of pavement, base course, drainage layers, and subbase course.

(4) 1.8 meters (72 inches) less the actual combined thickness of pavement, base course, drainage layers, and subbase course.

The prepared subgrade must meet the designated compaction requirements for nonfrost areas discussed in Chapter 6. The construction inspection personnel should be alert to verify that the processing of the subgrade will yield uniform soil conditions throughout the section.

b. Exceptional Conditions. An exception to the basic requirements for subgrade preparation are subgrades that are nonfrost susceptible or of very low frost susceptibility (NFS, S1, S2) to the depth prescribed for subgrade preparation. These subgrades contain no frost susceptible layers or lenses, as demonstrated and verified by extensive and thorough subsurface investigations and by the performance of nearby existing pavements. Also, fine-grained subgrades containing moisture well in excess of the optimum for compaction, with no feasible means of drainage nor of otherwise reducing the moisture content, and which consequently are not feasible to scarify and recompact, are also exceptions. If a wet fine-grained subgrade exists at the site, it will be necessary to prevent frost penetration with fill material. This may be done by raising the grade by an amount equal to the depth of subgrade preparation that otherwise would be prescribed, or by undercutting and replacing the wet fine-grained subgrade to that same depth. In either case, the fill or backfill material may be nonfrost susceptible or frost susceptible material. If the fill or backfill is frost susceptible, it should be subjected to the same subgrade preparation procedures prescribed above.

c. Cobbles or Boulders. A critical condition requiring the attention of designers and inspection personnel is the presence of cobbles or boulders in the subgrade. All stones larger than about 150 millimeters (6 inches) in diameter should be removed from fill materials for the full depth of frost penetration, either at the source or as the material is spread in the embankment. Any such large stones exposed during subgrade preparation work must also be removed, down to the full depth to which subgrade preparation is required. Failure to remove stones or large roots can result in increasingly severe pavement roughness as the stones or roots are heaved gradually upward toward the pavement surface. They eventually break through the surface in extreme cases, necessitating complete reconstruction.

d. Soil Conditions. Abrupt changes in soil conditions must not be permitted. Where the subgrade changes from a cut to a fill section, a wedge of subgrade soil in the cut section with the dimensions shown in Figure 20-8 should be removed and replaced with fill material. Discontinuities in subgrade conditions require the most careful attention of designers and construction inspection personnel, as failure to enforce strict compliance with the requirements for transitions may result in serious pavement distress.

e. Rock Excavation. In areas where rock excavation is required, the character of the rock and seepage conditions should be considered. In any case, the excavation should be made so that positive transverse drainage is provided and no pockets are left on the rock surface that will permit ponding of water within the depth of freezing. The irregular ground water availability created by such conditions may result in markedly irregular heaving under freezing conditions. It may be necessary to fill drainage pockets with lean concrete. At intersections of fills with rock cuts, the tapered transitions illustrated in Figure 20-8 are essential. Rock subgrades where large quantities of seepage are involved should be blanketed with a highly pervious material to permit the escape of water. Frequently, the fractures and joints in the rock contain frost susceptible soils. These materials should be cleaned out of the joints to the depth of frost penetration and replaced with nonfrost susceptible material. If this is impractical, it may be necessary to remove the rock to the full depth of frost penetration. An alternative method of treating rock subgrades, in-place fragmentation, has been used effectively in airfield construction. Blast holes 0.9 to 1.8 meters (3 to 6 feet) deep are commonly used. They are spaced suitable for achieving thorough fragmentation of the rock to permit effective drainage of water through the shattered rock and out of the zone of freezing in the subgrade. A tapered transition should be provided between the shattered rock cut and the adjacent fill. Underdrains are essential to quickly remove excess water.

11. CONTROL OF DIFFERENTIAL HEAVE AT DRAINS, CULVERTS, DUCTS, INLETS, HYDRANTS, AND LIGHTS.

a. Design Details and Transitions for Drains, Culverts, and Ducts. Drains, culverts, or utility ducts placed under pavements on frost-susceptible subgrades frequently experience differential heaving. Wherever possible, the placing of such facilities beneath pavements should be avoided. Where this cannot be avoided, construction of drains should be in accordance with the”correct” method indicated in Figure 20-9, while treatment of culverts and large ducts should conform with Figure 20-10. All drains of similar features should be placed first and the base and subbase course materials carried across them without bread so as to obtain maximum uniformity of pavement support. The practice of constructing the base and subbase course and then excavating back through them to lay drains, pipes, etc. is unsatisfactory as a marked discontinuity in support will result. It is almost impossible to compact material in a trench to the same degree as the surrounding base and subbase course materials. Also, the amount of fines in the excavated and backfilled material may be increased by incorporation of subgrade soil during the trench excavation or by manufacture of fines by the added handling. The poor experience record of combination drains—those intercepting both surface and subsurface water—indicates that the filter material should never be carried to the surface as illustrated in the “incorrect” column in Figure 20-9. Under winter conditions, this detail may allow thaw water accumulating at the edge of the pavement to feed into the base course. This detail is also undesirable because the filter is a poor surface and is subject to clogging, and the drain is located too close to the pavement to permit easy repair. Recommended practice is shown in the "correct" column in Figure 20-9.

b. Frost Protection and Transitions for Inlets, Hydrants, and Lights. Experience has shown that drain inlets, fueling hydrants, and pavement lighting systems, which have different thermal properties that the pavements in which they are inserted, are likely to be locations of abrupt differential heave. Usually, the roughness results from progressive movement of the inserted items. To prevent these damaging movements, the pavement section beneath the inserts and extending at least 1.5 meters (5 feet) radially from them should be designed to prevent freezing of frost-susceptible materials by sue of an adequate thickness of nonfrost-susceptible base course, and by use of insulation. Consideration should also be given to anchoring footings with spread bases at appropriate depths. Gradual transitions are required to surrounding pavements that are subject to frost heave.

12. PAVEMENT THICKNESS TRANSITIONS.

a. Longitudinal Transitions. Where interruptions in pavement uniformity cannot be avoided, differential frost heaving should be controlled by use of gradual transitions. Length of longitudinal transitions should vary directly with the speed of traffic and the amount of heave differential. Transition sections should begin and end directly under the pavement joints, and should in no case be shorter than one slab length. As an example, at an airfield where differentials of heave of 25 millimeters (1 inch) may be expected at changes from one subgrade soil condition to another, gradual changes in base thicknesses should be effected over distances of 61 meters (200 feet) for the runway area, 30.5 meters (100 feet) for taxiways, and 15.25 meters (50 feet) for aprons. The transition in each case should be located in the section having the lesser total thickness of pavement and base. Pavements designed to lower standards of frost heave control, such as shoulders and overruns, have less stringent requirements, but may nevertheless need transition sections.

b. Transverse Transitions. A need for transitions in the transverse direction arises at changes in total thickness of pavement and base, and at longitudinal drains and culverts. Any transverse transition beneath pavements that carry the principal wheel assemblies of aircraft traveling at moderate to high speed should meet the same requirements applicable to longitudinal transitions. Transverse transitions between the traffic areas C and D should be located entirely within the limits of traffic area D and should be sloped no steeper than 10 horizontal to 1 vertical. Transverse transitions between pavements carrying aircraft traffic and adjacent shoulder pavements should be located in the shoulder and should not be sloped steeper than 4 horizontal to 1 vertical.

13. OTHER MEASURES TO REDUCE FROST HEAVE. Another measure to reduce the effects of heave is the use of insulation to control depth of frost penetration. Insulation can only be used in shoulders and overruns. The use of synthetic insulating materials within a pavement cross section must have the approval of HQUSACE (CEMP-ET) or the appropriate Air Force Major Command. When synthetic insulating materials are used, transitions between cut and fill, changes in character and stratification of subgrade soils, subgrade preparation, and boulder removal should also receive special attention in field construction control.

14. REPLACEMENT OR RECONSTRUCTION OF EXISTING PAVEMENTS. Objectionable differential heave has been noticed where existing airfield pavements have been partially reconstructed or new segments added. These discontinuities in elevation can result in problems of snow removal,

ponding of water, surface icing, and loss of control of aircraft or unnecessary stresses to the aircraft or vehicles using the pavement. This objectionable and abrupt differential movement is caused by the use of different material in the base and subbase and/or the use of different thicknesses than existing material. Longitudinal abrupt differences have been noted where the keel section has been replaced on airfields. Transverse abrupt differences have been noticed in newly added taxiways where the total thickness of pavement, base, and subbase has been different from that previously used. The differences are most pronounced when the pavement type is changed from PCC to asphalt concrete. PCC pavements generally require smaller base and subbase thicknesses than asphalt concrete pavements resulting in deeper frost penetration and potentially greater frost heave. To minimize these abrupt differences in pavement elevation, pavement surface elevation surveys should be conducted in the summer and again in the winter when frost penetration is near its maximum depth. Both surveys should be completed before the new facility is designed. The difference in the two surveys will indicate the potential for abrupt differences in pavement surface elevation resulting from differing designs. The abrupt differences can be eliminated or substantially reduced by using proper transitions, or by using the same materials previously used. However, care must be taken if consideration is being given to the use of similar materials that resulted in the initial distress. Materials which are frost susceptible and placed too near the pavement surface can result in premature failure.

15. COMPACTION. Subgrade, subbase, and base-course materials must meet the applicable compaction requirements for nonfrost materials.

16. FLEXIBLE PAVEMENT DESIGN EXAMPLES FOR SEASONAL FROST CONDITIONS.

a. Example 1. Design an Air Force heavy-load pavement type B traffic area. The design freezing index at the site is 9,331-degree Celsius hours (700-degree Fahrenheit days). The highest elevation of ground water is about 915 millimeters (3 feet) below the surface of the subgrade. The subgrade is a lean clay (CL), with a plasticity index of 18. The average moisture content of the subgrade is 18 percent. The nonfrost design CBR of the lean clay subgrade is 13. A high quality crushed base-course material with a normal period CBR of 100 is to be used.

(1) Reduced subgrade strength design.

(a) The subgrade is classified as an F3 frost susceptible soil from Table 20-1. From Table 20-3, the FASSI value for an F3 soil is 3.5.

(b) Use the FASSI value with Figure 10-19 as though it were a CBR. Locate the value of 3.5 and move down to type B curve; the combined thickness of pavement required is 1.78 meters (70 inches).

(c) From Table 8-5, the minimum thickness of the surface course is 127 millimeters (5 inches). Therefore, the required base and subbase course thickness is 1.65 meters (65 inches).

(d) Compare pavement thickness with the limited subgrade frost penetration design.

(2) Limited subgrade frost penetration design.

(a) The moisture content of the base course is 3 percent, and the density of the base course is 2,400 kg/m^3 (150 lb/ft^3). From Table 8-5, a minimum thickness of a 127-millimeter

(5-inch) asphalt concrete layer is required. The frost penetration a from Figure 20-5 is 1,143 millimeters (45 inches).

(b) The required base thickness c for zero frost penetration from Equation 20-8 is:

$$c = a - p = 1{,}145 - 127 = 1{,}016 \text{ millimeters (40 inches)}$$

$$p = \text{asphalt concrete thickness of 127 millimeters (5 inches)}$$

(c) Compute water content ratio r from Equation 20-13. $r = 18/3 = 6$. Since $r > 2.0$ for type B traffic area, use $r = 2.0$ with Figure 20-6. From Figure 20-6, the allowable subgrade frost penetration is approximately 178 millimeters (7 inches). Again, from Figure 20-6, the design base thickness b as determined by the limited subgrade frost penetration method is 685 millimeters (27 inches).

(d) The base thickness of 685 millimeters (27 inches) is less than the thickness of 1,651 millimeters (65 inches) from the reduced subgrade design. In this case, the thickness from limiting subgrade frost penetration design is more economical than from the reduced subgrade design. Also, the thickness from the limited subgrade frost penetration is greater than that obtained from the nonfrost design (see Paragraph 5a, Example 1, Chapter 12). Therefore, the combined thickness (combined asphalt plus base and subbase material) of 813 millimeters (32 inches) will be used as the design thickness.

(e) The pavement structure could be made up of 127 millimeters (5 inches) of surface course, 102 millimeters (4 inches) of a NFS drainage layer beneath the surface course, 254 millimeters (10 inches) of NFS base course, 228 millimeters (9 inches) of S1 or S2 subbase, 102 millimeters (4 inches) of a NFS drainage layer. A geotextile fabric separation layer shall be placed between the subgrade and the drainage layer.

(f) No subgrade preparation is required because the 813-millimeter (32-inch) combined thickness of pavement and base exceeds two-thirds of the design frost penetration depth of 762 millimeters (30 inches).

b. Example 2. Design a type A traffic area on an Army Class III airfield as defined in Paragraph 4c, Chapter 2. The design freezing index of the area is 39,990-degree Celsius hours (3,000-degree Fahrenheit days). The subgrade is a mixture of poorly graded gravely sand and silty sand with a fine content of about 9 percent. The average moisture content of the subgrade is 9 percent. The nonfrost design CBR of the subgrade is 16.

(1) Reduced subgrade strength design.

(a) The subgrade can be classified as SP-SM soil. It also classifies as an F2 frost susceptible soil from Table 20-1. From Table 20-3, the FASSI value for an F2 soil is 6.5.

(b) From Figure 10-3 with a FASSI (CBR) value of 6.5, the combined thickness of pavement required is 330 millimeters (13.0 inches).

(c) From Table 8-3, the minimum thickness of the surface course is 51 millimeters (2 inches). Therefore, the required base and subbase course thickness is 279 millimeters (11.0 inches).

(d) Compare pavement thickness with the limited subgrade frost penetration design.

(2) Limited subgrade frost penetration design.

(a) The moisture content of the base course is assumed to be 3 percent. The density of the base course is assumed to be 2,403 kg/m^3 (150 lb/ft^3). From Table 8-3, a minimum thickness of a 51-millimeter (2-inch) asphalt concrete layer is required. The frost penetration a from Figure 20-5 is 3.6 meters (142 inches).

(b) The required base thickness c for zero frost penetration from Equation 20-8 is:

$$c = a - p = 142 - 2 = 140 \text{ inches in English units}$$

$$= 3{,}600 - 51 = 3{,}549 \text{ millimeters in SI units}$$

(c) In this case the base thickness of 3,549 millimeters (140 inches) is more than the thickness of 339 millimeters (13 inches) from the reduced subgrade design. Therefore, the thickness from reduced subgrade design is more economical than from the limiting subgrade frost penetration design. Also, the thickness from the reduced subgrade design is greater than that obtained from the nonfrost design. Therefore, the combined thickness of 330 millimeters (13.0 inches) will be used as the design thickness. The pavement structure could be made up of 51 millimeters (2 inches) of surface course, 100 millimeters (4 inches) of an NFS drainage layer beneath the surface course, and 178 millimeters (7.0 inches) of NFS base over a separation layer. A geotextile fabric could be placed between the subgrade and base course as a separation layer. Subgrade preparation is required to a depth of 610 millimeters (24 inches) based on the subgrade preparation criteria described in Paragraph 10a.

17. RIGID PAVEMENT DESIGN EXAMPLES FOR SEASONAL FROST CONDITIONS.

a. Example 1. Design an Air Force medium-load pavement. The design air freezing index at the site is 9,330-degree Celsius hours (700-degree Fahrenheit days). The highest elevation of groundwater is about 914 millimeters (3 feet) below the surface of the subgrade. The subgrade is a silty sand with 20 percent finer than 0.02 mm by weight. The average moisture content of the subgrade is 15 percent. The nonfrost design modulus of soil reaction k is 54 MN/m^3 (200 $lb/in.^3$). The 90-day concrete flexural strength R is 4.8 MPa (700 psi).

(1) Reduced subgrade strength design.

(a) From Table 20-1, the subgrade is classified as a F3 frost susceptible soil.

(b) Select several combined base thicknesses and obtain FAIR values from Figure 20-5 or from Equation 20-1. For example:

Combined Base Thickness, mm (in.)	FAIR Values, MN/m^3 (lb/in.^{3})
100 (4)	7.6 (28)
150 (6)	10.6 (40)
200 (8)	13.7 (51)
300 (12)	19.7 (74)
460 (18)	29.5 (108)
610 (24)	38.6 (142)

(c) Use the FAIR value with Figure 12-7 as though it were a k value and determine the thickness of PCC pavement.

Combined Base Thickness, mm (in.)	FAIR Value MN/m^3 (lb/in.^{3})	Traffic Area PCC Thickness, mm (in.)			
		A	B	C	D
100 (4)	7.6 (28)	627 (24.7)	620 (24.4)	500 (19.7)	386 (15.2)
150 (6)	10.6 (40)	594 (23.4)	584 (23.0)	465 (18.3)	353 (13.9)
200 (8)	13.7 (51)	566 (22.3)	556 (21.9)	439 (17.3)	330 (13.0)
300 (12)	19.7 (74)	523 (20.6)	516 (20.3)	399 (15.7)	292 (11.5)
460 (18)	29.5 (108)	475 (18.7)	467 (18.4)	356 (14.0)	254 (10.0)
610 (24)	38.6 (142)	439 (17.3)	432 (17.0)	320 (12.6)	244 (9.6)

(d) Plot combined base versus PCC thickness for the different traffic areas as shown in Figure 20-11. Locate equal or nearly equal thickness of PCC and base course as shown in the figure. From Figure 20-11, the minimum thickness for the combined base course and PCC layer are as follows:

Traffic Area	Combined Base Thickness, mm (in.)	PCC Pavement Thickness, mm (in.)
A	483 (19.0)	483 (19.0)
B	470 (18.5)	470 (18.5)
C	381 (15.0)	381 (15.0)
D	292 (11.5)	292 (11.5)
Shoulder[1]	152 (6.0)	152 (6.0)

[1] The thickness of the shoulder was determined in a similar fashion as for the other traffic areas. Use Figure 12-17 for determining pavement thickness.

(e) Compare these reduced subgrade strength pavement thicknesses with those required for the Limited Subgrade Frost Penetration Design procedure.

(2) Limited subgrade frost penetration design.

(a) From Figure 12-7, the minimum thickness of PCC concrete layer required in nonfrost areas are:

Traffic Area	PCC Thickness, mm (in.)
A	406 (16.0)
B	394 (15.5)
C	305 (12.0)
D	241 (9.5)

The average moisture content and density of the combined base is assumed to be 3 percent and 2,403 kg/m^3 (150 lb/ft^3), respectively. The frost penetration a is obtained from Figure 20-5 or from Equation 20-9. For pavement thickness exceeding 305 millimeters (12 inches), deduct 133-degree Celsius hours (10-degree Fahrenheit days) from the design freezing index for each inch in excess of 305 millimeters (12 inches).

Traffic Area	PCC Thickness mm (inches)	Design Freezing Index °C-hr (°F-days)	Frost Penetration, a, mm (in.)[1]
A	406 (16.0)	8,800 (660)	1,067 (42)
B	394 (15.5)	8,865 (665)	1,067 (42)
C	305 (12.0)	9,331 (700)	1,118 (44)
D	241 (9.5)	9,331 (700)	1,118 (44)

[1] Obtained from Equation 20-9.

(b) The required combined base thickness c for complete frost penetration into the subgrade from Equation 20-12 is:

$c = a - p$ $\qquad$ p = PCC thickness

Traffic Area	Frost Penetration, a, mm (in.)	PCC Thickness, p, mm (in.)	Combined Base Thickness c, mm (in.)
A	1,067 (42)	406 (16.0)	661 (26.0)
B	1,067 (42)	394 (15.5)	673 (26.5)
C	1,118 (44)	305 (12.0)	813 (32.0)
D	1,118 (44)	241 (9.5)	877 (34.5)

(c) Compute water content ratio r from Equation 20-13.

r = water content of subgrade/water content of base

= 15/3 = 5

For r ≥ 2.0, for types A and B traffic areas, use r = 2.0 with Figure 20-6. For r ≥ 3.0, for types C and D traffic areas use r = 3.0 with Figure 20-6. Determine the design combined base-course thickness (b) and amount of subgrade frost penetration (s) for the combined base thickness.

Traffic Area	Design Combined Base Thickness b mm (in.)	Subgrade Frost Penetration Depths mm (in.)
A	432 (17)	114 (4.5)
B	432 (17)	127 (5.0)
C	457 (18)	127 (5.0)
D and Overruns	508 (20)	127 (5.0)

(d) Compare these design pavement thicknesses with those obtained with the reduced subgrade strength design procedures.

In this case, the thicknesses required for traffic areas A, B, and C using the limited subgrade frost penetration design are more economical than from the reduced subgrade strength design. For traffic area D, even though the limited subgrade frost penetration design requires the greatest thickness of pavement and base, it may still be the most economical design as it requires only 241 millimeters (9.5 inches) of PCC versus the 292 millimeters (11.5 inches) required by the reduced subgrade strength design procedure. The designer must make a decision based upon a comparison of costs between the PCC and the base material. The design pavement thickness selection is shown below. The final thickness of PCC for the same base-course thickness for nonfrost conditions is also shown. The thicker value of the two will be used.

	Reduced Subgrade Strength Method mm (in.)			Limited Subgrade Frost Penetration mm (in.)		
Traffic Area	PCC	Combined Base	Total	PCC	Combined Base	Total
A	483 (19.0)	483 (19.0)	966 (38.0)	406 (16.0)	432 (17.0)	838 (33.0)
B	470 (18.5)	470 (18.5)	940 (37.0)	394 (15.5)	432 (17.0)	826 (32.5)
C	381 (15.0)	381 (15.0)	762 (30.0)	305 (12.0)	457 (18.0)	762 (30.0)
D	292 (11.5)	292 (11.5)	584 (23.0)	241 (9.5)	508 (20.0)	749 (29.5)

		Frost Design Thickness, mm (in.)		Nonfrost Design Thickness, mm (in.)	
Traffic Area	Design Method	PCC	Combined Base	PCC	Combined Base
A	LSFP	406 (16.0)	432 (17.0)	318 (12.5)	432 (17.0)
B	LSFP	394 (15.5)	432 (17.0)	318 (12.5)	432 (17.0)
C	LSFP	305 (12.0)	457 (18.0)	254 (10.0)	457 (18.0)
D	RSS or LSFP	292 (11.5) 241 (9.5)	292 (11.5) 508 (20.0)	203 (8.0)	292 (11.5)

(e) The combined base course can be divided into several layers having thicknesses as given in the following table. With F3 soils, in lieu of drainage layer under the PCC pavement, a drainage layer between the subbase and the separation layer should be considered. The divisions shown are one of many possibilities. Judgment must be used when layer thicknesses are selected.

Traffic Area	Combined Base Thickness mm (in.)	NFS Base Layer mm (in.)	S1 or S2 Subbase Layer mm (in.)	Drainage Layer mm (in.)	Separator Layer mm (in.)
A	432 (17.0)	229 (9.0)	--	102 (4)	102 (4)
B	432 (17.0)	229 (9.0)	--	102 (4)	102 (4)
C	457 (18.0)	254 (10.0)	--	102 (4)	102 (4)
D	292 (11.5)	89 (3.5)	--	102 (4)	102 (4)

(f) Compute the required depth of subgrade preparation.

Traffic Area	Total Pavement Thickness, mm (in.)	Frost Penetration, mm (in.)	Depth of Subgrade Preparation[1] mm (in.)
A	965 (38.0)	1,067 (42.0)	-102 (-4.0)
B	940 (37.0)	1,067 (42.0)	-127 (-5.0)
C	762 (30.0)	1,118 (44.0)	-356 (-14.0)
D	584 (23.0)	1,118 (44.0)	-533 (-21.0)

[1] No subgrade preparation required.

b. Example 2. Design an Air Force heavy-load pavement airfield. The design air freezing index at the site is 26,660-degree Celsius hours (2,000-degree Fahrenheit days). The highest elevation of groundwater is about 1.5 meters (5 feet) below the surface of the subgrade. The subgrade is a very fine silty sand with 20 percent finer than 0.02 mm by weight. The average moisture content of the subgrade is 21 percent. The nonfrost design modulus of soil reaction is 27.1 MN/m^3 (100 lb/in.^{3}). The 90-day concrete flexural strength R is 4.83 MPa (700 psi).

(1) Reduced subgrade design.

(a) From Table 20-1, the subgrade is classified as F4 frost susceptible soil.

(b) Select 6 combined base-course thicknesses and obtain FAIR values from Figure 20-1 or from Equation 20-3.

Combined Base Thickness, mm (in.)	FAIR Values, MN/m^3 (lb/in.^{3})
102 (4)	7.6 (28)
152 (6)	10.6 (40)
203 (8)	13.7 (51)
305 (12)	19.7 (74)
457 (18)	29.5 (108)
610 (24)	38.6 (142)

(c) Use FAIR values with Figure 20-7 as though they were k values and determine the thickness of PCC pavement.

Combined Base Thickness, mm (in.)	FAIR Value MN/m^3 (lb/in.^{3})	Traffic Area PCC Thickness, mm (in.)			
		A	B	C	D
102 (4)	7.6 (28)	693 (27.3)	688 (27.1)	572 (22.5)	450 (17.7)
152 (6)	10.6 (40)	671 (26.4)	666 (26.2)	546 (21.5)	432 (17.0)
203 (8)	13.7 (51)	653 (25.7)	648 (25.5)	531 (20.9)	419 (16.5)
305 (12)	19.7 (74)	622 (24.5)	617 (24.3)	508 (20.0)	399 (15.7)
457 (18)	29.5 (108)	594 (23.4)	589 (23.2)	485 (19.1)	379 (14.9)
610 (24)	38.6 (142)	574 (22.6)	572 (22.5)	467 (18.4)	363 (14.3)

(d) Plot base course versus PCC thickness for the different traffic areas as shown in Figure 20-12. Locate equal or nearly equal thickness of PCC and combined base course as shown in the figure. The minimum thicknesses for the base and PCC layers are as follows:

Traffic Area	Combined Base Thickness, mm (in.)	PCC Pavement Thickness, mm (in.)
A	579 (22.8)	579 (22.8)
B	577 (22.7)	577 (22.7)
C	483 (19.0)	483 (19.0)
D	386 (15.2)	386 (15.2)
Shoulder[1]	152 (6)	152 (6)

[1] The thickness of the shoulder was determined in a similar fashion as for the other traffic areas. Use Figure 12-16 to determine minimum pavement thickness.

(e) Compare these reduced subgrade strength pavement thicknesses with those required for the limited subgrade frost penetration design.

(2) Limited subgrade frost penetration design.

(a) From Figure 20-7, the minimum PCC thickness for nonfrost conditions is as follows:

Traffic Area	PCC Thickness, mm (in.)
A	599 (23.6)
B	597 (23.5)
C	490 (19.3)
D	384 (15.1)

For pavement thicknesses greater than 305 millimeters (12 inches), deduct 133-degree Celsius hours (10-degree Fahrenheit days) from the design freezing index for each 25 millimeters (1 inch) in excess of 508 millimeters (12 inches).

(b) Assuming the average moisture content and density of the combined base course is 7 percent and 2,403 kg/m^3 (150 lb/ft^3), respectively, the maximum frost penetration a is obtained from Figure 20-5 or from Equation 20-10.

Traffic Area	PCC Thickness mm (in.)	Design Freezing Index °C hr (°F-days)	Frost Penetration mm (in.)
A	592 (23.6)	25,114 (1,884)	2,235 (88)
B	597 (23.5)	25,127 (1,885)	2,235 (88)
C	490 (19.3)	25,687 (1,927)	2,286 (90)
D	384 (15.1)	26,246 (1,969)	2,311 (91)

(c) The required base thickness c for zero frost penetration into the subgrade from Equation 20-12 is as shown in the following tabulation:

Traffic Area	Frost Penetration, a mm (in.)	PCC Thickness, p mm (in.)	Combined Base Thickness, c mm (in.)
A	2,235 (88)	599 (23.6)	1,636 (64.4)
B	2,235 (88)	557 (23.5)	1,638 (64.5)
C	2,286 (90)	490 (19.3)	1,796 (70.7)
D	2,311 (91)	384 (15.1)	1,928 (75.9)

(d) Compute water content ratio r.

r = water content of subgrade/water content of base

= 21/7 = 3

For $r \geq 2.0$, for type A and B traffic areas, use $r = 2.0$ with Figure 20-6. For $r \geq 3.0$, for type C and D traffic areas use $r = 3.0$ with Figure 20-6. Determine the design combined base-course thickness b and amount of subgrade frost penetration s for the combined base thickness.

Traffic Area	Design Base Thickness b, mm (in.)	Subgrade Frost Penetration s, mm (in.)
A	1,054 (41.5)	287 (11.3)
B	1,054 (41.5)	287 (11.3)
C	988 (38.9)	259 (10.2)
D	1,059 (41.7)	277 (10.9)

(e) Compare these design pavement thicknesses with those obtained with the reduced subgrade strength design procedure.

	Reduced Subgrade Strength Method			Limited Subgrade Frost Penetration		
Traffic Area	PCC mm (in.)	Combined Base mm (in.)	Total mm (in.)	PCC mm (in.)	Combined Base mm (in.)	Total mm (in.)
A	579 (22.8)	579 (22.8)	1,158 (45.6)	599 (23.6)	1,054 (41.5)	1,654 (65.1)
B	577 (22.7)	577 (22.7)	1,153 (45.4)	597 (23.5)	1,054 (41.5)	1,651 (65.0)
C	483 (19.0)	483 (19.0)	965 (38.0)	490 (19.3)	988 (38.9)	1,478 (58.2)
D	386 (15.2)	386 (15.2)	772 (30.4)	384 (15.1)	1,059 (41.7)	1,443 (56.8)

The reduced subgrade strength method produced the more economical design for all traffic areas. A comparison must be made with the nonfrost pavement thickness. With F4 subgrade soils, in lieu of drainage layer under the PCC pavement, a drainage layer between the subbase and the separation layer should be considered. The divisions shown are one of many possibilities. Judgment must be used when layer thicknesses are selected.

Traffic Area	Total "Combined Base" Thickness mm (in.)	NFS Base Layer mm (in.)	S1 or S2 Subbase Layer mm (in.)	Drainage Layer mm (in.)	Separator Layer mm (in.)
A	1,168 (46.0)	610 (24.0)	356 (14)	102 (4)	102 (4)
B	1,156 (45.5)	622 (24.5)	330 (13)	102 (4)	102 (4)
C	965 (38.0)	508 (20.0)	250 (10)	102 (4)	102 (4)
D	775 (30.5)	419 (16.5)	152 (6)	102 (4)	102 (4)

(3) Subgrade preparation. The depth of subgrade preparation D will be the lesser of the following:

(a) D = 610 millimeters (24.0 inches).

(b) D = [2/3 · (maximum frost penetration)] - (Combined thickness of PCC, base, subbase and drainage layers).

Traffic Area	Frost Penetration mm (in.)	Combined Pavement Thickness, mm (in.)	Subgrade Preparation Depth, mm (in.)
A	2,235 (88)	1,168 (46.0)	330 (13.0)
B	2,235 (88)	1,156 (45.5)	330 (13.0)
C[1]	2,285 (90)	965 (38.0)	178 (7.0)
D[1]	2,311 (91)	775 (30.5)	381 (15.0)

[1] Use one-half rather than two-thirds frost penetration for traffic areas C and D.

(c) D = 1,829 millimeters (72 inches) - (Combined Pavement Thickness).

Traffic Area	Combined Pavement Thickness, mm (in.)	D, mm (in.)
A	1,168 (46.0)	660 (26.0)
B	1,156 (45.5)	673 (26.5)
C	965 (38.0)	864 (34.0)
D and Overruns	775 (30.5)	1,054 (41.5)

The Final Depth of Subgrade Preparation D will be:

Traffic Area	**D, mm (in.)**
A	330 (13.0)
B	330 (13.0)
C	179 (7.0)
D	381 (15.0)

CHAPTER 21

IMPROVING SKID RESISTANCE/REDUCING HYDROPLANING POTENTIAL OF RUNWAYS

1. GENERAL. This chapter presents procedures for improving skid resistance and reducing hydroplaning tendency of runways. It applies to the Army and Air Force. Navy guidance is contained in NAVFAC Criteria Office Memorandum dated 24 March 1999, Subject: INTERIM TECHNICAL GUIDANCE (ITG)-SKID RESISTANCE CRITERIA FOR AIRFIELD PAVEMENTS.

a. Skid resistance is the resistance to sliding by aircraft tires on a pavement surface. Skid resistance is related to the frictional resistance of the pavements. A high coefficient of friction is indicative of high skid resistance. Low friction resistance may result from polishing of the surface aggregate, rubber buildup, improper seal coating, or poor drainage.

b. Hydroplaning occurs when a tire looses contact with the surface as a result of the buildup of water pressure in the tire-ground contact area. The potential for hydroplaning is a function of speed, water depth, pavement texture, tire inflation pressure, and tread design.

c. Procedures for conducting friction testing and an approved equipment list are contained in Federal Aviation Administration Advisory Circular, AC 150/5320-12C, "Measurement, Construction, and Maintenance of Skid-Resistant Airport Pavement Surfaces".

2. IMPROVING RUNWAY FRACTION CHARACTERISTICS. New, reconstructed, or resurfaced runways must be grooved except when resurfaced with a Porous Friction Surface (PFS). The grooving is required to provide an acceptable surface for safe operation of aircraft. Friction characteristics of existing runways need to be improved when tests indicate the surface has a potential for hydroplaning. Considerations for improving the friction characteristics include grooving, Porous Friction Surfaces, retexturing, improving runway slopes, and rubber removal. Table 21-1, developed by the National Aeronautics and Space Administration, provides guidance on friction ratings for friction measuring equipment. Improving friction characteristics of existing runways should be considered when friction ratings are less than Good.

Table 21-1
Nominal Test Speed, 65 km/h (40 mph)

	Ground Vehicle Readings									
Braking Action Level	RCR	Grip-Tester	James Brake Index	MU-Meter	Surface Friction Tester	Runway Friction Tester	BV-11 Skiddo-Meter	Decel Meters	Locked Wheel Devices	ICAO INDE
Good	>17	>0.49	.0.58	>0.50	>0.55	>0.51	>0.59	>0.53	>0.51	5
Fair	12-17	0.34-0.49	0.40-0.58	0.35-0.50	0.38-0.54	0.35-0.51	0.42-0.59	0.37-0.53	0.37-0.51	3-4
Poor	6-11	0.16-0.33	0.20-0.39	0.15-0.34	0.18-0.37	0.18-0.34	0.21-0.41	0.17-0.36	0.18-0.36	2-3
NL	≤5	≤0.14	≤0.17	≤0.14	≤0.16	≤0.15	≤0.19	≤0.16	≤0.15	

a. Sawcut grooving is a proven way of reducing the hydroplaning potential of runways. Grooves drain water laterally, permit water to escape under tires, prevent buildup of surface water, and increase the texture of the pavement.

(1) Pavement condition. Grooves should only be applied to structurally adequate pavement free from defects. Pavements requiring corrective action should be overlaid or rehabilitated prior to grooving. Porous Friction Surfaces should not be grooved.

(2) Grooving flexible pavements. Studies indicate that grooving of flexible pavements does not cause any appreciable deterioration of the pavement nor has maintenance effort been increased. No problems have occurred from ice and snow removal. Minor distortion and creeping of grooves have been observed, but these conditions have not required maintenance or adversely affected pavement performance.

(3) Groove pattern. Grooves will be continuous for the entire length of the usable runway and perpendicular to the centerline. Grooves should terminate within 1.5 to 3 meters (5 to 10 feet) of pavement edge to allow for operation of grooving equipment. The standard groove configuration is 6 millimeters (¼ inch) ± 2 millimeters (± 1/16 inch) in depth by 6 millimeters (¼ inch) + 2 millimeters – 0 millimeters (+1/16 inch, -0 inch) in width by 38 millimeters (1 1/2 inch) – 3 millimeters + 0 millimeters (-1/8 inch, + 0 inch) center-to-center spacing. The recommended groove detail for airfield pavements is shown in Figure 21-1.

(4) Limitations. Do not groove within 6 inches (± 3 inches) of the runway centerline. Do not groove within 152 millimeters (6 inches) of transverse joints or working cracks, through compression seals, in-runway lighting fixtures or similar items, or the first 3 meters (10 feet) either side of an arresting barrier cable which requires hook engagement for operation. There is no need for grooving on either side of barrier cables that are placed on overruns.

b. Porous Friction Surfaces. A porous friction course is an open-graded, free draining asphalt mixture that can be placed on an existing pavement to minimize hydroplaning and to improve skid resistance. A PFS is placed in a layer varying from 19 to 25 millimeters (3/4 to 1 inch) thick. It has a coarse surface texture and is sufficiently porous to permit internal drainage as well as along the surface. Existing pavements should be in good condition before placing the mix. Concerns with PFS include rubber buildup that might prevent internal drainage, possible freezing of water trapped in voids, and loss of expertise in designing and constructing these surfaces. PFS should not be placed within 3 meters (10 feet) of an arresting gear cable.

c. Retexturing. Retexturing of runways has been successfully accomplished using several types of equipment. Contact the MAJCOM Pavements Engineers for guidance on Air Force projects and the TSMCX on Army projects.

APPENDIX B

AIRFIELD/HELIPORT DESIGN ANALYSIS OUTLINE

B-1. INTRODUCTION.

a. Purpose of Report. To describe the project design in sufficient detail for review, evaluation, and documentation of the design.

b. Scope of Report.

(1) State the design phase that the report covers.

(2) List topics discussed in report.

c. Project Description.

(1) Extent of proposed construction (new construction; runway extension; apron expansion; overlay; rehabilitation and repair; upgrade lighting; drainage, security, and navigational aids improvements; etc.)

(2) Purpose of proposed construction or improvements.

(3) Types and amount of construction activities (demolition, excavation and embankment, grading, paving, patching, marking, fencing, seeding, etc.)

d. Project Authorization (reference authorization letter, directive, or other pertinent items, with dates).

e. Design Criteria. (Reference the key criteria and directives used in the design, with dates. Since criteria are constantly being revised and updated, the key criteria should be documented so that the basis of the design can become a historical record.)

(1) Correspondence and Directives.

(2) Engineering Technical Letters (ETLs).

(3) Technical Manuals (TM's and AFMs).

(4) Engineering Circulars (ECs).

(5) Pavement Evaluations/Condition Surveys.

(6) Computer Programs.

(7) Other special design criteria.

B-2. SITE DESCRIPTION.

a. Location (location map with graphical scale).

(1) Existing airfield/heliport facilities (layout, type, etc.)

(2) Location of proposed project with respect to existing facilities, utilities, or improvements.

(3) Extent of proposed construction (size, dimensions, etc.).

b. Topography/Drainage of Site.

(1) Topography (hilly, rolling, flat, terrace, floodplain, etc.).

(2) Surface drainage (characteristics and direction).

(3) Subsurface drainage (characteristics, groundwater conditions and elevations, including seasonal variations).

(4) Existing surface and subsurface drainage facilities (type, location, capacity, condition, etc.).

c. Climate (use National Oceanographic and Atmospheric Administration or Military installation's weather service center for climatological data where available).

(1) Temperatures (especially with reference to frost condition and design air freezing index).

(2) Rainfall (particularly with respect to its effect on construction operations).

(3) Seasonal variations.

d. Vegetation (wooded, open, brush, cultivated fields).

e. Geology.

(1) Sequence and character of surface and near-surface deposits. Soil overburden (glacial, stream, loess deposits, etc.).

(2) Rock outcroppings.

B-3. FIELD INVESTIGATIONS.

a. Subgrade explorations (type of investigations, number, locations, depth, samples obtained).

b. Borrow explorations for fill (type of investigations, number, locations, depth, samples obtained).

c. Availability of construction materials (type of material, location; name and description of pits, quarries, or other sources; samples obtained).

(1) Sand and gravel deposits.

(2) Aggregates (base-course, concrete, and bituminous mixtures).

(3) Cementitious materials (portland cement, fly ash, and asphalt; type; class; grade).

(4) Water.

d. Evaluations of Existing Pavements (describe all evaluations conducted).

(1) Destructive.

(2) Nondestructive.

B-4. TESTING.

a. Laboratory (describe lab testing conducted).

b. Field (describe field testing conducted).

B-5. RESULTS OF INVESTIGATIONS AND TESTING.

a. Material Characterization.

(1) Subgrade characteristics (soil classifications, unit weights, moisture-density relationships, gradations, Atterberg limits, CBR and/or modulus of subgrade reaction, permeability, etc.).

(2) Characteristics of borrow (same as above).

(3) Characteristics of base and subbase material (same as above).

(4) Characteristics of pavement surfacing materials.

b. Groundwater and Subsurface Drainage Conditions.

c. Frost Conditions (where applicable).

(1) Frost susceptibility of materials (based on gradation and frost classification, laboratory freeze tests, heave measurements, observations or ice lense formations in test pits, etc.).

(2) Frost penetration (based on field observations or design air-freezing index and modified Berggen equation).

(3) Moisture availability.

(4) Mean annual temperature.

(5) Duration of freezing season.

(6) Number of freeze-thaw cycles.

d. Existing Pavement Evaluation/Characterization.

e. Summarize Adopted Design Parameters.

B-6. PAVEMENT THICKNESS DESIGN CRITERIA.

a. Load (include copy of Airfield/Heliport Mission List).

(1) Airfield/heliport/helipad class or type.

(2) Design aircraft or aircraft mix.

(3) Pass levels.

(4) Mission operational weights.

(5) Traffic areas.

B-7. PAVEMENT THICKNESS DESIGN.

a. Flexible Pavement Design (for each pavement feature).

(1) Design of curves or computer programs used.

(2) Layers (thicknesses, type, design CBR-values).

(3) Compaction requirements.

(4) Proof rolling requirements.

(5) Bituminous mixture requirements (gradation, stability).

(6) Selection of AC grade.

(7) Tack and prime coat requirements (type, grade).

(8) Grooving requirements.

b. Rigid Pavement Design (for each pavement feature).

(1) Design curves or computer programs used.

(2) Flexural strength.

(3) Layers (thicknesses, type, subgrade modulus values).

(4) Compaction requirements.

(5) Joint design (spacing, type).

(6) Joint sealant (type).

(7) Grooving requirements.

c. Overlay design (for each pavement feature).

(1) Type of design (flexible, rigid, bonded, unbonded).

(2) Existing paving system characteristics.

(3) Design curves or computer programs used.

(4) Overlay layers (thicknesses, type, etc.).

(5) Surface preparation requirements.

d. Frost Design (for each pavement feature).

(1) Design methodology limited subgrade frost penetration (LSFP) or reduced subgrade strength (RSS).

(2) Design air-freezing index (for LSFP method).

(3) FASSI or FAIR value (for RSS method).

(4) Design curves or computer program used.

(5) Layers (number, thickness, type).

(6) Special subgrade, subbase, and base course preparation for frost design.

B-8. DRAINAGE DESIGN.

a. General Criteria.

b. Hydrology.

c. Surface Drainage (including drainage plans and profiles).

d. Subsurface Drainage.

B-9. PROPOSED GRADES.

a. Longitudinal (for each pavement feature).

b. Transverse (for each pavement feature).

B-10. AIRFIELD LIGHTING AND NAVAIDS IMPROVEMENTS.

B-11. CONSTRUCTION MATERIALS.

a. Rigid Pavement.

(1) Coarse aggregate (type, gradation, deleterious limits, wear, particle shape).

(2) Fine aggregate (type, gradation, deleterious limits).

(3) Cement (type).

(4) Fly ash (class).

(5) Admixtures (type).

(6) Curing compound (type).

(7) Dowels (size, type).

(8) Reinforcing (size, type).

(9) Joint filler.

(10) Joint seals (type).

b. Flexible Pavement.

(1) Aggregates (type, gradation, percent fractured faces, wear).

(2) Mineral filler.

(3) Asphalt cement (grade).

(4) Prime coat material (type, grade).

(5) Tack coat material (type, grade).

c. Base Courses.

(1) Graded crushed-aggregate base course (gradation, percent fractured faces, wear).

(2) Rapid draining base course (RDM or OGM gradation, percent fractured faces, wear).

(3) Separation layer (gradation, design CBR-value).

(4) Subbase course (gradation, design CBR-value).

d. Borrow Material.

e. Surface and Subsurface Drainage System.

(1) Pipe (size, type).

(2) Structure construction.

(3) Bedding material.

(4) Filter material.

(5) Manhole construction.

f. Pavement Marking Materials.

B-12. LIST OF REQUIRED WAIVERS.

a. Reference regulation document (title, page, para.).

b. State the regulation in violation.

c. State the reason the waiver is required.

B-13. COST ESTIMATES.

a. Capital costs.

b. Life-cycle costs.

APPENDIX C

RECOMMENDED CONTRACT DRAWING OUTLINE

FOR AIRFIELD/HELIPORT PAVEMENTS

The list of drawings that follows should be used as a guide. All drawings may not be needed for all jobs.

C-1. TITLE SHEET.

a. Project Title.

b. Location.

c. Year

d. Volume Number.

C-2. INDEX SHEET.

a. Listing of Sheet Names.

b. Assigned Sheet Numbers (in sequential order).

C-3. COMBINED TITLE/INDEX SHEETS.

C-4. LEGEND.

a. Civil.

b. Electrical.

c. Mechanical.

d. Architectural.

C-5. LOCATION/SITE PLAN.

a. Base Map with State (Vicinity) Map.

b. Project Location.

c. Contractor Access Routes.

d. Location of Base Gates and any Restrictions.

e. Borrow/Waste Areas.

f. Batch Plant Area.

g. Contractor's Staging and/or Storage Area.

h. Utility Hookup Locations.

I. General or Special Notes.

j. Concurrent Construction (Not in Contract).

C-6. PHASING PLAN AND DETAILS.

a. Location and Sequencing of Work Areas.

b. Scheduling for each Phase of Project.

c. General Listing of Tasks to be Performed under each Phase.

d. Concurrent Construction that may Affect each Phase.

e. Location and Type of Area Control (Security) Measures.

(1) Temporary Barricades and Fencing.

(2) Obstruction Lighting.

(3) Temporary Pavement Markings (Closure Markings).

f. Traffic Circulation (Aircraft and Vehicular).

g. Special Notes.

(1) Security Measures.

(2) Contractor's Housekeeping Measures.

(3) Controls on Contractor's Traffic.

C-7. HORIZONTAL AND VERTICAL CONTROLS.

a. Layout.

b. Bench Marks (USGS Datum) with only one Master Bench Mark.

c. Control Stationing.

d. Horizontal Control (Coordinates).

C-8. GEOMETRIC LAYOUT PLAN (OPTIONAL).

a. Curve Data.

b. Control Stationing.

c. Geometric Layout.

C-9. BORING LOCATION PLAN AND BORING LOG DATA.

C-10. PAVEMENT REMOVAL PLAN.

a. Pavement Removal Limits (Dimensions, Stationing, etc.).

b. Type and Thickness of Pavement Removed.

c. Utilities and Structures Affected by the Removal.

(1) Manholes.

(2) Barrier Arresting Cables.

(3) Blast Deflectors.

(4) Runway/Taxiway Lighting.

(5) Communication Cables.

(6) Water/Sewer Lines.

(7) In Ground Aircraft Support Systems.

d. Special Notes Regarding Removals.

e. Location of Removal Sections.

C-11. REMOVAL SECTIONS AND DETAILS. Sections should be specific, not general or typical. Show several sections. Show new sections for changes in pavement type, thickness, or any other condition that has an impact on pavement construction. Sections should be complete both laterally and vertically for the entire pavement structure including subgrade preparation.

a. Removal Limits (Lateral Dimensions, Depth).

b. Show Make-Up of the Existing Pavement.

(1) Pavement Type and Thickness.

(2) Joint Type (Doweled, Tied, Contraction, etc.).

(3) Existing Reinforcing (if any).

c. Special Notes.

(1) Equipment Type/Size.

(2) Procedures.

(3) Housekeeping.

(4) Other.

C-12. EXISTING UTILITIES PLAN.

a. Show Existing Utility Locations and Type.

b. Show Pavement Penetrations.

C-13. PAVING PLAN.

a. Thickness.

b. Type.

c. Location.

d. Location of Section Cuts.

e. Stationing.

f. Dimensions.

C-14. PAVING SECTIONS. Make the sections specific. Do not overuse "Typical Sections." Cut a section wherever there is a change from one pavement section to another in any direction and on all pavement edges. The same section may be referenced numerous places on the plan sheets, but each location must be marked and properly annotated. Remember, only by including everything in the plans can the design be built as envisioned. One hour spent by the designer will save several hours work by the field engineer.

a. Include the entire paving section from surface through subgrade.

(1) Thickness of Surface.

(2) Prime Coat Requirements.

(3) Thickness of Bases and Subbases.

(4) Thickness of Drainage Layer.

(5) Depth and Type of Subgrade Preparation.

b. Jointing Locations and Type.

c. Surface Grades/Slope.

d. Subsurface Drainage/Subdrain Provisions.

C-15. PLAN AND PROFILE SHEETS.

a. Plan.

(1) Outline of Pavement.

(2) Utilities.

(3) Stationing.

(4) Geometrics.

b. Profile.

(1) Stationing.

(2) Elevations (new and existing).

(3) Vertical Curve Data.

(4) Utility Depth and Location.

C-16. GRADING AND DRAINAGE PLANS.

a. Contours (new and existing).

b. Surface and Subsurface Drainage System Layouts, Structure Locations, Types, and Sizes.

c. Ditch Alignment.

C-17. GRADING SECTIONS.

a. Cut/Fill Requirements.

b. Topsoil Requirements.

C-18. PAVEMENT SURFACE ELEVATIONS.

a. Spot Elevation Plan (joint intersections or grid pattern).

b. Spot Elevation Schedule.

C-19. PAVEMENT JOINTING PLANS.

a. Legend with Joint Types.

b. Joint Location.

C-20. JOINT AND JOINT SEALANT DETAILS.

C-21. REINFORCING DETAILS.

a. Dowels.

b. Reinforcement.

c. Tie Bars.

d. Complete Pavement Joint Details.

c. Schedules.

d. Details.

APPENDIX D

WAIVER PROCESSING PROCEDURES

D.1. Army:

D.1.1. Waiver Procedures:

D.1.1.1. Installation. The installation's design agent, aviation representative (Safety Officer, Operations Officer, and/or Air Traffic and Airspace AT&A Officer) and DEH Master Planner will:

D.1.1.1.1. Jointly prepare/initiate waiver requests.

D.1.1.1.2. Submit requests through the installation to the Major Command (MACOM).

D.1.1.1.3. Maintain a complete record of all waivers requested and their disposition (approved or disapproved). A list of waivers to be requested and those approved for a project should also be included in the project design analysis prepared by the design agent, aviation representative, or DEH Master Planner.

D.1.1.2. The MACOM will:

D.1.1.2.1. Ensure that all required coordination has been accomplished.

D.1.1.2.2. Ensure that the type of waiver requested is clearly identified as either "Temporary" or "Permanent." "Permanent Waivers" are required where no further mitigative actions are intended or necessary.

D.1.1.2.2.1. "Temporary Waivers" are for a specified period during which additional actions to mitigate the situation must be initiated to fully comply with criteria or to obtain a permanent waiver. Followup inspections will be necessary to ensure that mitigative actions proposed for each Temporary Waiver granted have been accomplished.

D.1.1.2.3. Review waiver requests and forward all viable requests to U. S. Army Aeronautical Service Agency (USAASA) for action. To expedite the waiver process, MACOMs are urged to simultaneously forward copies of the request to:

D.1.1.2.3.1. Director, U. S. Army Aeronautical Services Agency (USAASA), ATTN: ATAS-AI, 9325 Gunston Road, Suite N319, Fort Belvior, VA 22060-5582.

D.1.1.2.3.2. Commander, U.S. Army Safety Center (USASC), ATTN: CSSC-SPC, Bldg. 4905, 5th Ave., Fort Rucker, AL 36362-5363.

D.1.1.2.3.3. Director, U. S. Army Aviation Center (USAAVNC), ATTN: ATZQ-ATC-AT, Fort Rucker, AL 36362-5265.

D.1.1.2.3.4. Director, USACE Transportation Systems Center (TSMCX), ATTN: CENWO-ED-TX, 215 N 17th St., Omaha, NE 68102.

D.1.1.3. USAASA. USAASA is responsible for coordinating the following reviews for the waiver request:

D.1.1.3.1. Air traffic control assessment by USATCA.

D.1.1.3.2. Safety and risk assessment by USASC.

D.1.1.3.3. Technical engineering review by TSMCX.

D.1.1.3.4. From these reviews, USAASA formulates a consolidated position and makes the final determination on all waiver requests and is responsible for all waiver actions for Army operational airfield/airspace criteria.

D.1.2. Contents of Waiver Requests. Each request must contain the following information:

D.1.2.1. Reference to the specific standard and/or criterion to be waived by publication, paragraph, and page.

D.1.2.2. Complete justification for noncompliance with the airfield/airspace criteria and/or design standards. Demonstrate that noncompliance will provide an acceptable level of safety, economics, durability and quality for meeting the Army mission. This would include reference to special studies made to support the decision. Specific justification for waivers to criteria and allowances must be included as follows:

D.1.2.2.1. When specific site conditions (physical and functional constraints) make compliance with existing criteria impractical and/or unsafe; for example: the need to provide hangar space for all aircraft because of recurring adverse weather conditions; the need to expand hangar space closer to and within the runway clearances due to lack of land; maintaining fixed-wing Class A clearances when support of Class B fixed-wing aircraft operations are over 10% of the airfield operations.

D.1.2.2.2. When deviation(s) from criteria fall within a reasonable margin of safety and do not impair construction of long range facility requirements; for example, locating security fencing around and within established clearance areas.

D.1.2.2.3. When construction that does not conform to criteria is the only alternative to meet mission requirements. Evidence of analysis and efforts taken to follow criteria and standards must be documented and referenced.

D.1.2.3. The rationale for the waiver request, including specific impacts upon assigned mission, safety, and/or environment.

D.1.3. Additional Requirements:

D.1.3.1. Operational Factors. Include information on the following existing and/or proposed operational factors used in the assessment:

D.1.3.1.1. Mission urgency.
D.1.3.1.2. All aircraft by type and operational characteristics.
D.1.3.1.3. Density of aircraft operations at each air operational facility.
D.1.3.1.4. Facility capability (VFR or IFR).
D.1.3.1.5. Use of self-powered parking versus manual parking.
D.1.3.1.6. Safety of operations (risk management).
D.1.3.1.7. Existing NAVAIDS.

D.1.3.2. Documentation. Record all alternatives considered, their consequences, necessary mitigative efforts, and evidence of coordination.

D.2. Air Force:

D.2.1. Waivers to Criteria and Standards. When obstructions violate airfield imaginary surfaces or safe clearance criteria established in this manual, they must be analyzed to determine impact to aircraft operations. Facilities listed as permissible deviations (see attachment 14) do not require waiver if sited properly. Facilities constructed under previous standards should be documented as exemptions and programmed for replacement away from the airfield environment at the end of their normal life cycle, or when mission needs dictate earlier replacement. When documenting waiverable items, consider grouping adjacent supporting items with a controlling obstruction, or grouping related items such as a series of drainage structures, as one waiver. ***Example:*** The base operations building violates the 7H:1V Transitional Surface and apron clearance criteria. There are also four utility poles, a 36-inch tall fire hydrant, and numerous trees and shrubs located on the side of the building that is farthest away from the apron. These items are essential to provide architectural enhancement and utilities for this structure, but they also violate apron clearance criteria. Because these items are isolated from aircraft operations by the base operations building, they would not become a hazard to aircraft operations until the base operations building is relocated. Therefore, the base operations building is the controlling obstruction. Document the base operations building as an exemption (constructed under previous standards) and develop one waiver request for all supporting structures to analyze impact to aircraft operations.

D.2.1.1. Temporary Waivers (One Year or Less). Establish temporary waivers for obstructions caused by construction activities by documenting the deviations and establishing a plan (including the issuance of NOTAMs or airfield advisories) that will allow safe operations during the temporary period. Coordinate the plan with airfield management, flying safety, and flight operations before asking the Wing Commander for approval.

D.2.1.2. Permanent Waivers. Use a permanent waiver when:

D.2.1.2.1. Natural geographical features violate criteria, and it is not economical or practical to remove them.

D.2.1.2.2. Existing facilities deviate from criteria but removal is not feasible.

D.2.1.2.3. Installation, construction, or erection of a required facility or equipment item according to criteria in this manual is not practical.

D.2.1.2.4. Removal of the cause of the violation of criteria is not economical or practical.

D.2.2. Waiver Authority. Major Commands (MAJCOM) may waive deviation from airfield and airspace criteria in this manual. The responsible MAJCOM Civil Engineer approves the waiver after coordination with all appropriate staff offices and concurrence by the MAJCOM Directors of Operations and Safety. The appropriate staff office for the Air National Guard (ANG) is ANGRC/CEPD. This authority is not delegated below MAJCOM level unless published as a MAJCOM policy. The following are exceptions:

D.2.2.1. Permissible deviations to airfield and airspace criteria, which do not require waivers, are listed in Attachment 14 to this manual.

D.2.2.2. Permanent waivers may require approval or coordination from various field operating agencies when AFI 32-1042, *Standards for Marking Airfields* or AFI 32-1076, *Visual Air Navigation Facilitie*s, standards apply.

D.2.2.3. Waiver approval is required according to AFMAN 11-230, *Instrument Procedure*s, when deviations from criteria in AFMAN 32-1076 would constitute deviations from the instrument procedure criteria or obstructions to air navigational criteria in AFMAN 11-230 or AFJMAN 11-226, *United States Standard for Terminal Instrument Procedures (TERPS*).

D.2.2.4. Authority is delegated to the Wing Commander when temporary waivers for construction activities are involved.

D.2.3. Deviations From Criteria for Land Not Under Air Force Jurisdiction. Refer waivers to airfield and airspace criteria on land not under Air Force jurisdiction to the next level of command for ultimate resolution.

D.2.4. Effective Length of Waiver. Waivers will be reviewed annually.

D.2.5. Responsibilities:

D.2.5.1. HQ AFCESA/CESC:

D.2.5.1.1. Recommends policy on waivers and provides technical assistance on the waiver program.

D.2.5.2. HQ AFFSA/XA:

D.2.5.2.1. Reviews all requests for waivers (operational requirements) to sighting criteria and airspace requirements.

D.2.5.2.2. Approves all requests for waivers to instrument procedure criteria in AFMAN 11- 230 or AFJMAN 11-226.

D.2.5.2.3. Processes requests for waivers according to AFMAN 11-230.

D.2.5.3. MAJCOM/CE:

D.2.5.3.1. Coordinates with flight operations and flight safety offices to grant waivers.

D.2.5.3.2. Sets and enforces reasonable safety precautions.

D.2.5.3.3. Monitors actions to correct temporarily waived items within specified periods.

D.2.5.3.4. Establishes procedures to ensure an annual review of all waived items.
D.2.5.3.5. Establishes the administrative procedures for processing waivers.
D.2.5.3.6. Maintains (for record) one copy of all pertinent documents relative to each waiver, including a record of staff coordination on actions at base and command levels.

D.2.5.4. Base Civil Engineer:

D.2.5.4.1. Coordinates with base flight safety, airfield management, and flight operations offices to request waivers.
D.2.5.4.2. Following Airfield Management, Flight Safety, and Civil Engineer analysis and recommendation about a waiverable condition, annotates proposed waiver location on appropriate E series map for MAJCOM evaluation.
D.2.5.4.3. Establishes maps of approved waivered items in accordance with AFI 32-7062, Base Comprehensive Planning, and maintains this information on the appropriate E-series map (see AFI 32-7062, Attachment 7). Also see AFJMAN 11-226 US Standard for Terminal Instrument Procedures (TERPS), and AFMAN 11-230, Instrument Procedures.
D.2.5.4.4. Develops a Military Construction Program or other project to systematically correct non-permanent waivers.
D.2.5.4.5. Presents a summary of waived items to the Facility Board each year for information and action.
D.2.5.4.6. Establishes a procedure for recording, reviewing, and acting on waivers. Maintains records similar to those required at the MAJCOM.
D.2.5.4.7. Requests a temporary waiver from the facility commander for any construction projects which violate any airfield clearance criteria during or after the completion of the construction project. The base must request a temporary waiver at least 45 days before the scheduled construction start date, or an emergency temporary waiver when 45 days are not possible. **NOTE:** Quick reaction or emergency maintenance and repair requirements are exempt from this requirement; however, the Base Civil Engineer will coordinate with base flight safety and flight operations offices to ensure implementation of safety measures.
D.2.5.4.8. Advises the MAJCOM of any canceled waivers.

D.2.5.5. ANGRC/CEP (for ANG facilities):

D.2.5.5.1. Develops policy on waivers and manages the ANG waiver program.
D.2.5.5.2. Processes and coordinates inquiries and actions for deviations to criteria and standards.

D.3. Navy and Marine Corps:

D.3.1. Applicability:

D.3.1.1. Use of Criteria. The criteria in this manual apply to Navy and Marine Corps aviation facilities located in the United States, its territories, trusts, and possessions. Where a Navy or Marine Corps aviation facility is a tenant on a civil airport, use these criteria to the extent practicable; otherwise, FAA criteria apply. Where a Navy or Marine Corps aviation facility is host to a civilian airport, these criteria will apply. Apply these standards to the extent practical at overseas locations where the Navy and Marine Corps have vested base rights. While the criteria in this manual are not intended for use in a theater-of-operations situation, they may be used as a guideline where prolonged use is anticipated and no other standard has been designated.
D.3.1.2. Criteria at Existing Facilities. The criteria will be used for planning new aviation facilities and new airfield pavements at existing aviation facilities (exception: primary surface width for Class B runway). Existing aviation facilities have been developed using previous standards which may not conform to the criteria herein. Safety clearances at existing aviation facilities need not be upgraded solely for the purpose of conforming to this criteria. However, at existing aviation

facilities where few structures have been constructed in accordance with previous safety clearances, it may be feasible to apply the revised standards herein.

D.3.2. Approval. Approval from Headquarters NAVFACENGCOM must be obtained prior to revising safety clearances at existing airfield pavements to conform with new standards herein. NAVFACENGCOM will coordinate the approval with the Naval Air Systems Command and CNO/CMC as required.

D.3.3. Obtaining Waiver. Once safety clearances have been established for an aviation facility, there may be occasions where it is not feasible to meet the designated standards. In these cases a waiver must be obtained from the Naval Air Systems Command. The waiver and its relation to the site approval process is defined in NAVFACINST 1010.44, *Shore Facilities Planning Manual*.

D.3.4. Exemptions From Waiver. Certain navigational and operational aids normally are sited in violation of airspace safety clearances in order to operate effectively. The following aids are within this group and require no waiver from NAVAIR, provided they are sited in accordance with NAVFAC Definitive Designs (P-272) and/or the NAVFAC Design Manuals (DM Series):

D.3.4.1. Approach lighting systems.

D.3.4.2. Visual Approach Slope Indicator (VASI) systems and Precision Approach Path Indicator (PAPI).

D.3.4.3. Permanent Optical Lighting System (OLS), portable OLS and Fresnel lens equipment.

D.3.4.4. Runway distance markers.

D.3.4.5. Arresting Gear systems including signs.

D.3.4.6. Taxiway guidance, holding, and orientation signs.

D.3.4.7. All beacons and obstruction lights.

D.3.4.8. Arming and de-arming pad.

APPENDIX E

DETERMINATION OF FLEXURAL STRENGTH AND MODULUS OF ELASTICITY OF BITUMINOUS CONCRETE

E-1. SCOPE. These procedures describe preparation and testing of bituminous concrete to determine flexural strength and modulus of elasticity. The procedures are an adaptation from tests conducted on portland cement concrete (PCC) specimens.

E-2. APPLICABLE STANDARDS. The standard applicable to this procedure is ASTM C 78.

E-3. APPARATUS. The following apparatus are required:

a. A testing machine capable of applying repetitive loadings for compaction of beam specimens 152 by 152 by 533 millimeters (6 by 6 by 21 inches) to the design density (an Instron electromechanical testing machine meets this requirement).

b. A steel mold, suitably reinforced to withstand compaction of specimens without distortion.

c. Two linear variable differential transformers (LVDTs).

d. A 22,240-Newton (5,000-pound) load cell.

e. An X-Y recorder.

f. A testing machine for load applications conforming to ASTM C 78 (a Baldwin or Tinius Olsen hydraulic testing machine is suitable for this purpose).

E-4. MATERIALS. Sufficient aggregate and bitumen meeting applicable specifications to produce six 152- by 152- by 533-millimeter (6- by 6- by 21-inch) test specimens are required. In the event the proportioning of aggregate and bitumen, bitumen content, and density of compacted specimens are not known, additional materials will be required to conduct conventional Marshall tests to develop the needed mix design data.

E-5. SAMPLE PREPARATION.

a. Prepare in a laboratory mixer four portions of paving mixture for one 152- by 152- by 533-millimeter (6- by 6- by 21-inch) beam test specimen consisting of aggregate and bitumen in the proportions indicated for optimum bitumen content. The total quantity of paving mixture should be such that when compacted to a uniform 152- by 152-millimeter (6- by 6-inch) cross section, the density of the beam will be as specified from previous laboratory mix design tests or other sources. The temperature of the paving mixture at the time of mixing should be such that subsequent compaction can be accomplished at 121 ± 2.8 degrees Celsius (250 ± 5 degrees Fahrenheit). Place two of the four portions in the 152- by 152- by 533-millimeter (6- by 6- by 21-inch) reinforced steel mold and compact to a 76-millimeter (3-inch) thickness with a 152- by 152-millimeter (6- by 6-inch) foot attached to the repetitive loading machine. Shift the mold between load applications to distribute the compaction effort uniformly. Add the remaining two portions and continue compaction until the paving mixture is compacted to exactly a 152- by

152-millimeter (6- by 6-inch) cross section. After compaction, place a 152- by 533-millimeter (6- by 21-inch) steel plate on the surface of the paving mixture and apply a leveling load of 8,896 Newtons (2,000 pounds) to the plate. Prepare six beam test specimens in the manner described.

b. After cooling, remove the beams from the molds and rotate 90 degrees so that the smooth, parallel sides will become the top and bottom. Cement an L-shaped metal tab with quick-setting epoxy glue to each 152- by 533-millimeter (6- by 21-inch) side of the beams on the beams' neutral axes at midspan. The taps should be drilled for attachment of the LVDTS. Cure the beams at 10 ± 1.7 degrees Celsius (50 ± 3 degrees Fahrenheit) for 4 days prior to testing.

E-6. TEST PROCEDURES.

a. Condition three specimens each at 10 and 24 ± 1.7 degrees Celsius (50 and 75 ± 3 degrees Fahrenheit) for at least 12 hours prior to testing. If testing occurs immediately after curing the specimens at 10 ± 1.7 degrees Celsius (50 ± 3 degrees Fahrenheit) for 4 days, no additional conditioning is required for the specimens tested at this temperature.

b. Place the specimen in the test machine as described in ASTM C 78. Place thin Teflon strips at the point of contact between the test specimens and the load-applying and load-support blocks. While the beams are being prepared for testing, place an additional support block at midspan to prevent premature sagging of the beams. Remove this support block immediately prior to the initiation of load application. Mount the LVDTs on laboratory stands on each side of the beams, and attach the LVDTs to the L-shaped tabs on the sides of the beams. Connect the LVDTs and load cell to the X-Y recorder. Make final adjustments and checks on specimens and test equipment. Apply loading in accordance with ASTM C 78, omitting the initial 4,448-Newton (1,000-pound) load.

E-7. CALCULATIONS

a. The modulus of rupture R is calculated from the following equation (from ASTM C 78):

$$R = \frac{PL}{bd^2} \qquad \text{(E-1)}$$

where

R = modulus of rupture, MPa (psi)

P = maximum applied load, Newtons (pounds)

L = span length, millimeters (inches) (457 millimeters (18 inches))

b = average width of beam, millimeters (inches)

d = average depth (height) of beam, millimeters (inches)

b. The modulus of elasticity E is calculated from the following equation:

$$E = \frac{23PL^3}{1296\Delta I}\,k \qquad \text{(E-2)}$$

where

E = static Young's modulus of elasticity, MPa (psi)

P = applied load, Newtons (pounds)

L = span length, millimeters (inches) (457 millimeters (18 inches))

Δ = deflection of neutral axis, millimeters (inches), under load, P

I = moment of inertia, millimeter^4 (inch^4) (=$bd^3/12$)

b = average width of beam, millimeters (inches)

d = average depth (height) of beam, millimeters (inches)

k = Pickett's correction for shear (third-point loading). (Values of E for bituminous beams should be calculated without using Pickett's correction K for shear).

E-8. REPORT. The report shall include the following:

a. Gradation of Aggregate.

b. Type and Properties of Bituminous Cement.

c. Bituminous Concrete Mix Design Properties.

d. Bituminous Concrete Beam Properties.

e. Modulus of Rupture.

f. Modulus of Elasticity.

APPENDIX F

CURVES FOR DETERMINING EFFECTIVE STRAIN REPETITIONS

F-1. GENERAL. This appendix contains plots (Figures F-1 through F-22) for converting aircraft operations to effective repetitions of strain when given the type of aircraft, the effective thickness of the pavement, and the offset from the center of the runway or taxiway.

F-2. COMPUTER PLOTS. A computer program was developed by the U.S. Army Engineer Research and Development Center (ERDC) for producing the plots for effective strain repetitions. Should the plots not be adequate, the computer program could be used to determine the conversion factors for any design situation. Information for accessing the computer programs is described in Chapter 1.

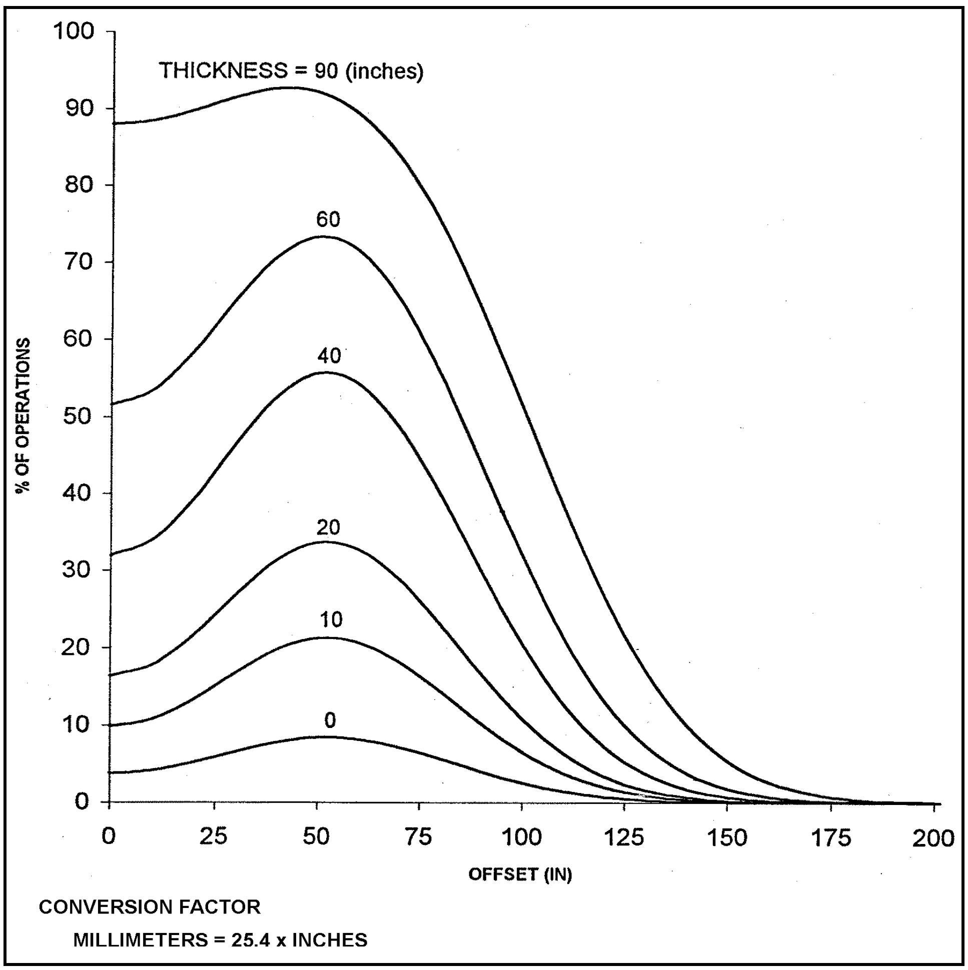

Figure F-1. Effective repetitions of the strain for UH-60 aircraft, types B, C, and secondary traffic areas.

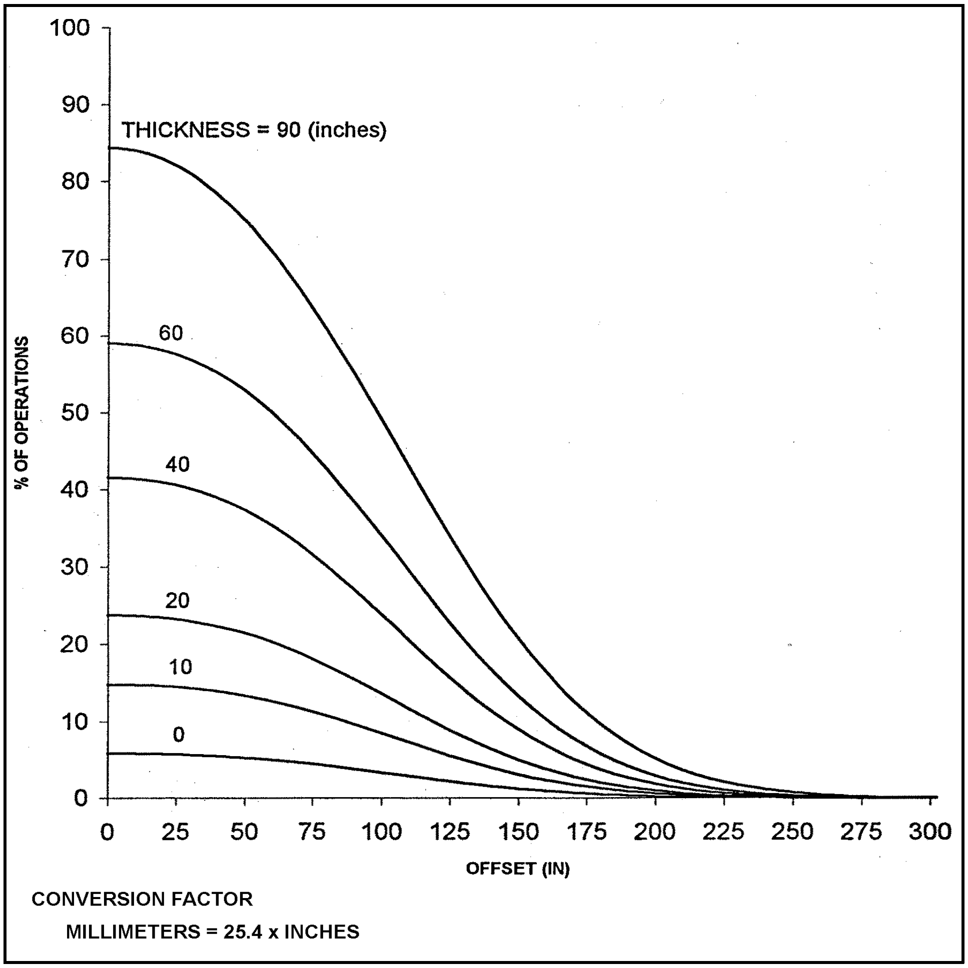

Figure F-2. Effective repetitions of strain for UH-60 aircraft, type A or primary traffic areas

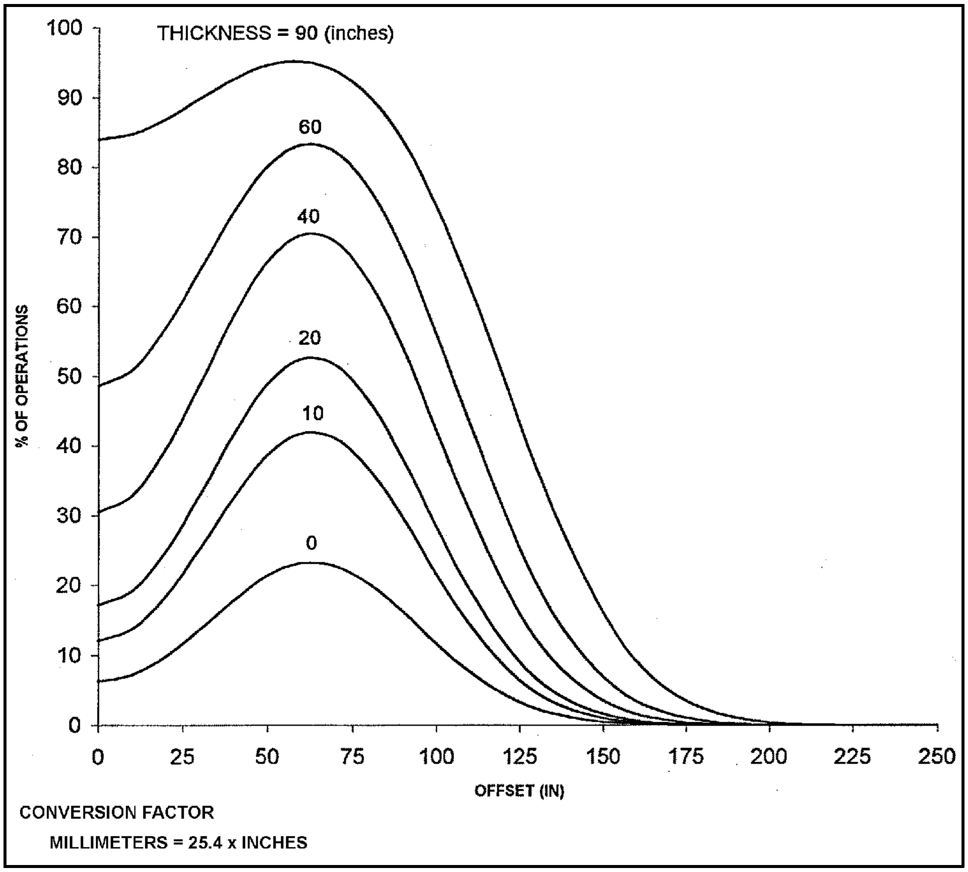

Figure F-3. Effective repetitions of strain for CH-47 aircraft, types B, C, or secondary traffic areas

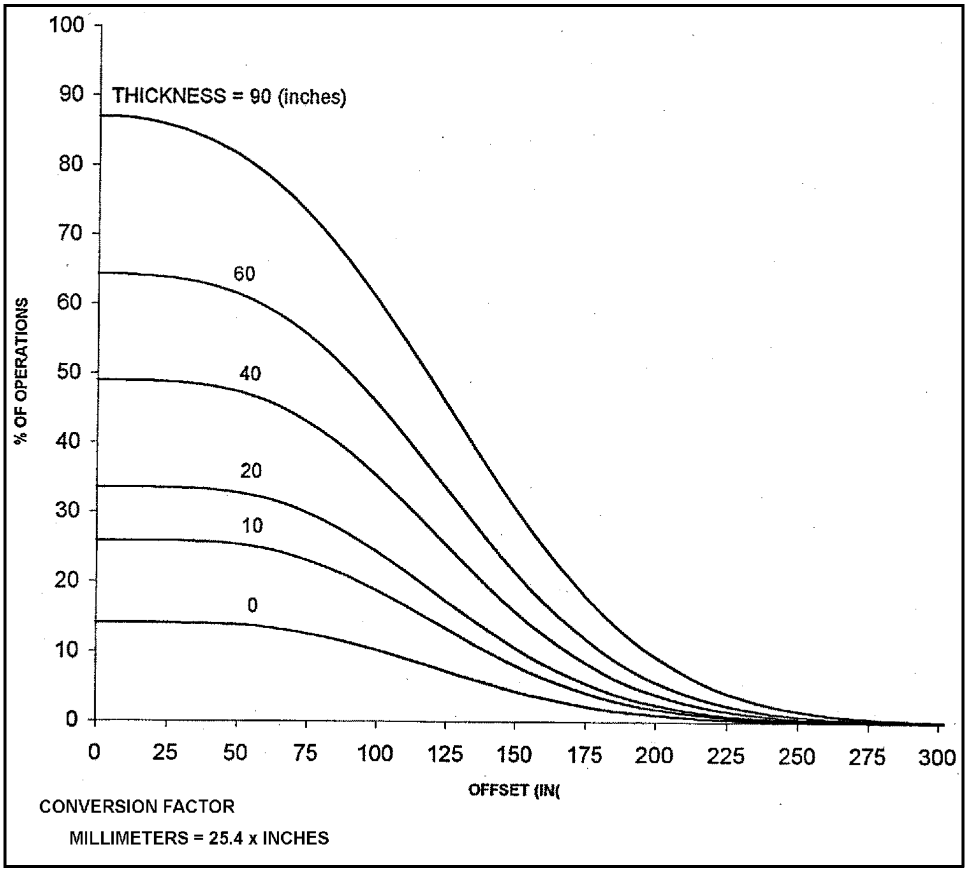

Figure F-4. Effective repetitions of strain for CH-47 aircraft, type A or primary traffic areas

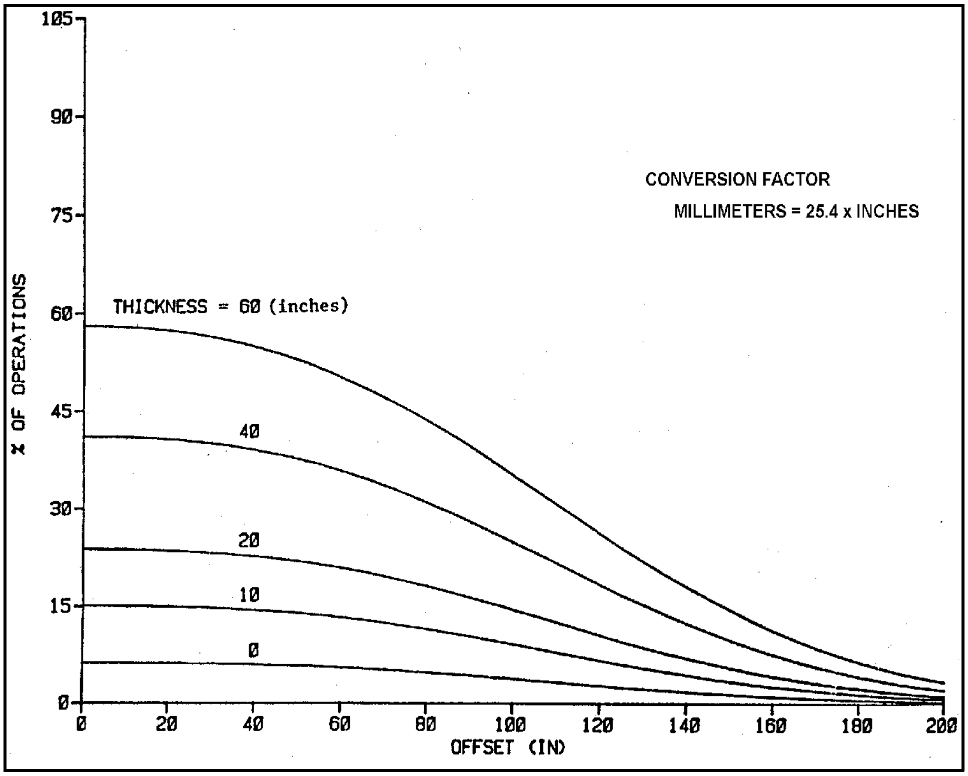

Figure F-5. Effective repetitions of strain for OV-1 aircraft, types B, C, or secondary traffic areas

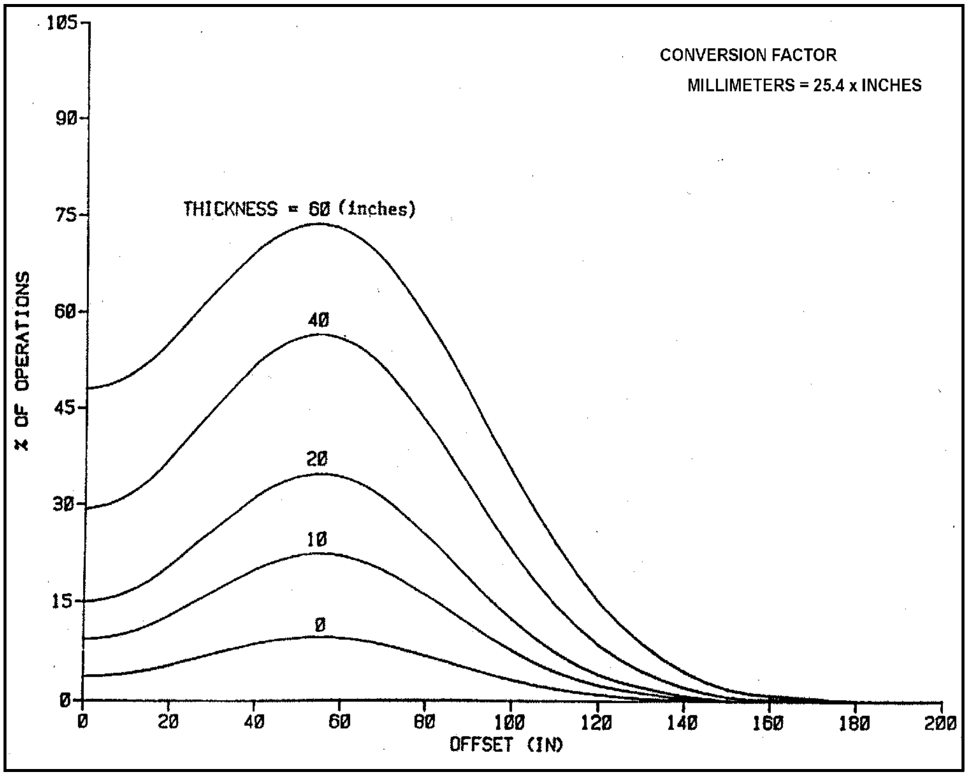

Figure F-6. Effective repetitions of strain for OV-1 aircraft, type A or primary traffic areas

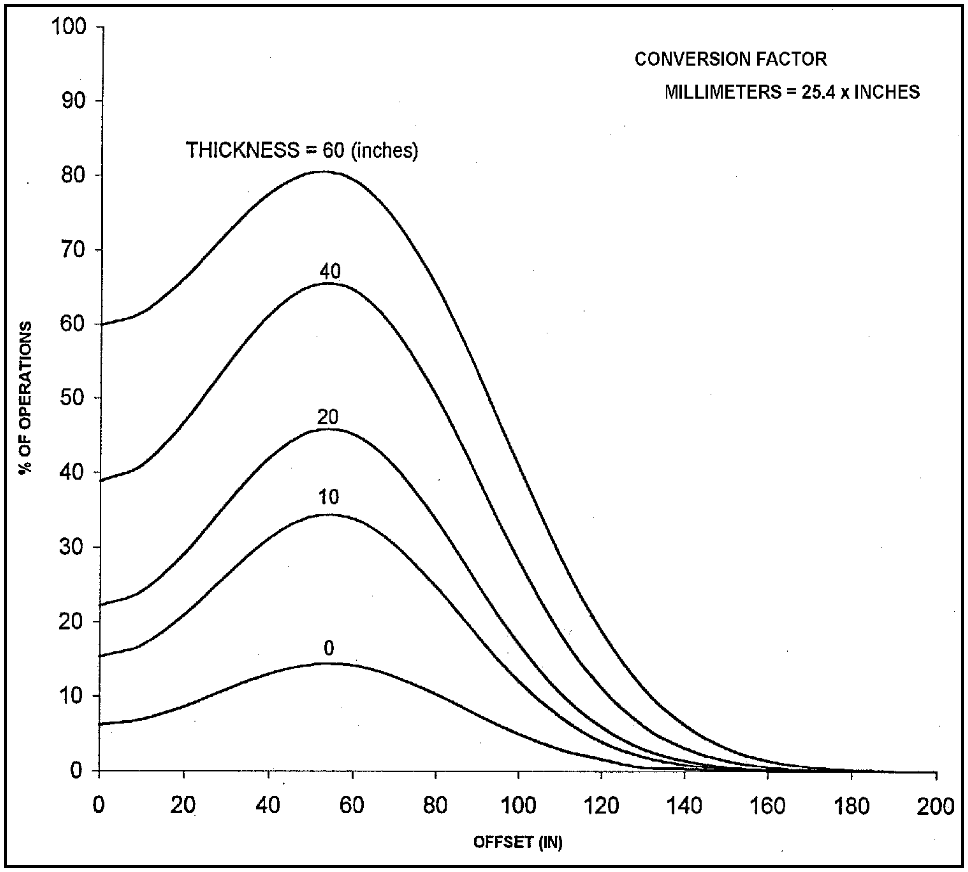

Figure F-7. Effective repetitions of strain for C-12 aircraft, types B, C, or secondary traffic areas

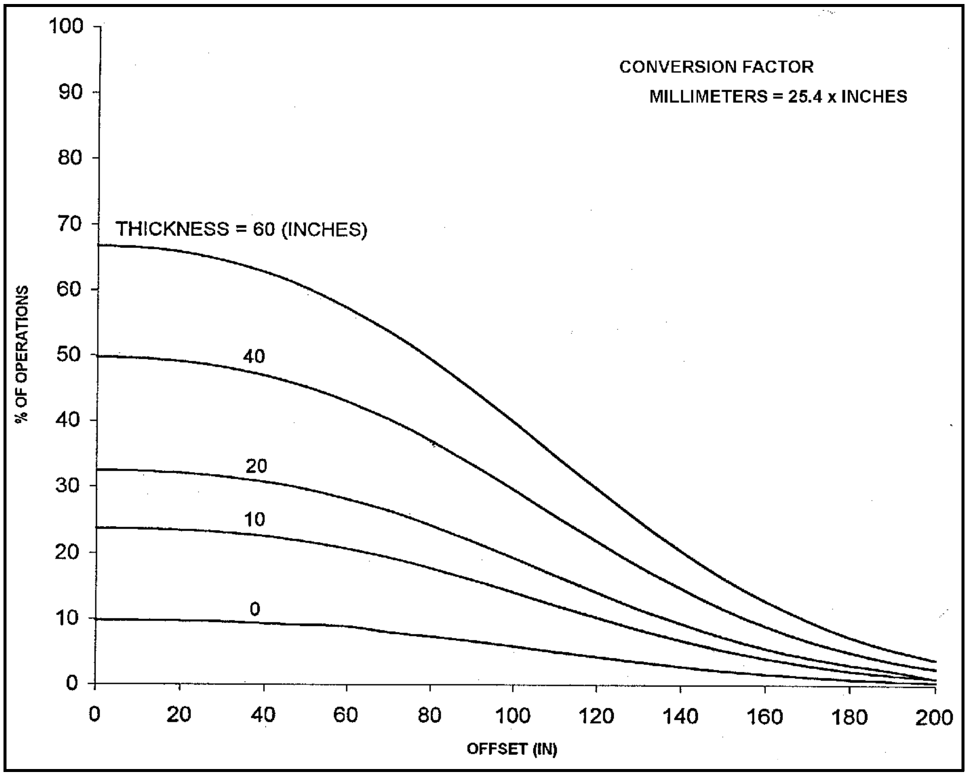

Figure F-8. Effective repetitions of strain for C-12 aircraft, type A or primary traffic areas

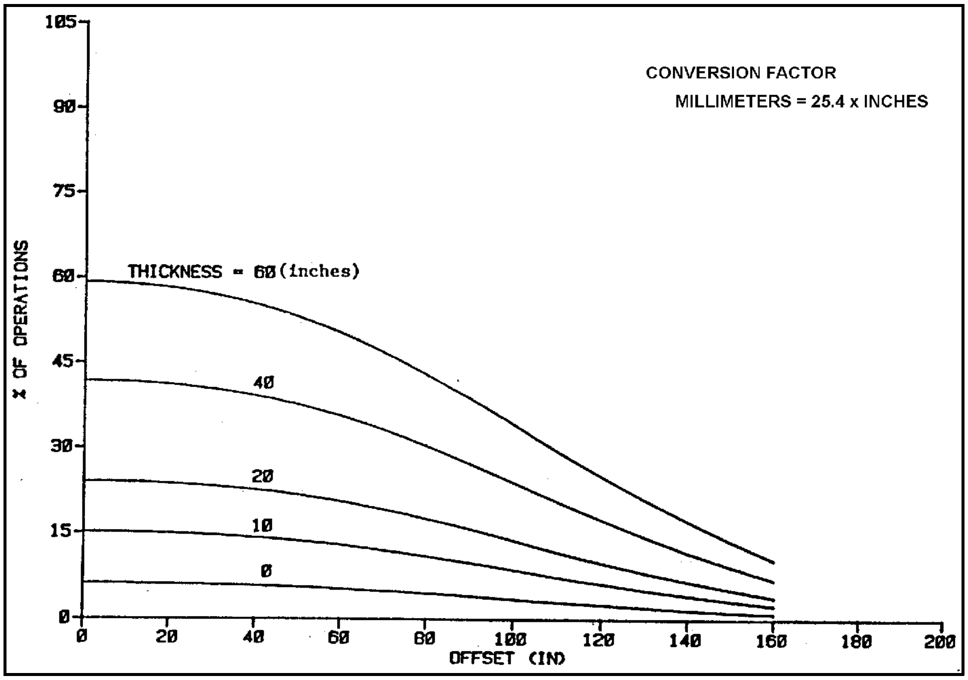

Figure F-9. Effective repetitions of strain for C-130 aircraft, types B, C, or secondary traffic areas

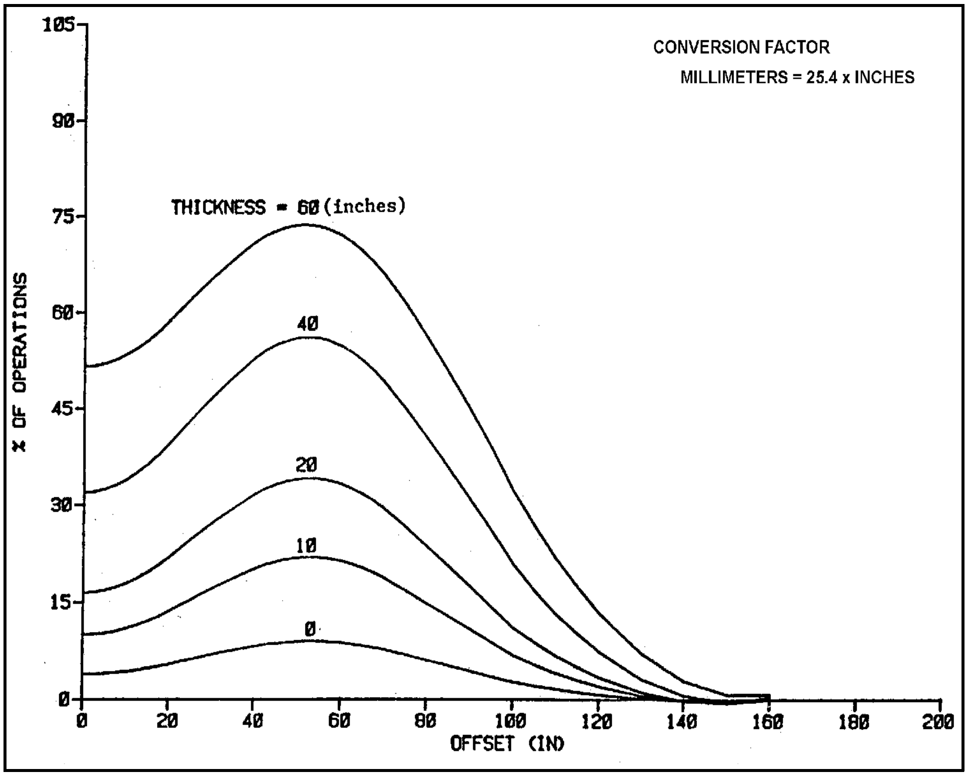

Figure F-10. Effective repetitions of strain for C-130 aircraft, type A or primary traffic areas

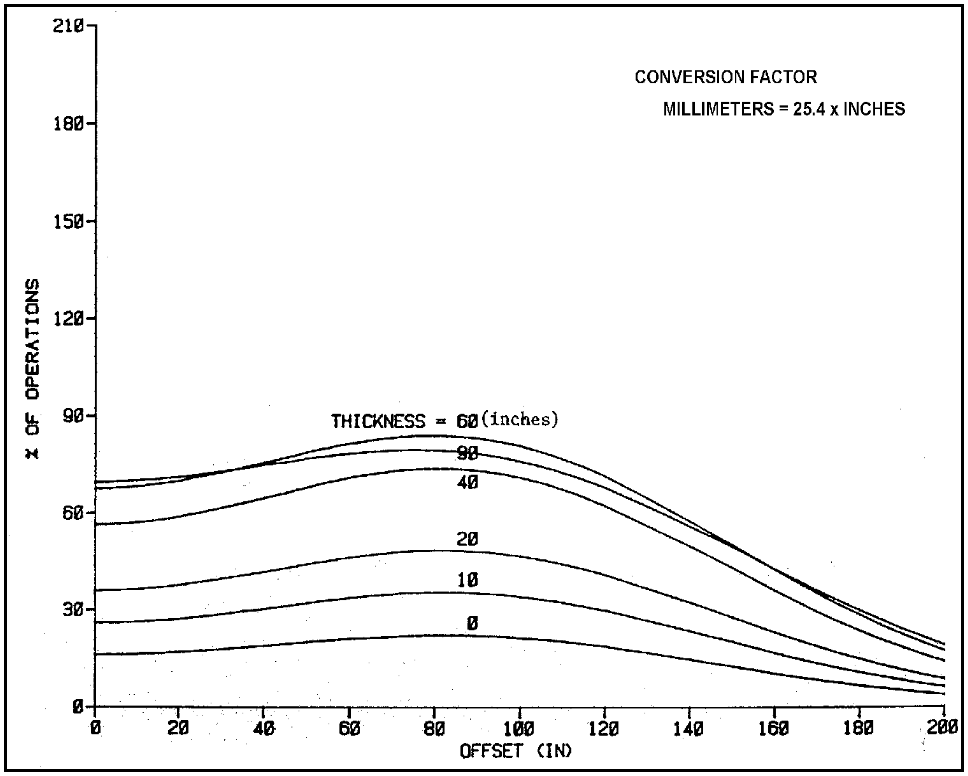

Figure F-11. Effective repetitions of strain for F-15 aircraft, Air Force types B and C traffic areas

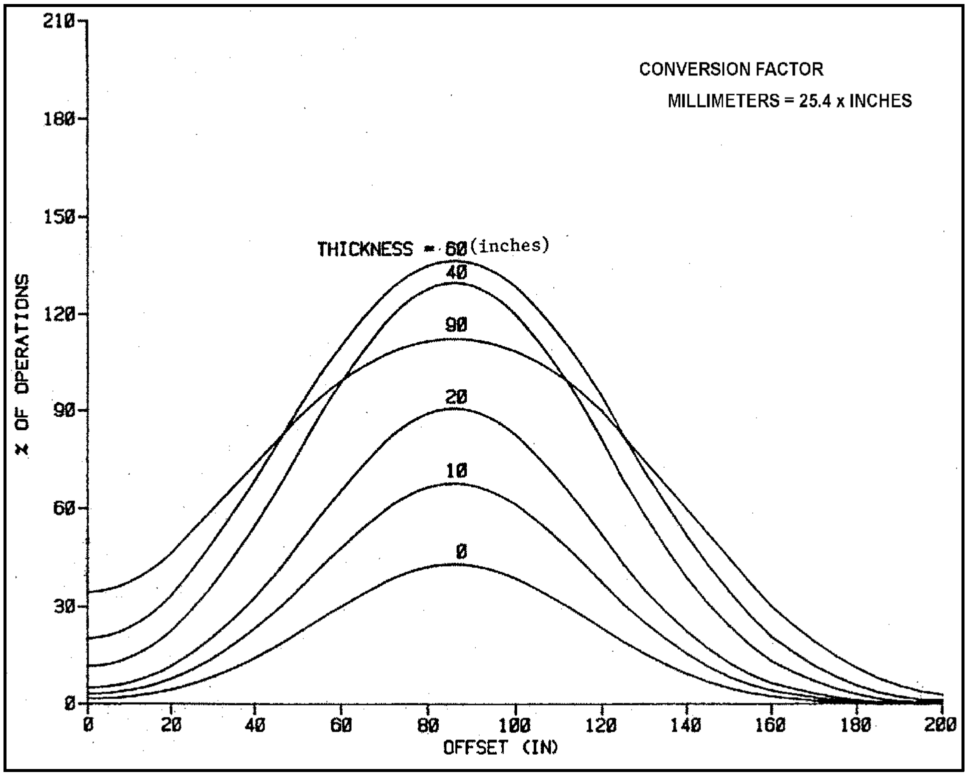

Figure F-12. Effective repetitions of strain for F-15 aircraft, Air Force type A traffic areas

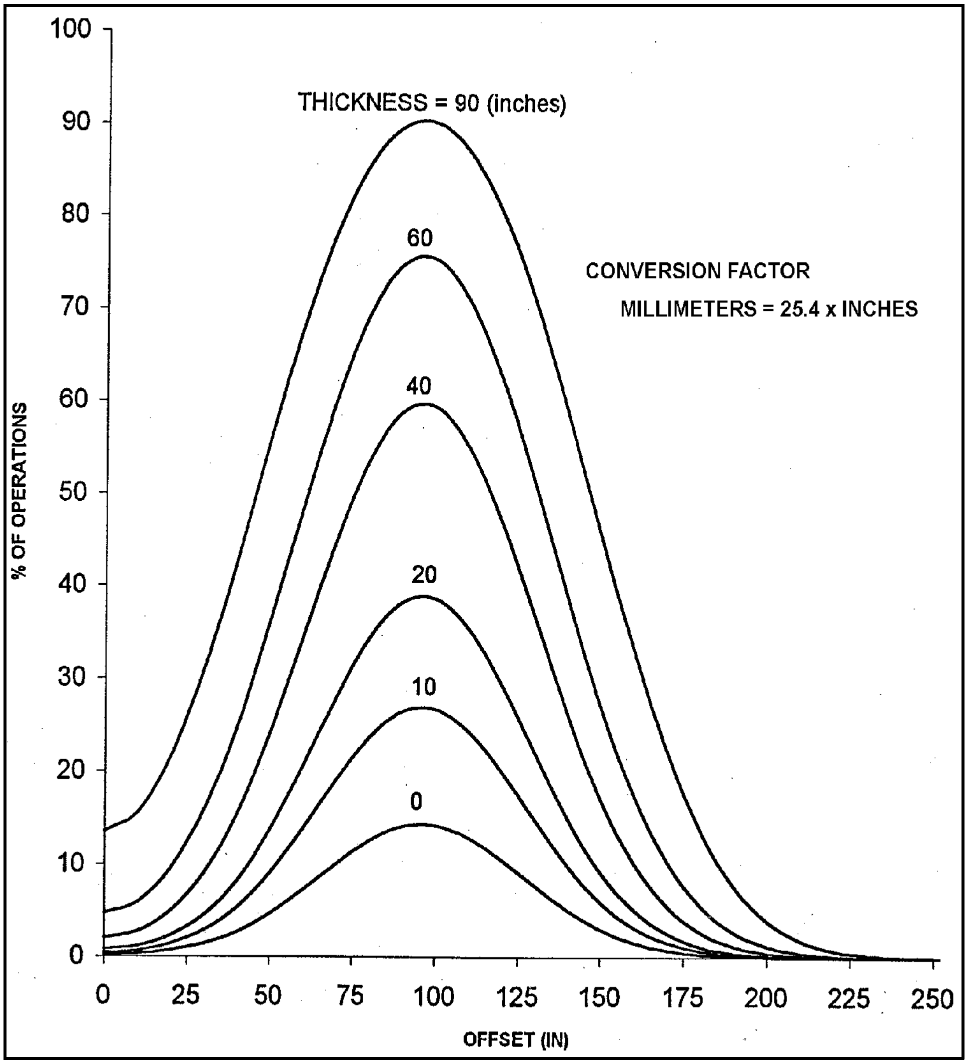

Figure F-13. Effective repetitions of strain for F-14 aircraft, types B, C and secondary traffic areas

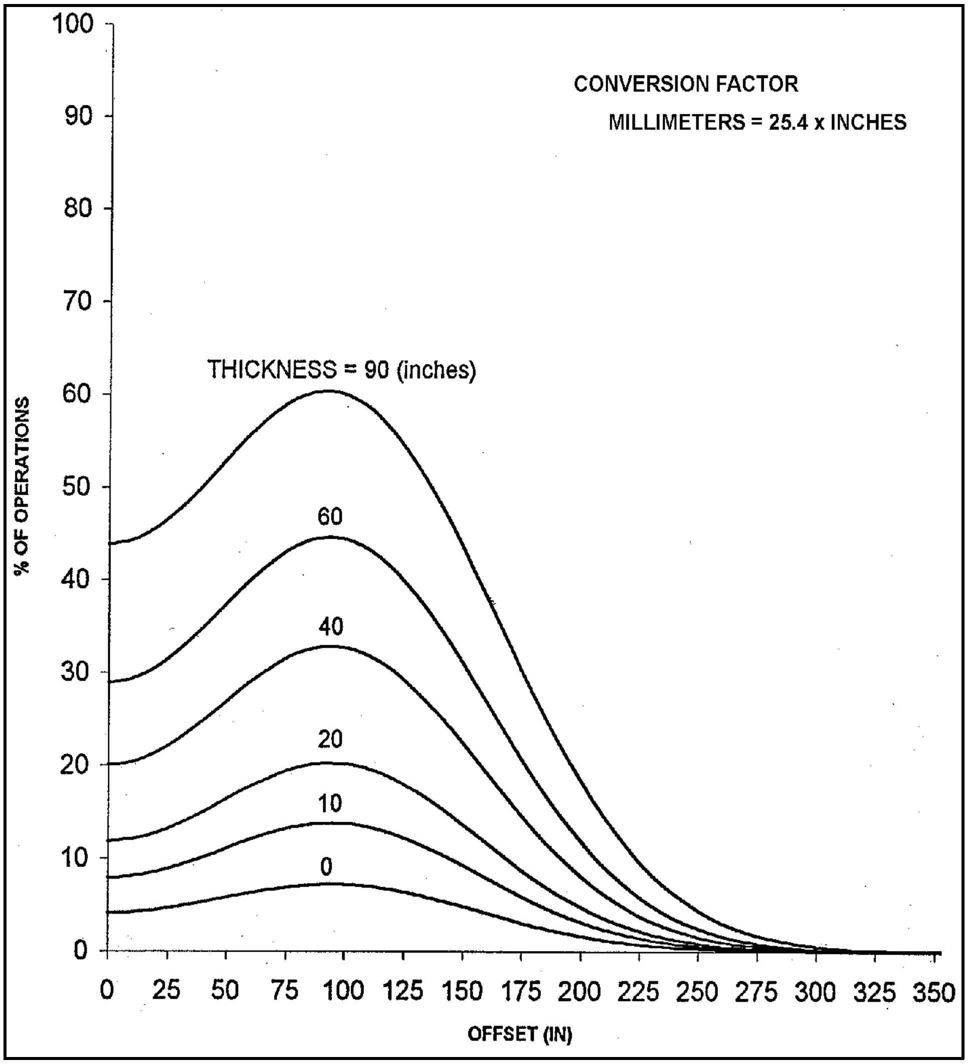

Figure F-14. Effective repetitions of strain for F-14 aircraft, type A or primary traffic areas

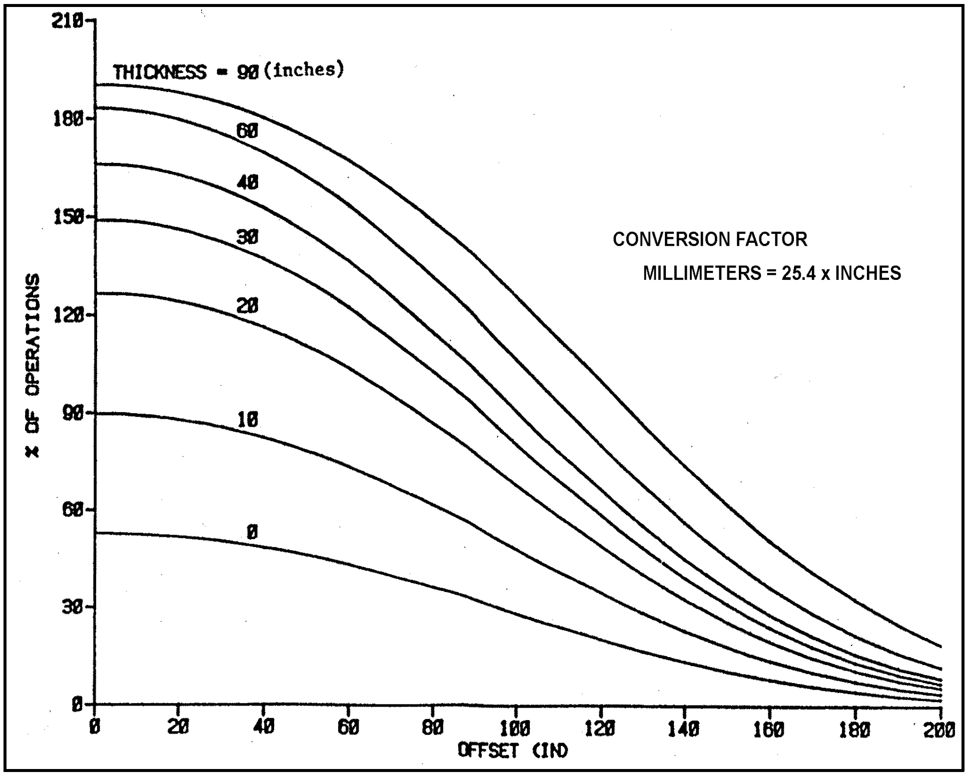

Figure F-15. Effective repetitions of strain for B-52 aircraft, types B, C or secondary traffic areas

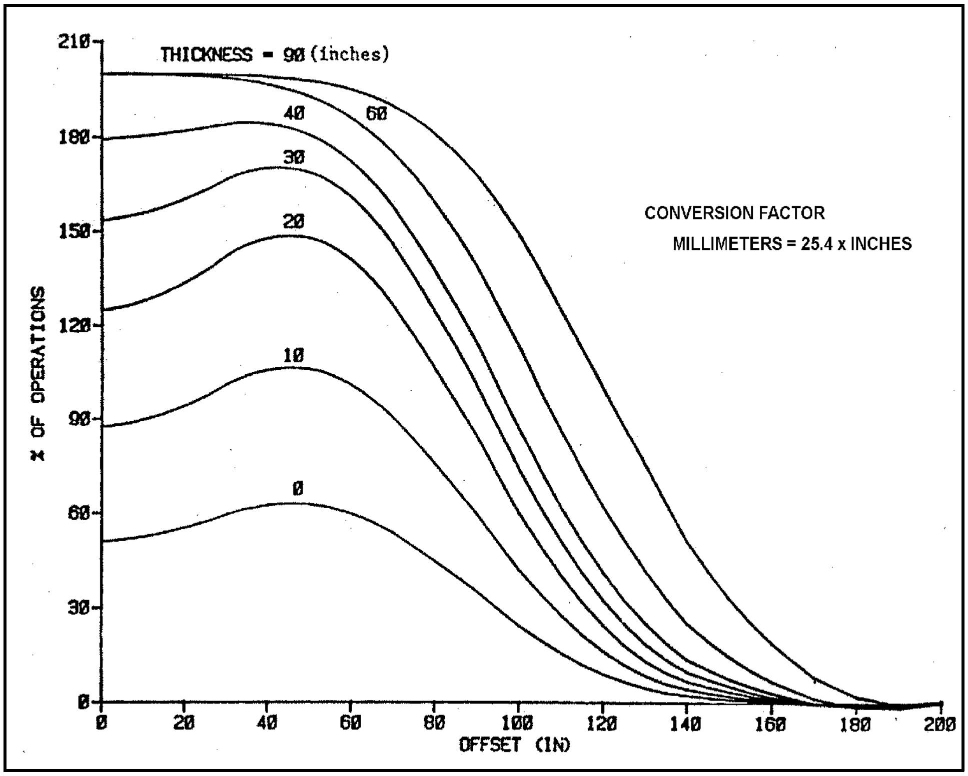

Figure F-16. Effective repetitions of strain for B-52 aircraft, type A or primary traffic areas

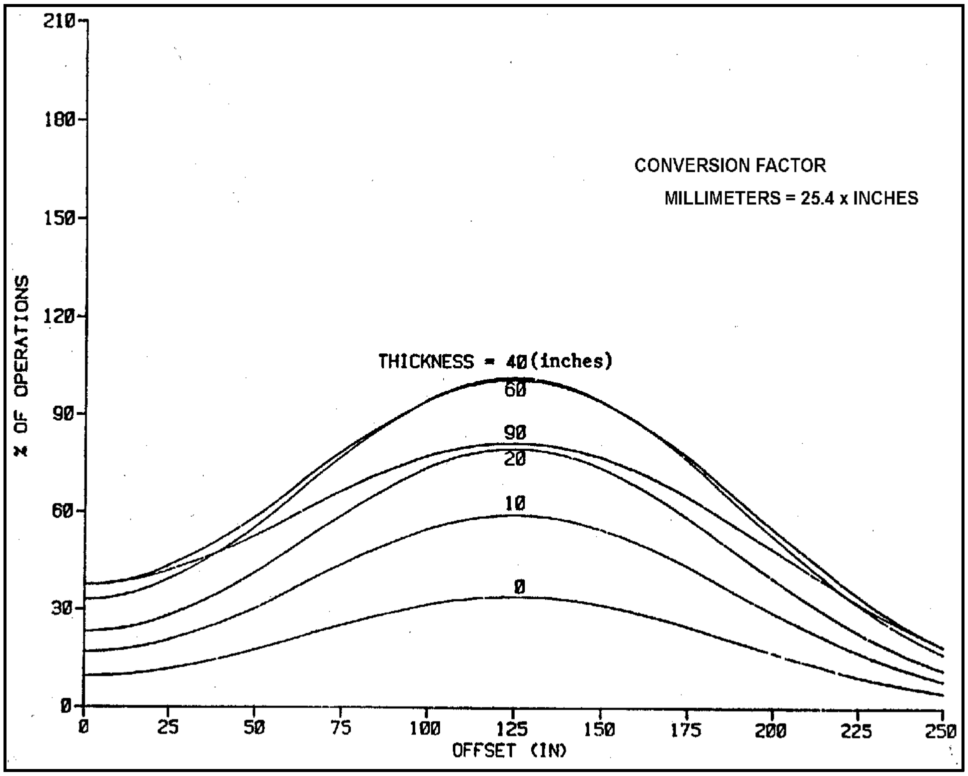

Figure F-17. Effective repetitions of strain for B-1 and C-141 aircraft, types B, C, or secondary traffic areas

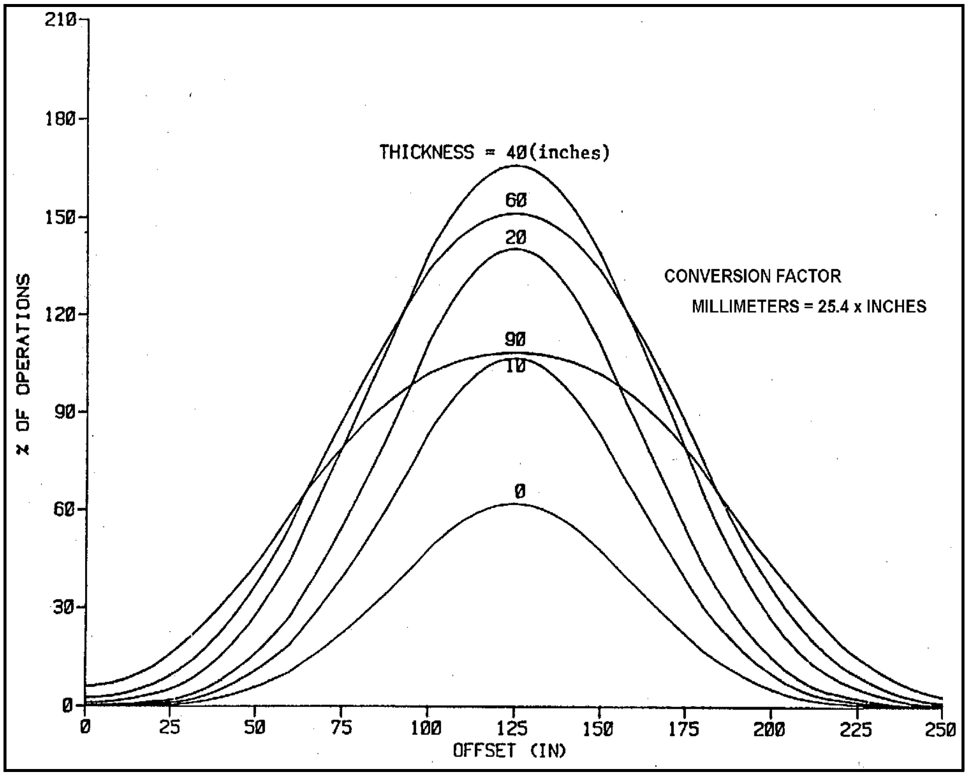

Figure F-18. Effective repetitions of strain for B-1 and C-141 aircraft, type A or primary traffic areas

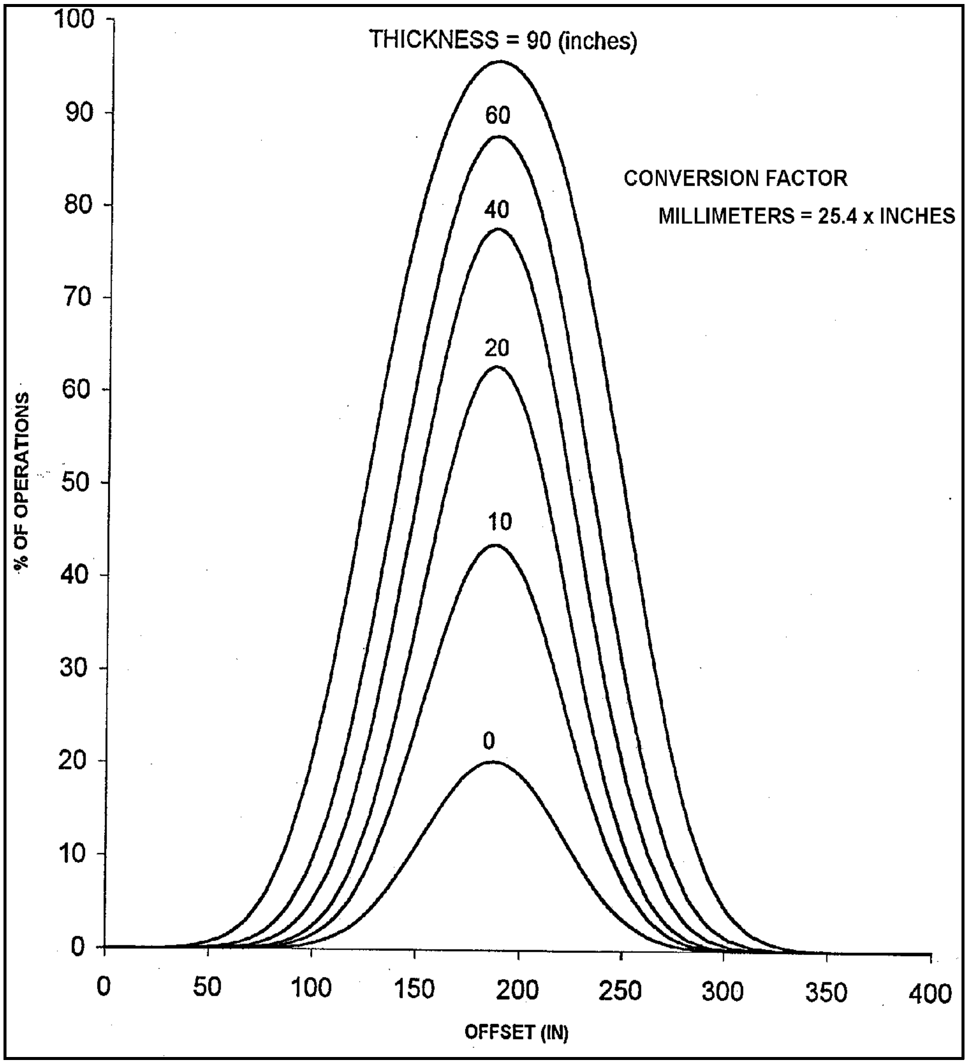

Figure F-19. Effective repetitions of strain for P-3 aircraft, types B, C, or secondary traffic areas

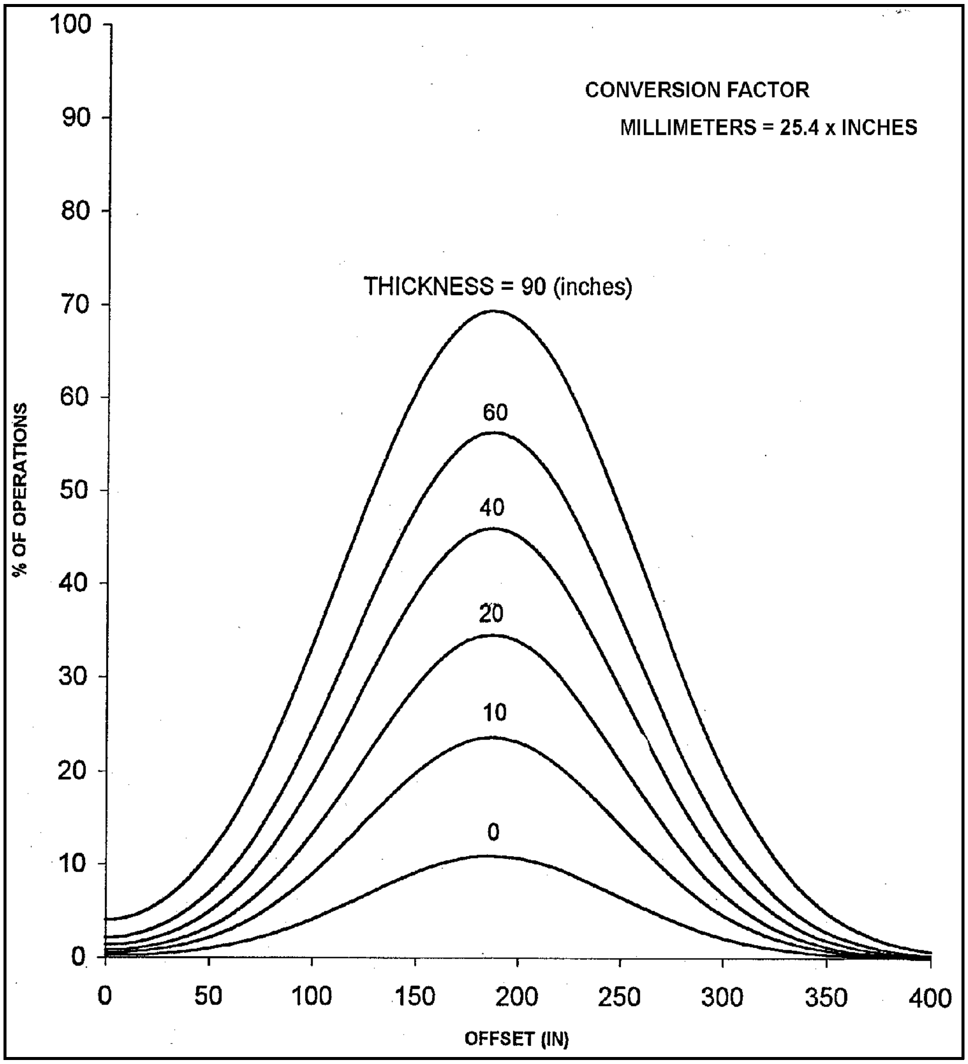

Figure F-20. Effective repetitions of strain for P-3 aircraft, type A or primary traffic areas

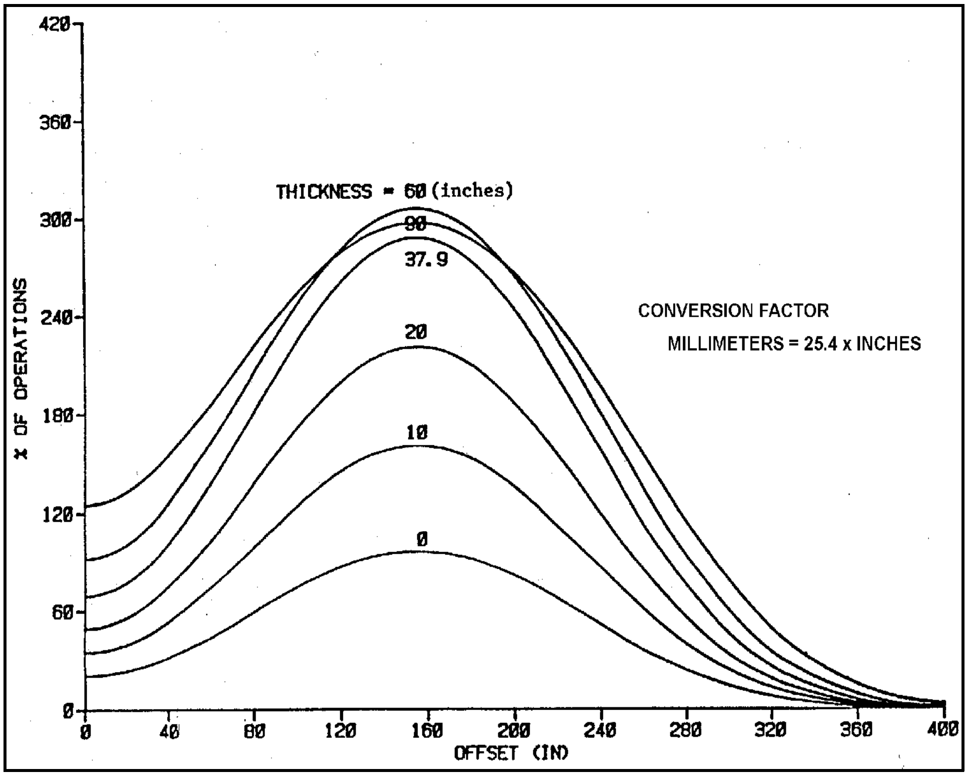

Figure F-21. Effective repetitions of strain for C-5 aircraft, types B, C, or secondary traffic areas

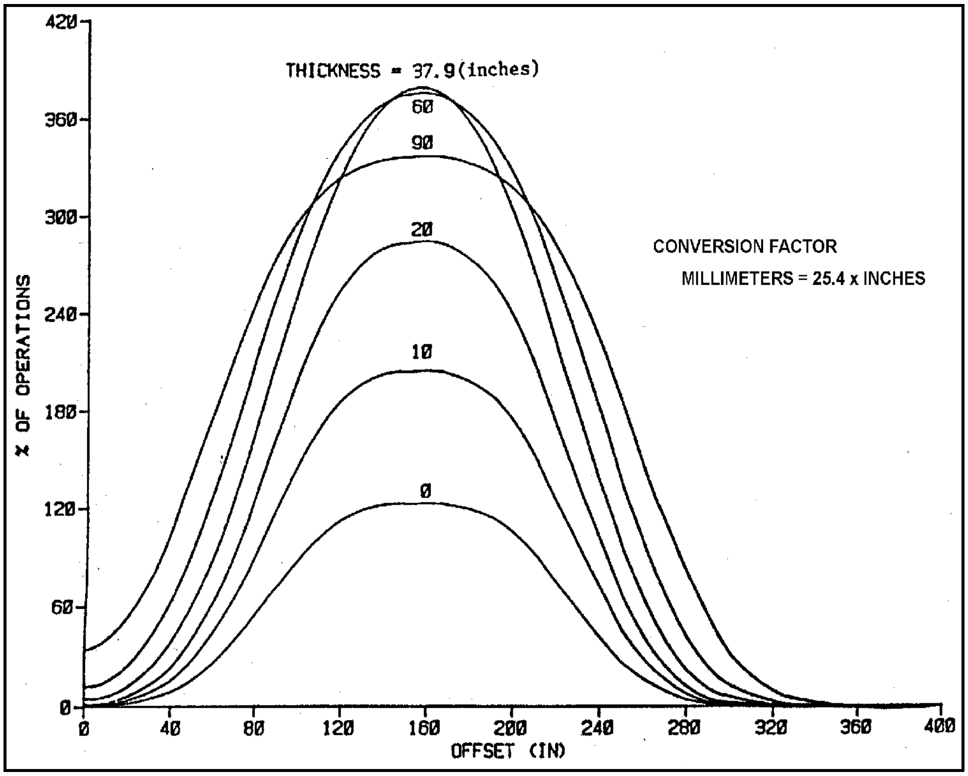

Figure F-22. Effective repetitions of strain for C-5 aircraft, type A or primary traffic areas

APPENDIX G

PROCEDURE FOR PREPARATION OF BITUMINOUS

CYLINDRICAL SPECIMENS

G-1. SCOPE. This procedure describes the preparation of cylindrical specimens of bituminous paving mixture suitable for dynamic modulus testing. The procedure is intended for densegraded bituminous concrete mixture containing up to 25-millimeter (1-inch) maximum-size aggregate.

G-2. APPLICABLE STANDARDS. The following ASTM publications are applicable to this procedure: D 1559, D 1560, and D 1561.

G-3. SPECIMENS. Approximately 4,000 grams of bituminous mixture should be prepared as specified by ASTM D 1560. Cylindrical specimens should be 102 millimeters (4 inches) in diameter by 203 millimeters (8 inches) in height.

G-4. APPARATUS.

a. Testing Apparatus. The apparatus used in preparing the specimens should be as specified by ASTM D 1561, except that steel molding cylinders with 6.3-millimeter (1/4-inch) wall thickness having an inside diameter of 102 millimeters (4 inches) and height of 254 millimeters (10 inches) should be used.

b. Measurement System. The measurement system should consist of a two-channel recorder, stress and strain measuring devices, and suitable signal amplification and excitation equipment. The measurement system should have the capability for determining loading up to 13,344 Newtons (3,000 pounds) from a recording with a minimum sensitivity of 2 percent of the test load per millimeter of chart paper. This system should also be capable of use in determining strains over a range of full-scale recorder outputs from 300 to 5,000 microunits of strain. At the highest sensitivity setting, the system should be able to display 4 microunits of strain or less per millimeter on the recorder chart.

c. Recorder Amplitude. The recorder amplitude should be independent of frequency for tests conducted up to 20 hertz.

d. Measurement of Axial Strain. The values of axial strain should be measured by bonding two wire strain gauges at midheight opposite each other on the specimens. (The Baldwin Lima Hamilton SR-4 Type A-1S 13 strain gauge has been found satisfactory for this purpose). The gauges are wired in a wheatstone bridge circuit with two active gauges on the test specimen exposed to the same environment as the test specimen. The temperature-compensating gauges should be at the same position on the specimen as the active gauges. The sensitivity and type of measurement device should be selected to provide the strain readout required above.

e. Load Measurements. Loads should be measured with an electronic load cell meeting requirements for load and stress measurements above.

G-5. PROCEDURE.

a. Procedure. The compaction temperature for the bituminous mixture should be as specified by ASTM D 1561. For the first step in molding specimens, heat the compaction mold to the same temperature as the mix. Next, place the compaction mold in position in the mold holder and insert a paper disk 102 millimeters (4 inches) in diameter to cover the baseplate of the mold holder. Weigh out one-half of the required amount of bituminous mixture for one specimen at the specified temperature and place uniformly in the insulated feeder trough, which has been preheated to the compaction temperature for the mixture. By means of the variable transformer controlling the heater, maintain the compactor foot sufficiently hot to prevent the mixture from adhering to it. By means of a paddle of suitable dimensions to fit the cross section of the trough, push 30 approximately equal portions of the mixture continuously and uniformly into the mold while 30 tamping blows at a pressure of 1.7 Mpa (250 psi) are applied. Immediately place the remaining one-half of the mixture uniformly in the feeder trough. Push 30 approximately equal portions of the mixture into the mold in a continuous and uniform manner while applying tamping blows at a pressure of 1.7 MPa (250 psi). If sandy or unstable material is involved and there is undue movement of the mixture under the compactor foot, reduce the compaction temperature and compactor foot pressure until kneading compaction can be accomplished.

b. Immediately after compaction with the California kneading compactor, apply a static load to the specimen using a compression testing machine. Apply the load by the double-plunger method in which metal followers are employed as free-fitting plungers on the top and bottom of the specimen. Apply the load on the specimen at a rate of 13 millimeters (0.5 inches) per minute until an applied pressure of 6.9 MPa (1,000 psi) is reached. Release the load immediately. After the compacted specimen has cooled sufficiently so that it will not deform on handling, remove it from the mold. Place the specimen on a smooth flat surface and allow to cool to room temperature. Cylindrical specimens will have approximately the same bulk specific gravity as specimens prepared as specified by ASTM D 1559 and ASTM D 1561.

APPENDIX H

PROCEDURE FOR DETERMINING THE DYNAMIC MODULUS

OF BITUMINOUS CONCRETE MIXTURES

H-1. GENERAL. The purpose of this procedure is to determine dynamic modulus values of bituminous concrete mixtures. The procedure described covers a range of both temperature and loading frequency. The minimum recommended test series consists of testing at 4.5, 21, and 37.8 degrees Celsius (40, 70, and 100 degrees Fahrenheit) at loading frequencies of 2 and 10 hertz for each temperature. The method is applicable to bituminous paving mixtures similar to the 25.4, 19, 12.7, and 9.5 millimeter (1-, 3/4-, 1/2-, and 3/8-inch), and No. 4 mixes as defined by Table 3 of ASTM D 3515.

H-2. APPLICABLE STANDARDS. The following ASTM standards are applicable to this procedure: C 617, D 1559, D 1561, and D 3515.

H-3. SUMMARY PROCEDURE. The dynamic modulus test is run by applying a sinusoidal (haversine) axial compressive stress to a specimen of bituminous concrete at a given temperature and loading frequency. The resulting recoverable axial strain response of the specimen is measured and used to calculate the dynamic modulus.

H-4. DEFINITIONS. The following terms are used in this procedure:

a. Dynamic Modulus. The absolute value of the complex modulus which defines the elastic properties of a linear viscoelastic material subjected to a sinusoidal loading.

b. Complex Modulus. A complex number which defines the relationship between stress and strain for a linear viscoelastic material.

c. Linear material. A material whose stress-to-strain ratio is independent of the loading stress applied.

H-5. APPARATUS. An electrohydraulic testing machine with a frequency generator capable of producing a haversine wave form has proven to be most suitable for use in dynamic modulus testing. The testing machine should have the capability of applying loads over a range of frequencies from 1 to 20 hertz and stress levels up to 0.69 MPa (100 psi). The temperature control system should be capable of a temperature range of 0.0 to 49 degrees Celsius (32 to 120 degrees Fahrenheit). The temperature chamber should be large enough to hold six specimens. A hardened steel disk with a diameter equal to that of the test specimen should be used to transfer the load from the testing machine to the specimen.

H-6. SPECIMENS. The laboratory-molded specimens should be prepared according to Appendix H. A minimum of three specimens is required for testing. The molding procedure is as follows: Cap all specimens with a sulfur mortar meeting ASTM C 617 requirements prior to testing. Bond the strain gauges with epoxy cement to the sides of the specimen near midheight in position to measure axial strains. (Baldwin Lima Hamilton EPY 150 Epoxy Cement has been found satisfactory for this purpose. On specimens with large-size aggregate, care must be taken so that the gauges are attached over areas between the aggregate faces). Wire the strain gauges as required in paragraph G-5 and attach suitable lead wires and connectors.

H-7. PROCEDURE. The following testing procedure is recommended:

a. Place test specimens in a controlled temperature cabinet, and bring them to the specified test temperature. A dummy specimen with a thermocouple in the center can be used to determine when the desired test temperature is reached.

b. Place a specimen in the loading apparatus, and connect the strain gage wires to the measurement system. Put the hardened steel disk on top of the specimen and center both under the loading apparatus. Adjust and balance the electronic measuring system as necessary.

c. Apply the haversine loading to the specimen without impact and with loads varying between (0 and 35 psi) for each load application for a minimum of 30 seconds and not exceeding 45 seconds at temperature of 4.5, 21, and 37.8 degrees Celsius (40, 70, and 100 degrees Fahrenheit) and at loading frequencies of 2 hertz for taxiway design and 10 hertz for runway design. If excessive deformation (greater than 2,500 microunits of strain) occurs, reduce the maximum loading stress level to 0.12 MPa (17.5 psi).

d. Test three specimens at each temperature and frequency condition twice. Start at the lowest temperature and repeat the test at the next highest temperature. Bring the specimens to the specified test temperature before each test is commenced.

e. Monitor both the loading stress and the axial strain during the test. Increase the recorder chart speed so that one cycle covers 25 to 50 millimeters of chart paper for five to ten repetitions before the end of the test.

f. Complete the loading for each test within 2 minutes from the time specimens are removed from the temperature control cabinet. The 2-minute testing time limit is waived if loading is conducted within a temperature control cabinet meeting requirements in paragraph H-5.

H-8. CALCULATIONS. Measure the average amplitude of the load and the strain over the last three loading cycles to the nearest 1/2 millimeter. Calculate the loading stress σ_o using the equation

$$\sigma_o = \frac{H_1 L}{H_2 A} \qquad \text{(H-1)}$$

where

H_1 = measured height of load, millimeters (inches)

H_2 = measured chart height, millimeters (inches)

L = full-scale load amplitude determined by settings on the recording equipment, Newtons (pounds)

A = cross-section area of the test specimen, square millimeters (square inches)

Calculate the recoverable axial strain ϵ_o using the equation

$$\epsilon_o = \frac{H_3 S}{H_4}$$

where

H_3 = measured height of recoverable strain, millimeters (inches)

H_4 = measured chart height, millimeters (inches)

S = full-scale strain amplitude determined by settings on the recording equipment

Calculate the dynamic modulus $|E^*|$ using the equation

$$|E*| = \frac{\sigma_o}{\epsilon_o} \qquad \text{(H-3)}$$

where

σ_o = axial loading stress, MPa (psi)

ϵ_o = recoverable axial strain, millimeters per millimeter (inches per inch)

Report the average dynamic modulus at temperatures of 4.5, 21, and 37.8 degrees Celsius (40, 70, and 100 degrees Fahrenheit) for each loading frequency at each temperature.

APPENDIX I

PROCEDURE FOR ESTIMATING THE MODULUS OF ELASTICITY OF BITUMINOUS CONCRETE

I-1. GENERAL. The procedure for estimating the modulus of elasticity of bituminous concrete presented here is based on relationships developed by Shell.[1] Parameters needed for input into this method are:

a. Ring-and-ball softening point in degrees Celsius (degrees Fahrenheit) of the bituminous material used in the mix in accordance with ASTM D 36.

b. Penetration of the bituminous material, in 1/10 millimeters in accordance with ASTM D 5.

c. Volume concentration of the aggregate C_v used in the mix defined by

$$C_v = \frac{\text{aggregate volume}}{\text{aggregate volume} + \text{bitumen volume}} \qquad \text{(I-1)}$$

I-2. STEPS OF PROCEDURE. The steps in using this method are as follows:

a. Penetration Index. With known values of penetration and ring-and-ball softening point, enter Figure I-1 and determine the penetration index PI.

b. Stiffness Modulus. The next step involves the use of the nomograph presented in Figure H-2. In addition to the PI, two other values are required: the temperature of the bituminous concrete mix for which the modulus value is desired and the estimated loading frequency or time of loading to which the prototype pavement will be subjected. Use of a loading frequency of 2 hertz is recommended for taxiway design and 10 hertz for runway design. With values for the loading frequency and the difference in temperature between the bituminous concrete and the ring-and-ball softening point, a stiffness value for the bitumen S_{bit} can be determined from the appropriate PI line at the top of the nomograph. The value of S_{bit} is then used to determine the modulus of the mix S_{mix}.

c. Determining Modulus of Mix S_{mix}. A value for S_{mix} may be determined by

$$s_{mix} = s_{bit}\left[1 + \left(\frac{2.5}{n}\right)\left(\frac{c_v}{1 - c_v}\right)\right]^n \qquad \text{(I-2)}$$

---

[1] Heukelom, W., and Klomp, A. J. G. (1964). "Road Design and Dynamic Loading." *Proceedings, Association of Asphalt Paving Technologists*. Vol 33, 92-125.

where

$$n = 0.83 \log \left(\frac{400{,}000}{s_{bit}} \right) \tag{I-3}$$

The value thus determined for S_{mix} is in units of kilograms per square centimeter.

d. Corrected Aggregate Volume Concentration. This expression should be used for aggregate volume concentrations of 0.7 to 0.9 and air void contents of 3 percent or less. For larger air void contents, use a corrected aggregate volume concentration (C'_v)

$$C'_v = \frac{c_v}{1 + \Delta air\ void\ content} \tag{I-4}$$

where Δair void content is the actual air void content (expressed in decimal form) minus 0.03. Equation I-4 is valid only when

$$c_B \geq \frac{2}{3}\,(1 - c'_v) \tag{I-5}$$

where

$$c_B = \frac{bitumen\ volume}{aggregate\ volume + bitumen\ volume} \tag{I-6}$$

APPENDIX J

PROCEDURE FOR DETERMINING THE MODULUS OF ELASTICITY OF UNBOUND GRANULAR BASE AND SUBBASE COURSE MATERIALS

J-1. PROCEDURE.

a. Relationships. The procedure is based on relationships developed for the resilient modulus of unbound granular layers as a function of the thickness of the layer and type of material. The modulus relationships are shown in Figure J-1. Modulus values for layer n (the upper layer) are indicated on the ordinate, and those for layer n + 1 (the lower layer) are indicated on the abscissa. Essentially linear relationships are indicated for various thicknesses of base- and subbase-course materials. For subbase courses, relationships are shown for thicknesses of 102, 127, 152, 178, and 203 millimeters (4, 5, 6, 7, and 8 inches). For subbase courses having a design thickness of 203 millimeters (8 inches) or less, the applicable curve or appropriate interpolation can be used directly. For a design subbase-course thickness in excess of 203 millimeters (8 inches), the layer should be divided into sublayers of approximately equal thickness and the modulus of each sublayer determined individually. For base courses, relationships are shown for thicknesses of 102, 152, and 254 millimeters (4, 6, and 10 inches). These relationships can be used directly or by interpolation for design base course thicknesses up to 254 millimeters (10 inches). For design thicknesses in excess of 254 millimeters (10 inches), the layer should also be divided into sublayers of approximately equal thickness and the modulus of each sublayer determined individually.

b. Modulus Values. To determine modulus values from this procedure, Figure J-1 is entered along the abscissa using modulus values of the subgrade or underlying layer (modulus of layer n + 1). At the intersection of the curve applicable to this value with the appropriate thickness relationship, the value of the modulus of the overlying layer is read from the ordinate (modulus of layer n). This procedure is repeated using the modulus value just determined as the modulus of layer n + 1 to determine the modulus value of the next overlying layer.

J-2. EXAMPLES.

a. Thickness. Assume a pavement having a base-course thickness of 102 millimeters (4 inches) and a subbase-course thickness of 203 millimeters (8 inches) over a subgrade having a modulus of 69 MPa (10,000 psi). Initially, the subgrade is assumed to be layer n + 1 and the subbase course to be layer n. Entering Figure I-1 with a modulus of layer n + 1 of 69 MPa (10,000 psi) and using the 203-millimeter (8-inch) subbase course curve, the modulus of the subbase (layer n) is 127.5 MPa (18,500 psi). In order to determine the modulus value of the base course, the subbase course is now assumed to be layer n + 1 and the base course to be layer n. Entering Figure J-1 with a modulus value of layer n + 1 of 127.5 MPa (18,500 psi) and using the 102 millimeter (4-inch) base-course relationship, the modulus of the base course is 248 MPa (36,000 psi). Modulus values determined for each layer are indicated in Figure J-2.

b. Design Thickness. If, in the first example, the design thickness of the subbase course had been 305 millimeters (12 inches), it would have been necessary to divide this layer into two 152-millimeter- (6-inch-) thick sublayers. Then, using the procedure described above for the second example, the modulus values determined for the lower and upper sublayers of the subbase course and for the base course are 121, 176, and 303 MPa (17,500, 25,500, and 44,000 psi), respectively. These values are shown in Figure J-3.

c. Relationships. The relationships indicated in Figure I-1 can be expressed as

$$E_n = E_{n+1}\ (1 + 10.52 \log t - 2.10 \log E_{n+1} \log t) \quad \text{(J-1)}$$

where

n = a layer in the pavement system

E_n = resilient modulus (in psi) of layer n

E_{n+l} = the resilient modulus (in psi) of the layer beneath layer n

t = the thickness (in inches) of layer n for base-course materials and as

$$E_n = E_{n+1}\ (1 + 7.18 \log t - 1.56 \log E_{n+1} \log t) \quad \text{(J-2)}$$

for subbase-course materials. Use of these equation for direct computation of modulus values for the examples given above yields the value indicated in parentheses in Figures I-2 and I-3. It can be seen that comparable values are obtained with either graphical or computational determination of the modulus value for either material.

APPENDIX K

PROCEDURE FOR DETERMINING THE FLEXURAL MODULUS AND FATIGUE CHARACTERISTICS OF STABILIZED SOILS

K-1. LABORATORY PROCEDURE.

a. General. The procedure involves application of a repetitive loading to a laboratory-prepared beam specimen under controlled stress conditions. Applied load and deflection along the neutral axis and at the lower surface are monitored, and the results are used to determine the flexural modulus and fatigue characteristics.

b. Specimen Preparation. Beam specimens should be prepared following the general procedures indicated in ASTM D 1632. This method describes procedures for molding 76- by 76- by 286-millimeter (3- by 3- by 11-1/4-inch) specimens; however, any size mold may be used for the test. For soils containing aggregate particles larger than 19 millimeters (3/4 inch), it is recommended that molds on the order of 102 by 102 to 152 by 152 millimeters (4 by 4 to 6 by 6 inches) be used. In general, specimens should have an approximately square crosssectional configuration and a length adequate to accommodate an effective test span equal to three times the height or width. Specimens should be molded to the stabilizer treatment level, moisture content, and density expected in the field structures. Cement-treated materials should be moist-cured for 7 days. Lime-treated materials should be cured for 28 days at 23 degrees Celsius (73 degrees Fahrenheit).

c. Equipment. The following equipment is required:

(1) Loading frame capable of receiving specimen for third-point loading test.

(2) Electrohydraulic testing machine. This machine must be capable of applying static and haversine loads.

(3) Load cell (approximately 907-kilogram (2,000-pound) capacity).

(4) Two LVDT's and one SR-4 type strain gauge.

(5) Recording equipment for monitoring deflection, strain, and load.

(6) Miscellaneous pins and yokes, as described in the equipment setup below for mounting the LVDT'S.

d. Equipment Setup. Details of the equipment setup are shown in Figures K-1 to K-3. The beam should be positioned so that the molding laminations are horizontal. The three yokes are positioned over the top of the beam and held in place by threaded pins, positioned along the neutral axis. The end pins, pins A and C, are positioned directly over the end reaction points, and the middle pin, pin B, is positioned at the center of the beam. A metal bar rests on top of the pin. At the A position, the bar is equipped with a lower vertical tab having a hole that slips loosely over the pin. A nut is placed on the end of the pin to prevent the bar from slipping. At the center or B position, the bar is equipped with a vertical tap onto which an LVDT is cemented in a vertical position. At this point on the bar, there is a hole through which the LVDT core pin falls to rest on the B pin. This pin must be fabricated with flat sides on the shaft to provide a horizontal surface on which the LVDT core pin rests. At the C position, the end of the bar simply rests on the unthreaded portion of the C pin. A nut is placed on the end of the C pin to prevent excessive side movement of the bar end. This type of bar, pin, and LVDT arrangement is provided on both sides of the beam. Although no dimensions are provided in Figures K-1 to K-3, this type of equipment can easily be dimensioned and fabricated to fit any size beam. Either steel or aluminum may be used. The beam should be positioned and arranged to accommodate third point loading as indicated in Figure K-2. As the beam bends under loading, defection at the center is measured by determining the movement of the LVDT stems from their original positions. The LVDTs are connected to the monitoring system to give an average deflection reading. Since it is also desired to determine the maximum tensile strain of the beam under loading, an SR-4 strain gauge should be attached to the lower beam surface with epoxy or some other suitable cement and should also be connected to the monitoring system. If it is not possible to determine strain directly, a strain value may be found using Equation K-2.

e. Test Procedure. The flexural beam test is a stress-controlled test. Therefore, an initial specimen should be statically loaded to failure, and the stress level for the initial repetitive load tests should be set at 50 percent of the maximum rupture load. The repetitive load test should be conducted using a haversine wave form, a loading duration of 0.5 second, and a frequency of about 1 hertz. To develop a strain repetition pattern, it is recommended that tests be conducted at 40, 50, 60, and 70 percent of the maximum rupture value; however, stress levels can be varied to higher or lower levels. Data to be monitored include load, deflection along the neutral axis, strain at the lower surface of the specimen, and number of repetitions.

f. Reporting of Test Results.

(1) Flexural Modulus. The flexural modulus should be determined at 100, 1,000, and 10,000 load repetitions or at failure. This value may be determined from load deflection data monitored at these repetition levels using the expression

$$E_f = \frac{23PL^3}{1296dI}\left(1 + 2.11\ \frac{h}{(L)}\right)^2 \qquad \text{(K-1)}$$

where

E_f = flexural modulus, MPa (psi)

P = maximum load amplitude, kilograms (pounds)

L = specimen length, millimeters (inches)

d = deflection at the neutral axis, millimeters (inches)

I = moment of inertia, millimeters^4 (inch^4)

h = specimen height, millimeters (inch)

The value to be used for E_f in the performance model is the arithmetic mean of all values obtained during the test.

(2) Fatigue characteristics. Fatigue characteristics are presented as a plot of strain indicated at the bottom surface of the specimen versus load repetitions at failure. Generally, the value of the strain obtained during the first few load repetitions is the value to be plotted. If no direct means of measuring strain is available, a strain value ϵ may be computed using the expression

$$\epsilon = \frac{PLh}{6E_f I} \qquad \text{(K-2)}$$

K-2. GRAPHICAL DETERMINATION OF FLEXURAL MODULUS FOR CHEMICALLY STABILIZED SOILS (CRACKED SECTION). The procedure for determining a flexural modulus value for chemically stabilized soils based on the cracked section concept involves the use of a relationship between unconfined compressive strength and flexural modulus determined analytically. This relationship is shown in Figure K-2. To use this relationship, specimens of the stabilized material should be molded and tested following procedures indicated in ASTM D 1633. Values obtained from the unconfined compression test can then be used to determine the values of the equivalent cracked section modulus using Figure K-2.

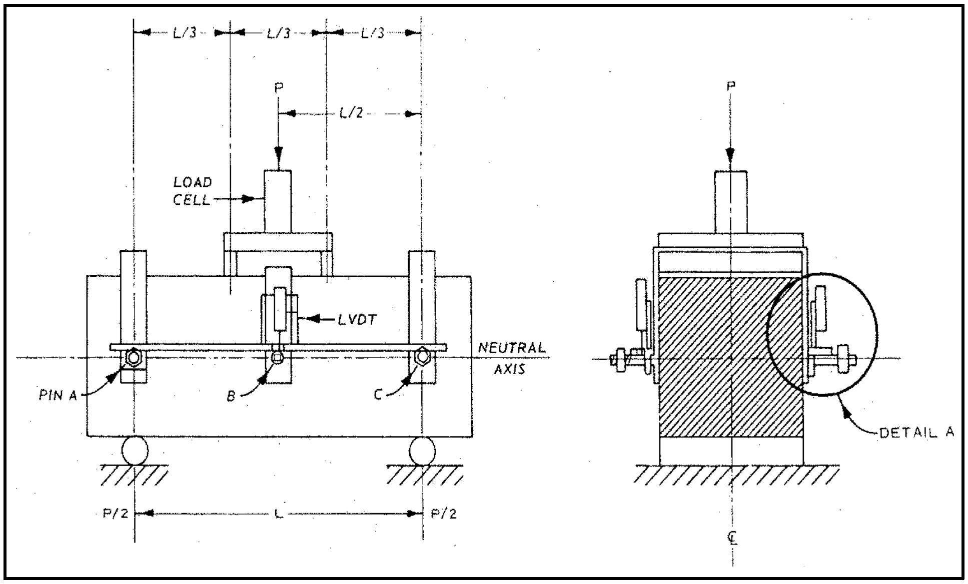

Figure K-1. General view of equipment setup

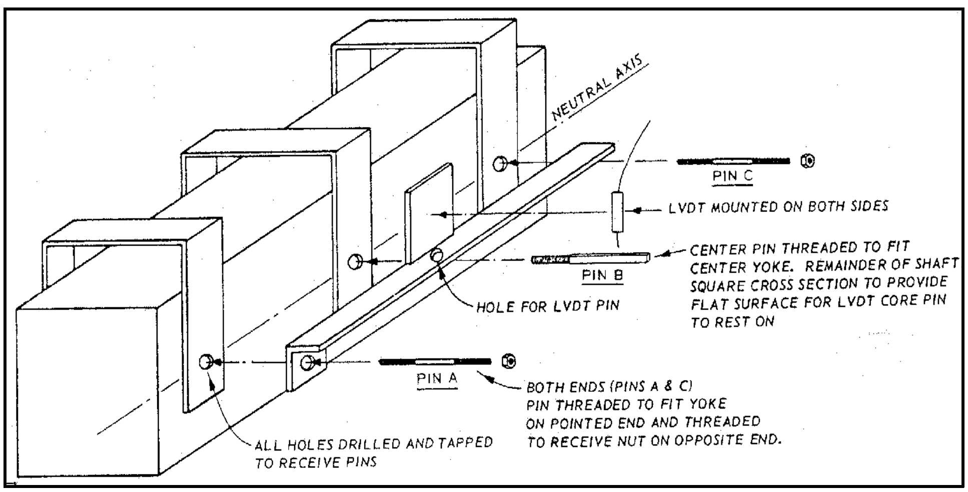

Figure K-2. Details of equipment setup

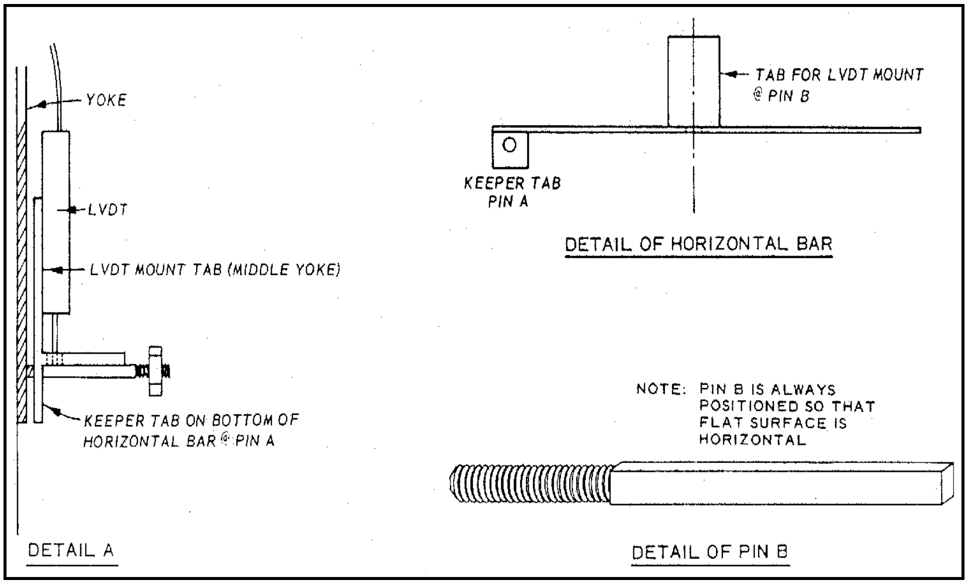

Figure K-3. Miscellaneous details

APPENDIX L

PROCEDURE FOR DETERMINING RESILIENT

MODULUS OF SUBGRADE MATERIAL

L-1. GENERAL. The objective of this test procedure is to determine a modulus value for subgrade soils by means of resilient triaxial techniques. The test is similar to a standard triaxial compression test, the primary exception being that the deviator stress is applied repetitively and at several stress levels. This procedure allows testing of soil specimens in a repetitive stress state similar to that encountered by a soil in a pavement under a moving wheel load.

L-2. DEFINITIONS. The following symbols and terms are used in the description of this procedure:

σ_1 = total axial stress

σ_3 = total radial stress; i.e., confining pressure in the triaxial test chamber

$\sigma_d = \sigma_1 - \sigma_3$ = deviator strain; i.e, the repeated axial stress in this procedure

ϵ_1 = total axial strain due to σ_d

ϵ_R = resilient or recoverable axial strain due to σ_d

ϵ_{R1} = resilient or recoverable axial strain due to σ_d in the direction perpendicular to ϵ_R

$M_R = \sigma_d/\epsilon_{Rl}$ = resilient modulus

$\theta = \sigma_1 + 2\sigma_3 = \sigma_d + 3\sigma_3$ = sum of the principal stresses in the triaxial state of stress

σ_1/σ_3 = principal stress ratio

Load duration = time interval over which the specimen is subject to a deviator stress

Cycle duration = time interval between successive applications of a deviator stress

L-3. SPECIMENS. Various diameter soil specimens may be used in this test with the specimen height at least twice the diameter. Undisturbed or laboratory molded specimens can be used. Methods for laboratory preparation of molded specimens and for backpressure saturation of specimens are given in the following paragraphs.

L-4. PREPARATION OF SPECIMENS. Specimens shall have an initial height of not less than 2.1 times the initial diameter, though the minimum initial height of a specimen must be 2.25 times the diameter if the soil contains particles retained on the No. 4 sieve. The maximum particle size permitted in any specimen shall be no greater than one-sixth of the specimen diameter. Triaxial specimens 35.5, 71, 102, 152, 305, and 381 millimeters (1.4, 2.8, 4, 6, 12, and 15 inches) in diameter are most commonly used.

a. Cohesive Soils Containing Negligible Amounts of Gravel. Specimens 35.5 millimeters (1.4 inches) in diameter are generally satisfactory for testing cohesive soils containing a negligible amount of gravel, while specimens of larger diameter may be advisable for undisturbed soils having marked stratification, fissures, or other discontinuities. Depending on the type of sample, specimens shall be prepared by either of the following procedures:

(1) Trimming Specimens of Cohesive Soil. A sample that is uniform in character and sufficient in amount to provide a minimum of three specimens is required. For undisturbed soils, samples about 127 millimeters (5 inches) in diameter are preferred for triaxial tests using 35.5-millimeter-(1.4-inch-) diameter specimens. Specimens shall be prepared in a humid room and tested as soon as possible thereafter to prevent evaporation of moisture. Extreme care shall be taken in preparing the specimens to preclude the least possible disturbance to the structure of the soil. The specimens shall be prepared as follows:

(a) Cut a section of suitable length from the sample. As a rule, the specimens should be cut with the long axes parallel to the long axis of the sample; any influence of stratification is commonly disregarded. However, comparative tests can be made, if necessary, to determine the effects of stratification. When a 127-millimeter- (5-inch-) diameter undisturbed sample is to be used for 35.5-millimeter- (1.4-inch-) diameter specimens, cut the sample axially into quadrants using a wire saw or other convenient cutting tool. Use three of the quadrants for specimens; seal the fourth quadrant in wax and preserve it for a possible check test.

(b) Carefully trim each specimen to the required diameter, using a trimming frame or similar equipment. Use one side of the trimming frame for preliminary cutting and the other side for final trimming. Ordinarily, the specimen is trimmed by pressing the wire saw or trimming knife against the edges of the frame and cutting from top to bottom. In trimming stiff or varved clays, move the wire saw from the top and bottom toward the middle of the specimen to prevent breaking off pieces at the ends. Remove any small shells or pebbles encountered during the trimming operations. Carefully fill voids on the surface of the specimen with remolded soil obtained from the trimming. Cut specimen to the required length (usually 76 to 89 millimeters (3 to 3-1/2 inches) for 35.5-millimeter- (1.4-inch-) diameter specimens and 152 to 178 millimeters (6 to 7 inches) for 71-millimeter- (2.8-inch-) diameter specimens) using a miter box.

(c) From the soil trimmings, obtain 200 grams of material for specific gravity and water content determination.

(d) Weigh the specimen to an accuracy of ± 0.01 gram for 35.5-millimeter- (1.4-inch-) diameter specimens and ± 0.1 grams for 71-millimeter- (2.8-inch-) diameter specimens.

(e) Measure the height and diameter of the specimen to an accuracy of ± 0.25 millimeters (0.01 inch). Specimen dimensions based on measurements of the trimming frame guides and miter box length are not sufficiently accurate. The average height H_o of the specimen should be determined from at least four measurements, while the average diameter should be determined from measurements at the top, center, and bottom of the specimen, as follows:

$$D_o = \frac{D_t + 2D_c + D_b}{4} \qquad \text{(L-1)}$$

where

D_o = average diameter

D_t = diameter at top

D_C = diameter at center

D_b = diameter at bottom

(2) Compacting Specimens of Cohesive Soil. Specimens of compacted soil may be trimmed, as described above, from samples formed in a compaction mold (a 102-millimeter- (4-inch-) diameter sample is satisfactory for 35.5-millimeter- (1.4-inch-) diameter specimens), though it is preferable to compact individual specimens in a split mold having inside dimensions equal to the dimensions of the desired specimen. The method of compacting the soil into the mold should duplicate as closely as possible the method that will be used in the field. In general, the standard impact type of compaction will not produce the same soil structure and stress-deformation characteristics as the kneading action of the field compaction equipment. Therefore, the soil should preferably be compacted into the mold (whether a specimen-size or a standard compaction mold) in at least six layers, using a pressing or kneading action of a tamper having an area in contact with the soil of less than one-sixth the area of the mold, and thoroughly scarifying the surface of each layer before placing the next. The sample shall be prepared, thoroughly mixed with sufficient water to produce the desired water content, and then stored in an airtight container for at least 16 hours. The desired density may be produced by either kneading or tamping each layer until accumulative weight of soil placed in the mold is compacted to a known volume, or adjusting the number of layers, the number of tamps per layer, and the force per tamp. For the latter method of control, special constant-force tampers (such as the Harvard miniature compactor for 35.5-millimeter- (1.4-inch-) diameter specimens or similar compactors for 71-millimeter- (2.8-inch-) diameter and larger specimens) are necessary. After each specimen compacted to finished dimensions has been removed from the mold, proceed in accordance with steps c through e of (1) above.

b. Cohesionless Soils Containing Negligible Amounts of Gravel. Soils which possess little or no cohesion are difficult if not impossible to trim into a specimen. If undisturbed samples of such materials are available in sampling tubes, satisfactory specimens can usually be obtained by freezing the sample to permit cutting out suitable specimens. Samples should be drained before freezing. The frozen specimens are placed in the triaxial chamber, allowed to thaw after application of the chamber pressure, and then tested as desired. Some slight disturbance probably occurs as a result of the freezing, but the natural stratification and structure of the material are retained. In most cases, however, it is permissible to test cohesionless soils in the remolded state by forming the specimen at the desired density or at a series of densities which will permit interpolation to the desired density. Specimens prepared in this manner should generally be 71 millimeters (8 inches) in diameter or larger, depending on the maximum particle size. The procedure for forming the test specimen shall consist of the following steps:

(1) Oven-dry and weigh an amount of material sufficient to provide somewhat more than the desired volume of specimen.

(2) Place the forming jacket, with the membrane inside, over the specimen base of the triaxial compression device.

(3) Evacuate the air between the membrane and the inside face of the forming jacket.

(4) After mixing the dried material to avoid segregation, place the specimen, by means of a funnel or special spoon, inside the forming jacket in equal layers. For 71-millimeter- (8-inch-) diameter specimens, 10 layers of equal thickness are adequate. Starting with the bottom layer, compact each layer by blows with a tamping hammer, increasing the number of blows per layer linearly with the height of the layer above the bottom layer. The total number of blows required for a specimen of a given material will depend on the density desired. Considerable experience is usually required to establish the proper procedure for compacting a material to a desired uniform density by this method. A specimen formed properly in the above-specified manner, when confined and axially loaded, will deform symmetrically with respect to its midheight, indicating that a uniform density has been obtained along the height of the specimens.

(5) As an alternate procedure, the entire specimen may be placed in a loose condition by means of a funnel or special spoon. The desired density may then be achieved by vibrating the specimen in the forming jacket to obtain a specimen of predetermined height and corresponding density. A specimen formed properly in this manner, when confined and axially loaded, will deform symmetrically with respect to its mid height.

(6) Subtract weight of unused material from original weight of the sample to obtain weight of material in the specimen.

(7) After the forming jacket is filled to the desired height, place the specimen cap on the top of the specimen, roll the ends of the membrane over the specimen cap and base, and fasten the ends with rubber bands or o-rings. Apply a low vacuum to the specimen through the base and remove the forming jacket.

(8) Measure height and diameter as specified in paragraph L-4.

c. Soils Containing Gravel. The size of specimens containing appreciable amounts of gravel is governed by the requirements of this paragraph. If the material to be tested is in an undisturbed state, the specimens shall be prepared according to the applicable requirements of a and b above, with the size of specimen based on an estimate of the largest particle size. In testing compacted soils, the largest particle size is usually known, and the entire sample should be tested, whenever possible, without removing any of the coarser particles. However, it may be necessary to remove the particles larger than a certain size to comply with the requirements for specimen size, though such practice will result in lower measured values of the shear strength and should be avoided if possible. Oversize particles should be removed and, if comprising more than 10 percent by weight of the sample, be replaced by an equal percentage by weight of material retained on the No. 4 sieve and passing the maximum allowable sieve size. The percentage of material finer than the No. 4 sieve thus remains constant. It will generally be necessary to prepare compacted samples of material containing gravel inside a forming jacket placed on the specimen base. If the material is cohesionless, it should be oven-dried and compacted in layers inside the membrane and forming jacket using the procedure in b above as a guide. When specimens of very high density are required, the samples should be compacted preferably by vibration to avoid rupturing the membrane. The use of two membranes will provide additional insurance against possible leakage during the test as a result of membrane rupture. If the sample contains a significant amount of fine-grained material, the soil usually must posses the proper water content before it can be compacted to the desired density. Then, a special split compaction mold is used for forming the specimen. The inside dimensions of the mold are equal to the dimensions of the triaxial specimen desired. No membrane is used inside the mold, as the membrane can be readily placed over the compacted specimen after it is removed from the split mold. The specimen should be compacted to the desired density in accordance with paragraph L-4.

L-5. Q TEST WITH BACK-PRESSURE SATURATION.

a. Equipment Setup. For the Q test with back-pressure saturation, the apparatus should be set up similar to that shown in Figure L-1. Filter strips should not be used and as little volume changes as possible should be permitted during the test. Complete the steps outlined in paragraph L-4 and the following steps:

(1) Record all identifying information for the sample project number or name, boring number, and other pertinent data on a sheet.

(2) Place one of the prepared specimens on the base.

(3) Place a rubber membrane in the membrane stretcher, turn both ends of the membrane over the ends of the stretcher, and apply a vacuum to the stretcher. Carefully lower the stretcher and membrane over the specimen. Place the specimen cap on the top of the specimen and release the vacuum on the membrane stretcher. Turn the ends of the membrane down around the base and up around the specimen cap and fasten the ends with o-rings or rubber bands. With a 35.5-millimeter- (1.4-inch-) diameter specimen of relatively insensitive soils, it is easier to roll the membrane over the specimen.

(4) Assemble the triaxial chamber and place it in position in the loading device. Connect the tube from the pressure reservoir to the base of the triaxial chamber. With valve C on the pressure reservoir closed and valves A and B open, increase the pressure inside the reservoir and allow the pressure fluid to fill the triaxial chamber. Allow a few drops of the pressure fluid to escape through the vent valve (valve B) to ensure complete filling of the chamber with fluid. Close valve A and the vent valve.

b. Back-Pressure Procedure. Then apply a 0.02-MPa (3-psi) chamber pressure to the specimen with all drainage valves closed. Allow a minimum of 30 minutes for stabilization of the specimen pore water pressure, measure the change of deformation ΔH, and begin back-pressure procedures as follows:

(1) Estimate the magnitude of the required back pressure by theoretical relations. Specimens should be completely saturated before any appreciable consolidation is permitted for ease and uniformity of saturation as well as to allow volume changes during consolidation to be measured with the burette; therefore, the difference between the chamber pressure and the back pressure should not exceed 0.034 MPa (5 psi) during the saturation phase. To ensure that a specimen is not prestressed during the saturation phase, the back pressure must be applied in small increments, with adequate time between increments to permit equalization of pore water pressure throughout the specimen.

(2) With all valves closed, adjust the pressure regulators to a chamber pressure of about 0.048 MPa (7 psi) and a back pressure of about 0.013 MPa (2 psi). Record these pressures on a data sheet. Next, open valve A to apply the back pressure through the specimen cap. Immediately, open valve G and read and record the pore pressure at the specimen base. When the measured pore pressure becomes essentially constant, close valves F and G and record the burette

reading. (If an electrical pressure transducer is used to measure the pore pressure, valve G may be safely left open during the entire saturation procedure).

(3) Using the technique described above, increase the chamber pressure and the back pressure in increments, maintaining the back pressure at about 0.034 MPa (5 psi) less than the chamber pressure. The size of each increment might be 0.034, 0.069, or even 0.138 MPa (5, 10, or even 20 psi) depending on the compressibility of the soil specimen and the magnitude of the desired consolidation pressure. Open valve G and measure the pore pressure at the base immediately upon application of each increment of back pressure and observe the pore pressure until it becomes essentially constant. The time required for stabilization of the pore pressure may range from a few minutes to several hours depending on the permeability of the soil. Continue adding increments of chamber pressure and back pressure until, under any increment, the pore pressure reading equals the applied back pressure immediately upon opening valve G.

(4) Verify the completeness of saturation by closing valve F and increasing the chamber pressure by about 0.034 MPa (5 psi). The specimen shall not be considered completely saturated unless the increase in pore pressure immediately equals the increase in chamber pressure.

c. Chamber Pressure. After verification of saturation, and remeasurement of ΔH, close all drainage lines leading to the back pressure and pore water measurement apparatus. Holding the maximum applied back pressure constant, increase the chamber pressure until the difference between the chamber pressure and the back pressure equals the desired effective confining pressure as follows. With valves A and C closed, adjust the pressure regulator to preset the desired chamber pressure. The range of chamber pressures for the three specimens will depend on the loadings expected in the field. The maximum confining pressure should be at least equal to the maximum normal load expected in the field so that the shear strength data need not be extrapolated for use in design analysis. Record the chamber pressure on data sheets. Now open valve A and apply the preset pressure to the chamber. Application of the chamber pressure will force the piston upward into contact with the ram of the loading device. This upward force is equal to the chamber pressure acting on the cross-sectional area of the piston minus the weight of the piston minus piston friction.

d. Operation.

(1) Start the test with the piston approximately 2.5 millimeters (0.1 inch) above the specimen cap. This allows compensation for the effects of piston friction, exclusive of that which may later develop as a result of lateral forces. Set the load indicator to zero when the piston comes into contact with the specimen cap. In this manner, the upward thrust of the chamber pressure on the piston is also eliminated from further consideration. Contact of the piston with the specimen cap is indicated by a slight movement of the load indicator. Set the strain indicator and record on the data sheet the initial dial reading at contact. Axially strain the specimen at a rate of about 1 percent per minute for plastic materials or about 0.3 percent per minute for brittle materials that achieve maximum deviator stress at about 3 to 6 percent strain; at these rates, the elapsed time to reach maximum deviator stress would be about 15 to 20 minutes.

(2) Observe and record the resulting load at every 0.3 percent strain for about the first 3 percent and, thereafter, at every 1 percent or, for large strains, at every 2 percent strain; sufficient readings should be taken to completely define the shape of the stress-strain curve so frequent readings may be necessary as failure is approached. Continue the test until an axial strain of 15 percent has been reached; however, when the deviator stress decreases after attaining a

maximum value and is continuing to decrease at 15 percent strain, the test shall be continued to 20 percent.

(3) For brittle soils (i.e., those in which maximum deviator stress is reached at 6 percent axial strain or less), tests should be performed at rates of strain sufficient to produce times to failure as set forth above; however, when the maximum deviator stress has been clearly defined, the rate may be increased such that the remainder of the test is completed in the same length of time as that taken to reach maximum deviator stress. However, for each group of tests about 20 percent of the samples should be tested at the rates set forth above.

(4) Upon completion of axial loading, release the chamber pressure by shutting off the air supply with the regulator and opening valve C. Open valve B and draw the pressure fluid back into the pressure reservoir by applying a low vacuum at valve C. Dismantle the triaxial chamber. Make a sketch of the specimen, showing the mode of failure.

(5) Remove the membrane from the specimen. For 35.5-millimeter- (1.4-inch-) diameter specimens, carefully blot any excess moisture from the surface of the specimen and determine the water content of the whole specimen. For 71-millimeter- (2.8-inch-) diameter or larger specimens, it is permissible to use a representative portion of the specimen for the water content determination. It is essential that the final water content be determined accurately, and weighings should be verified, preferably by a different technician.

(6) Repeat the test on the two remaining specimens at different chamber pressures, though using the same rate of strain.

L-6. EQUIPMENT.

a. Triaxial Test Cell.

(1) A triaxial cell suitable for use in resilience testing of soils is shown in Figure L-2. This equipment is similar to most standard cells, except that it is somewhat larger so that it can facilitate the internally mounted load and deformation measuring equipment and the equipment has additional outlets for the electrical leads from the measuring devices. For the type of equipment shown, air or nitrogen is used as the cell fluid.

(2) The external loading source may be any device capable of providing a variable load of fixed cycle and load duration, ranging from a simple cam-and-switch control of static weights or air pistons to a closed-loop electrohydraulic system. A load duration of 0.2 seconds and a cycle duration of 3 seconds have been satisfactory for most applications. A square-wave load form is recommended.

b. Deformation-Measuring Equipment.

(1) The deformation-measuring equipment consists of LVDTs attached to the soil specimen by a pair of clamps. Two LVDTs are used for the measurement of axial deformation. The clamps and LVDTs are shown in position on a soil specimen in Figure L-2. Details of the clamps are shown in Figure L-3. Load is measured by placing a load cell between the specimen cap and the loading piston as shown in Figure L-2.

(2) Use of the type of measuring equipment described above offers several advantages:

(a) It is not necessary to reference deformations to the equipment, which deforms during loading.

(b) The effect of end-cap restrain on soil response is virtually eliminated.

(c) Any effects of piston friction are eliminated by measuring loads inside the triaxial cell.

(3) In addition to the measuring devices it is also necessary to maintain suitable recording equipment. Simultaneous recording of load and deformation is desirable. The number of recording channels can be reduced by wiring the leads from the LVDTs so that only the average signal from each pair is recorded. The introduction of switching and balancing units permits use of a single-chamber recorder.

c. Additional Equipment. In addition to the equipment described above, the following items are also used:

(1) A 9- to 27-metric ton- (10- to 30-short ton-) capacity loading machine.

(2) Calipers, a micrometer gauge, and a steel rule (calibrated to 0.25 millimeter (0.01 inch)).

(3) Rubber membranes, 0.25 to 0.635 millimeter (0.01 to 0.025 inch) thick.

(4) Rubber O-rings.

(5) A vacuum source with a bubble chamber and regulator.

(6) A back-pressure chamber with pressure transducers.

(7) A membrane stretcher.

(8) Porous stones.

L-7. PREPARATION OF SPECIMENS AND PLACEMENT IN TRIAXIAL CELL. The following steps should be followed in preparing and placing specimens:

a. In accordance with procedures specified in paragraph L-5, prepare the specimen and place it on the baseplate complete with porous stones, cap, and base and equipped with a rubber membrane secured with o-rings. Check for leakage. If back-pressure saturation is anticipated for cohesive soils, procedures indicated in paragraph L-5a should be followed. For purely noncohesive soils, it will be necessary to maintain the vacuum during placement of the LVDTs. The specimen is now ready to receive the LVDTs.

b. Extend the lower LVDT clamp and slide it carefully down over the specimen to approximately the lower third point of the specimen.

c. Repeat this step for the upper clamp, placing it at the upper third point. Ensure that both clamps lie in horizontal planes.

d. Connect the LVDTs to the recording unit, and balance the recording bridges. This step will require recorder adjustments and adjustment of the LVDT stems. When a recording bridge balance has been obtained, determine (to the nearest 0.25 millimeter (0.01 inch)) the vertical spacing between the LVDT clamps and record this value.

e. Place the triaxial chamber in position. Set the load cell in place on the specimen.

f. Place the cover plate on the chamber. Insert the loading piston and obtain a firm connection with the load cell.

g. Tighten the tie rods firmly.

h. Slide the assembled apparatus into position under the axial loading device. Bring the loading device to a position in which it nearly contacts the loading piston.

I. If the specimen is to be back-pressure saturated, proceed in accordance with paragraph L-5.

j. After saturation has been completed, rebalance the recorder bridge to the load cell and LVDTs.

L-8. RESILIENCE TESTING OF COHESIVE SOILS.

a. General. The resilient properties of cohesive soils are only slightly affected by the magnitude of the confining pressure σ_3. For most applications, this effect can be disregarded. When back-pressure saturation is not used, the confining pressure used should approximate the expected in situ horizontal stresses. These will generally be on the order of 0.0069 to 0.034 MPa (1 to 5 psi). A chamber pressure of 0.021 MPa (3 psi) is a reasonable value for most testing. If back-pressure saturation is used, the chamber pressure will depend on the required saturation pressure.

b. Resilient Properties. Resilient properties are highly dependent on the magnitude of the deviator stress σ_d. It is therefore necessary to conduct the tests for a range in deviator stress values. The following procedure should be followed:

(1) If back-pressure saturation is not used, connect the chamber pressure supply line and apply the confining pressure (equal to the chamber pressure). If back-pressure saturation is used, the chamber pressure will already have been established.

(2) Rebalance the recording bridges for the LVDTs and balance the load cell recording bridge.

(3) Begin the test by applying 500 to 1,000 repetitions of a deviator stress of not more than one-half the unconfined compressive strength.

(4) Decrease the deviator load to the lowest value to be used. Apply 200 repetitions of load, recording the recovered vertical deformation at or near the last repetition.

(5) Increase the deviator load, recording deformations as in step 4. Repeat over the range of deviator stresses to be used.

(6) At the completion of the loading, reduce the chamber pressure to zero. Remove the chamber LVDTs and load cell. Use the entire specimen for the purpose of determining the moisture content.

c. The results of the resilience tests can be presented in the form of a summary table, such as Table L-1, and graphically as is shown in Figure L-4 for the resilient modulus.

L-9. RESILIENCE TESTING OF COHESIONLESS SOILS.

a. General. The resilient modulus of cohesionless soils M_R is dependent upon the magnitude of the confining pressure σ_3 and is nearly independent of the magnitude of the repeated axial stress. Therefore, it is necessary to test cohesionless materials over a range of confining and axial stresses. (The confining pressure is equal to the chamber pressure less the back pressure for saturated specimens). The following procedure should be used for this type of test:

(1) Use confining pressures of 0.034, 0.069, 0.103, and 0.138 MPa (5, 10, 15, and 20 psi) at each confining pressure, and test at five values of the principal stress difference corresponding to multiples (1, 2, 3, 4) of the cell pressure.

(2) Before beginning to record deformations, apply a series of conditioning stresses to the material to eliminate initial loading effects. The greatest amount of volume change occurs during the application of the conditioning stresses. Simulation of field conditions suggest that drainage of saturated specimens should be permitted during the application of these loads but that the test loading (beginning in step 6 below) should be conducted in an undrained state.

(3) Set the axial load generator to apply a deviator stress of 0.069 MPa (10 psi) (i.e., a stress ratio equal to 3). Activate the load generator and apply 200 repetitions of this load. Stop the loading.

(4) Set the axial load generator to apply a deviator stress of 0.138 MPa (20 psi) (i.e., a stress ratio equal to 5). Activate the load generator and apply 200 repetitions of this load. Stop the loading.

(5) Repeat as in step 4 above maintaining a stress ratio equal to 6 and using the following order and magnitude of confining pressures: 0.069, 0.138, 0.069, 0.034, 0.021, and 0.0069 MPa (10, 20, 10, 5, 3, and 1 psi).

(6) Begin the record test using a confining pressure of 0.0069 MPA (1 psi) and an equal value of deviator stress. Record the resilient deformation after 200 repetitions. Increase the deviator stress to twice the confining pressure and record the resilient deformation after 200 repetitions. Repeat until a deviator stress of four times the confining pressure is reached (stress ratio of 5).

(7) Repeat as in step 6 above for each value of confining pressure.

(8) When the test is completed, decrease the back pressure to zero, reduce the chamber pressure to zero, and dismantle the cell. Remove the LVDT clamps, etc. Remove the soil specimen, and use the entire amount of soil to determine the moisture content.

b. Calculations. Calculations can be performed using a similar tabular arrangement as was shown in Table L-1. Test results should be presented in the form of a plot of log M_R versus log of the sum of the principal stresses as shown in Figure L-5.

L-10. INTERPRETATION OF TEST RESULTS.

a. Cohesive Soils. As previously indicated, test results for cohesive soils are presented in the form of a plot of resilient modulus M_R versus deviator stress σ_d. Normally for cohesive soils, the test results will indicate that the resilient modulus decreases rapidly with increases in deviator stress. Thus, selection of a resilient modulus from the laboratory tests results requires an estimate of the deviator stress at the top of the subgrade with respect to the design aircraft. For a properly designed pavement, the deviator stress at the top of the subgrade will primarily be a function of the subgrade modulus and the design traffic level. Shown in Figure L-6 are relationships between deviator stress at the top of the subgrade and applicable subgrade modulus values determined from an analysis of the pavement sections. The relationships shown in Figure L-6 were determined using a layered elastic pavement model with the modulus values as input parameters and the deviator stress values as computed responses. Thus, these relationships are essentially limiting criteria. Relationships are shown for 1,000, 10,000, 100,000, and 1,000,000 repetitions of strain. To determine the appropriate modulus value to use in the performance model, the test results from the resilient modulus tests on the laboratory specimens are superimposed on the appropriate relationship from Figure L-6, and the design modulus value is taken from the intersection of the plotted functions.

b. Example on Cohesive Soils. Assume a design problem involving 100,000 repetitions of strain. Figure L-7 shows a plot of relationships taken from Figure L-6 superimposed on test results from a laboratory resilient modulus test. For this particular design, a subgrade modulus value of 62 MPa (9,000 psi) would be used.

c. Cohesionless Soils. For cohesionless soils, laboratory test results are presented in the form of a plot of resilient modulus versus the first stress invariant, i.e., sum of the principal stress θ. For cohesionless soils, this relationship is generally linear in form on a log-log plot, with the resilient modulus being directly proportional to the sum of the principal stresses. Selection of a specific resilient modulus value for use in the design model requires an estimate of the sum of the principal stresses at the top of the subgrade. Since a cohesionless material is involved, the influence of both applied stresses and estimated overburden stresses from the pavement structure must be considered. In Figure L-8, a relationship is shown between the pavement thickness and the sum of the principal stresses at the top of the subgrade due to overburden. In Figure L-9, relationships are shown between the subgrade modulus and limiting values of the sum of the principal stresses due to applied force. For each figure, relationships are shown for 1,000, 10,000, 100,000, and 1,000,000 repetitions of stress. Using the value of the estimated pavement thickness, that part of the total sum of the principal stresses due to overburden can be obtained from Figure L-8. The applicable relationship from Figure L-9 is then selected and adjusted to include the influence of overburden by increasing all values of the principal stress sum by the value obtained from Figure L-8. Thus, a new limiting relationship is obtained and replotted. The results of the laboratory modulus test are superimposed on the plot, and the design subgrade modulus values are taken at the intersection of these relationships.

d. Example on Cohesionless Soils. Assume a design problem involving a pavement having an estimated initial thickness of 762 millimeters (30 inches). The design aircraft has a dual-wheel main gear assembly, and the design life is for 100,000 repetitions of strain. From Figure L-8, the value of the sum of the principal stresses due to overburden is 0.045 MPa (6.5 psi). Using the 100,000 strain repetition curve from Figure L-9, the value obtained from Figure L-8 is added to all values of the sum of the principal stresses indicated in the relationship and the adjusted curve is replotted (Figure L-10). The result of adjusting the original relationship is to shift it to the right of its original position. In Figure G-10, the results of laboratory resilient modulus tests on specimens of the subgrade soil are also shown. From the intersection of these two relationships, a design modulus M_R of 103 MPa (15,000 psi) is determined.

e. Special Considerations. In some situations, the laboratory curve may not converge with the limiting stress-modulus relationship within the range of values indicated. Obviously, two possibilities are involved in this situation: the laboratory relationships could plot above or below the limiting criteria curve. In the former case, since all values of the sum of the principal stresses indicated by the laboratory curve would exceed the stress criteria within the region under consideration, the value of 207 MPa (30,000 psi) should be used for the subgrade modulus. In the latter case, the initial design thickness value should be increased and the limiting criteria curve readjusted until convergence with the laboratory relationships is obtained.

APPENDIX M

PROCEDURES FOR DETERMINING THE FATIGUE LIFE OF BITUMINOUS CONCRETE

M-1. LABORATORY TEST METHOD.

a. General. A laboratory procedure for determining the fatigue life of bituminous concrete paving mixtures containing aggregate with maximum sizes up to 31.8 millimeters (1-1/2 inches) is described in this chapter. The fatigue life of a simply supported beam specimen subjected to third-point loading applied during controlled stress-mode flexural fatigue tests is determined.

b. Definitions. The following symbols are used in the description of this procedure:

(1) ϵ = initial extreme fiber strain (tensile and compressive, inches per inch)

(2) N_f = fatigue life of the specimen, number of load repetitions to fracture.

Extreme fiber strain of simply supported beam specimens subjected to third-point loadings, which produces uniaxial bending stresses, is calculated from

$$\epsilon = \frac{12td}{(3L^2 - 4a^2)} \qquad \text{(M-1)}$$

where

t = specimen depth, millimeters (inches)

d = dynamic deflection of beam center, millimeters (inches)

L = reaction span length, millimeters (inches)

a = L/3, millimeters (inches)

c. Test Equipment.

(1) The repeated flexure apparatus is shown in Figure M-1. It accommodates beam specimens 381 millimeters (15 inches) long with widths and depths not exceeding 76 millimeters (3 inches). A 1,361-kilogram- (3,000-pound-) capacity electrohydraulic testing machine capable of applying repeated tension-compression loads in the form of haversine waves for 0.1-second durations with 0.4-second rest periods is used for flexural fatigue tests. Any dynamic testing machine or pneumatic pressure system with similar loading capabilities is also suitable. Third-point loading, i.e., loads applied at distances of L/3 from the reaction points, produces an approximately constant bending moment over the center 102 millimeters (4 inches) of a 381-millimeter- (15-inch-) long beam specimen with widths and depths not exceeding 76 millimeters (3 inches). A sufficient load, approximately 10 percent of the load deflecting the beam upward, is applied in the opposite

direction, forcing the beam to return to its original horizontal position and holding it at that position during the rest period. Adjustable stop nuts installed on the flexure apparatus loading rod prevent the beam from bending below the initial horizontal position during the rest period.

(2) The dynamic deflection of the beam's center is measured with an LVDT. An LVDT suitable for this purpose is the Sheavitz type 100 M-L. The LVDT core is attached to a nut bonded with epoxy cement to the center of the specimen. Outputs of the LVDT and the electrohydraulic testing machine's load cell, through which loads are applied and controlled, can be fed to any suitable recorder. The repeated flexure apparatus is enclosed in a controlled-temperature cabinet capable of controlling temperatures within ±0.28 degrees Celsius (±½ degree Fahrenheit). A Missimer's model 100 by 500 carbon dioxide plug-in temperature conditioner has been found to provide suitable temperature control.

d. Specimen Preparation. Beam specimens 380 millimeters (15 inches) long with 59-millimeter (3-1/2-inch) depths and 83 millimeter (3-1/4-inch) widths are prepared according to ASTM D 3202. If there is undue movement of the mixture under the compactor foot during beam compaction, the temperature, foot pressure, and number of tamping blows should be reduced. Similar modifications to compaction procedures should be made if specimens with less density are desired. A diamond-blade masonry saw is used to cut 76-millimeter (3-inch) or slightly less deep by 76 millimeters (3-inch) or slightly less wide test specimens from the 380-millimeter- (15-inch-) long beams. Specimens with suitable dimensions can also be cut from pavement samples. The widths and depths of the specimens are measured to the nearest 0.25 millimeter (0.01 inch) at the center and at 51 millimeters (2 inches) from both sides of the center. Mean values are determined and used for subsequent calculations.

e. Test Procedures.

(1) Repeated flexure apparatus loading clamps are adjusted to the same level as the reaction clamps. The specimen is clamped in the fixture using a jig to position the centers of the two loading clamps 51 millimeters (2 inches) from the beam center and to position the centers of the two reactions clamps 165 millimeters (6-1/2 inches) from the beam center. Double layers of Teflon sheets are placed between the specimen and the loading clamps to reduce friction and longitudinal restraint caused by the clamps.

(2) After the beam has reached the desired test temperature, repeated loads are applied. Duration of a load repetition is 0.1 second with 0.4-second rest periods between loads. The applied load should be that which produces an extreme fiber stress level suitable for flexural fatigue tests. For fatigue tests on typical bituminous concrete paving mixtures, the following ranges of extreme fiber stress levels are suggested:

Temperatures, degrees Celsius (degrees Fahrenheit)	**Stress Level Range MPa (psi)**
13 (55)	1.03 to 3.1 (150 to 450)
21 (70)	0.52 to 2.1 (75 to 300)
30 (85)	0.24 to 1.38 (35 to 200)

The beam center point deflection and applied dynamic load are measured immediately after 200 load repetitions for calculation of extreme fiber strain ϵ. The test is continued at the constant stress level until the specimen fractures. The apparatus and procedures described have been found suitable for flexural fatigue tests at temperatures ranging from 4.4 to 38 degrees Celsius (40 to 100 degrees Fahrenheit) and for extreme fiber stress levels up to 3.1 MPa (450 psi). Extreme fiber stress levels for flexural fatigue tests at any temperature should not exceed that which causes specimen fracture before at least 1,000 load repetitions are applied.

(3) A set of 8 to 12 fatigue tests should be run for each temperature to adequately describe the relationship between extreme fiber strain and the number of load repetitions to fracture. The extreme fiber stress should be varied such that the resulting number of load repetitions to fracture ranges from 1,000 to 1,000,000.

f. Report and Presentation of Results. The report of flexural fatigue test results should include the following:

(1) Density of test specimens.

(2) Number of load repetitions to fracture, N_f.

(3) Specimen temperature.

(4) Extreme fiber stress, σ.

The flexural fatigue relationship is plotted in Figure M-2.

M-2. PROVISIONAL FATIGUE DATA FOR BITUMINOUS CONCRETE. Use of the graph shown in Figure M-3 to determine a limiting strain value for bituminous concrete involves first determining a value for the elastic modulus of the bituminous concrete. Using this value and the design pavement service life in terms of load repetitions the limiting tensile strain in the bituminous concrete can be read from the ordinate of the graph.

APPENDIX N

PROCEDURE FOR DETERMINING THE RESILIENT MODULUS

OF GRANULAR BASE MATERIAL

N-1. PROCEDURE. This procedure is designed to determine resilient properties of granular base (subbase) materials. The test is similar to a standard triaxial compression test, the primary exception being that the deviator stress is applied repetitively at several stress levels. The procedure allows testing under a repetitive stress state similar to that encountered in a base (subbase) course layer in a pavement under a moving wheel load.

N-2. DEFINITIONS. The following symbols and terms are used in the description of this procedure:

a. σ_1 = total axial stress.

b. σ_3 = total radial stress, i.e., confining pressure in the triaxial test.

c. σ_d = deviator stress (σ_1 - σ_3), i.e., the repeated axial stress in this procedure.

d. ϵ_1 = total axial strain due to σ_d.

e. ϵ_R = resilient axial strain due to σ_d.

f. ϵ_ℓ = resilient lateral strain due to σ_d.

g. M_R = the resilient modulus = σ_d/ϵ_R.

h. v_R = the resilient Poisson's ratio = ϵ_ℓ/ϵ_R.

i θ = sum of the principal stresses in the triaxial state of stress ($\sigma_1 + 2\sigma_3 = \sigma_d + 3\sigma_3$).

j. σ_1/σ_3 = principal stress ratio.

k. Load duration = time interval during which the sample is subjected to a stress deviator.

l. Cycle duration = time interval between successive applications of the deviator stress.

N-3. SPECIMENS. For base-course materials, 152-millimeter- (6-inch-) diameter specimens are generally required with the maximum particle size being limited to 25 millimeters (1 inch). The specimen height should be at least twice the diameter.

N-4. EQUIPMENT.

a. Triaxial Test Cell. The triaxial cell shown schematically in Figure N-1 is suitable for use in resilient testing of soils. The equipment is similar to most standard cells. However, there are a few specialized criteria that must be met to provide acceptable test results. Generally, the equipment is slightly larger than most standard cells to accommodate the 152-millimeter- (6-inch-) diameter specimens and the internally mounted load and deformation measuring equipment.

Additional outlets for the electrical leads from these measuring devices are required. Cell pressures of 80 psi are generally sufficient to duplicate the maximum confining pressures under aircraft loadings. Compressed air is generally used as the confining fluid to avoid detrimental effects of water on the internally mounted electronic measuring equipment.

b. End Platens. End platens should be "frictionless," as "barreling" caused by end restraint jeopardizes resilient Poisson's ratio values by causing lateral deformations to be concentrated in the middle of the specimen. Furthermore, nonuniform displacements can create problems with axial strain measurements due to realignment of the LVDT clamps. Whereas "frictionless" platens (Figure N-2) may not be entirely frictionless under short-term repetitive loadings, they constitute an improvement over conventional end platens. The essential features of "frictionless" end platens are hard polished end plates, coated by high-vacuum silicone grease, and covered by a thin rubber sheet. If externally mounted axial deformation measuring devices such as an LVDT or potentiometer mounted on the loading piston, or devices measuring the total specimen displacements are used, the use of frictionless caps and bases with grease invalidates any measurements. In this case, the deformation due to the grease and rubber sheet or Teflon probably exceeds the actual deformation of the specimen. Hence, frictionless caps and bases are restricted to use with internally mounted deformation sensors.

c. Repetitive Loading Equipment. The external loading source may be any device capable of providing a variable load of fixed cycle and load duration, ranging from simple switch control of static weights or air pistons to a close-loop electrohydraulic system. A load duration of 0.1 to 0.2 second and a cycle duration of 3 seconds have been found satisfactory for most applications. A haversine wave form is recommended; however, a rectangular wave form can be used.

d. Deformation and Load Measuring Equipment. The deformation measuring equipment consists of four LVDTs attached to the soil specimen with a pair of clamps, as shown in Figure N-1. Two LVDTs are used to measure axial deformations, and two are used to measure lateral deformations. Figures N-3 and N-4 show the details of the clamps for attaching the LVDTs to the soil specimens. Only alternating current transducers that have a minimum sensitivity of 0.2 millivolt per 0.025 millimeter (0.001 inch) per volt should be used. Load is measured with an internally mounted load cell that is sufficiently lightweight so as not to provide any significant inertia forces. It should have a capacity no greater than two to three times that of the maximum applied load and a minimum sensitivity of 2 millivolts per volt.

e. Additional Equipment. In addition to the equipment described above, the following items are also used:

(1) Calipers, a micrometer gauge, and a steel rule (calibrated to 0.25 millimeter (0.01 inch)).

(2) Rubber membranes (0.03 to 0.06 millimeter (0.012 to 0.025 inch) thick) and a membrane stretcher.

(3) Rubber O-rings.

(4) Guide rods for positioning LVDT clamps.

(5) Epoxy for cementing clamps to membrane.

(6) A vacuum source with a bubble chamber (optional) and regulator.

(7) Specimen forming jacket.

f. Recommendations. It is also necessary to have a fast recording system for accurate testing. It is recommended, for analog recording equipment, that the resolution of the parameter being controlled be better than 1.5 percent of the maximum value of the parameter being measured and that any variable amplitude signals be changed from high to low resolution as required during the test. If multichannel recorders are not available, by introducing switching and balancing units, a single-channel recorder can be used.

N-5. PREPARATION OF SPECIMENS AND PLACEMENT IN TRIAXIAL CELL. The following procedures describe a step-by-step account for preparing remolded specimens. Generally, for base-course materials, 152-millimeter- (6-inch-) diameter specimens are required with the maximum particle size being limited to 25 millimeters (1 inch) in diameter.

a. Material Preparation. The material should be air-dried and subsequently sufficient water added to bring the material to the desired compaction water content (usually field condition). Sealing the material in a container for 24 hours prior to compaction will allow the moisture to equilibrate. For well-graded materials, it may be necessary to break the material down into several sieve sizes and recombine for each layer to prevent serious segregation of material in the specimen. If the compaction effort required to duplicate the desired testing water content and density is not known, sufficient material for several specimens may have to be prepared. The compaction effort required will then be established on a trial-and-error basis.

b. Specimen Compaction. Generally, base-course materials are compacted on the triaxial cell baseplate using a split mold. If the particles are angular, two membranes may be required: one used during compaction and the second placed after compaction to seal any holes punctured in the membrane. A successful procedure has been to use a Teflon-lined mold and a thin sheet of wrapping paper instead of a membrane. Often the density is sufficiently high and the water content such that effective cohesion will permit a free-standing specimen to be prepared. In this case, the wrapping paper is carefully removed and a membrane substituted. In most cases, impact or kneading compaction is used. Vibratory compaction is only permitted on uniform materials where segregation is not a problem. The specimens should be compacted in layers, the height of which exceeds the maximum particle size.

(1) It may be necessary to place a thin layer of fine sand in the bottom layer to provide a smooth bearing surface. Likewise, after compacting and trimming the topmost layer (it may be necessary to remove large particles from this layer), fine sand can be sieved on the surface to fill in the voids and provide a smooth bearing surface for the top cap.

(2) The top cap should be centered and lightly tapped to level and ensure a good smooth contact of the cap on the specimen. A level placed on top of the cap is used to check leveling. The forming mold is then removed, the membrane placed using a membrane stretcher and sealed with O-rings or a hose clamp, and a vacuum applied. Leakage should be checked by using a bubble chamber or closing the vacuum line and observing if a vacuum is maintained in the specimen. Specimen dimensions should be measured to determine density conditions. A π-tape has been found most useful for diametrical measurements.

c. Placement of LVDT Measurement Clamps.

(1) Measure the diameter as accurately as possible at the location of the LVDT clamps for calculation of radial strains. Place the lower LVDT clamp in the specimen at approximately the lower third point of the specimen. A “jig” or gauge rods have been used successfully to assist in placing the clamps. The lower LVDT clamp generally holds the LVDT body. Repeat the procedure for the upper clamp being careful to align the clamps so that the LVDT core matches the LVDT body. It is essential that the clamps lie in a horizontal plane and their spacing be precisely known for calculating the axial strain. Again, gauge rods or a “jig” in conjunction with a small level have been used successfully for this operation. With the clamps in a position and secured by the springs, a small amount of epoxy (a “5-minute” epoxy has been used; rubber cement was found unacceptable) is placed on top of the four contact points and allowed to dry.

(2) Install the LVDTs and connect the recording unit. Generally, ±0.10-millimeter (0.040-inch) LVDTs are used for radial deformation, and ± 0.25-millimeter (0.100-inch) LVDTs are used for axial deformations. Balance the vertical spacing between LVDT clamps or check gauge rods for secure contact, and record LVDT readings and spacing. Remove gauge rods and assemble triaxial chamber. Any shifting of LVDT clamps during chamber assembly will be noted by LVDT reading changes and can be accounted for.

d. Resilient Testing. The resilient properties of granular materials are dependent primarily upon confining pressure and to a lesser extent upon cyclic deviator stress. Therefore, it is necessary to conduct the tests for a range of confining pressures and deviator stress values. Generally, chamber pressure values of 0.014, 0.027, 0.041, and 0.069 MPa (2, 4, 6, and 10 psi) are suitable. Ratios of σ_1/σ_3 of 2, 3, 4, and 5 are typically used for the cyclic deviator stress. Tests should be conducted in an undrained condition with excess pressures relieved after application of each stress state. The testing procedure is as follows:

(1) Balance the recorders and recording bridges and record calibration steps.

(2) Apply about 0.014 MPa (2 psi) axial load σ_d as a seating load simulating the weight of the pavement and ensuring contact is maintained between the loading piston and top cap during testing.

(3) Condition the specimen by applying 500 to 1,000 load repetitions with drainage lines open. This conditioning stress should be the maximum stress expected to be applied to the specimen in the field by traffic. If this is unknown, a chamber pressure of 0.034 to 0.069 MPa (5 to 10 psi) and a deviator stress (σ_1 - σ_3) twice the chamber pressure can be used.

(4) Decrease the chamber pressure to the lowest value to be used. Apply 200 load repetitions of the smallest deviator stress under undrained conditions, recording the resilient deformations and load at or near the 200th repetition. After 200 load repetitions, relieve any pore pressures, increase the deviator stress to the next highest value, and repeat procedure over the range of deviator stresses to be used.

(5) After completing the stress states for the initial confining pressure, repeat for each succeedingly higher chamber pressure.

(6) After completion of the loading, remove the axial load, apply a vacuum to the specimen, release the confining pressure, and disassemble the triaxial chamber.

(7) Check the calibration of the LVDTs and load cell.

(8) Dry the entire specimen for determination of the water content.

N-6. COMPUTATIONS AND PRESENTATION OF RESULTS.

a. Computation. The computations consist of the following:

(1) From the measured dimensions and weights, compute and record the initial dry density, degree of saturation, and water content.

(2) The resilient modulus is computed and recorded for each stress state using the following formulas:

(a) Resilient axial strain $\epsilon_R = \Delta H_r/H_i$.

(b) Resilient lateral strain $\epsilon_L = \Delta D_r/D_i$.

(c) Deviator stress $\sigma_d = \Delta P/A_O$.

(d) Resilient modulus $M_R = \sigma_d/\epsilon_R$.

(e) Resilient Poisson's ratio $v_R = \epsilon_L/\epsilon_R$.

where

ΔH_r = resilient change in gauge height (distance between LVDT clamps) after specified number of load repetitions.

H_i = instantaneous gauge height after specified number of load repetitions. Can be calculated from $H_O - \Delta H$. If ΔH is small, H_o can be used.

H_O = initial gauge height or distance between LVDTs less adjustment occurring during triaxial chamber assembly.

ΔH = permanent change in gauge height.

ΔP = change in axial load, maximum axial load minus surcharge load.

A_O = original cross-sectional area of specimen.

ΔD_r = resilient change in diameter after specified number of load repetitions.

D_i = instantaneous diameter after specified number of load repetitions. Can be calculated from $D_O + \Delta D$.

D_o = initial specimen diameter.

ΔD = permanent change in specimen diameter.

b. Presentation of Results. Test results should be presented in the form of plots of log M_R versus log of the sum of the principal stresses and v_r versus the principal stress ratio (Figure N-5). The equation of the line for resilient modulus is $M_R = K_1\theta^{K_2}$ where K_1 is the intercept when θ = 1 psi and K_2 is the slope of the line.

FOREWORD

The Unified Facilities Criteria (UFC) system is prescribed by MIL-STD 3007 and provides planning, design, construction, sustainment, restoration, and modernization criteria, and applies to the Military Departments, the Defense Agencies, and the DoD Field Activities in accordance with USD (AT&L) Memorandum dated 29 May 2002. UFC will be used for all DoD projects and work for other customers where appropriate. All construction outside of the United States, its territories, and possessions is also governed by Status of Forces Agreements (SOFA), Host Nation Funded Construction Agreements (HNFA), and in some instances, Bilateral Infrastructure Agreements (BIA). Therefore, the acquisition team must ensure compliance with the most stringent of the UFC, the SOFA, the HNFA, and the BIA, as applicable.

UFC are living documents and will be periodically reviewed, updated, and made available to users as part of the Military Department's responsibility for providing technical criteria for military construction. Headquarters, U.S. Army Corps of Engineers (HQUSACE), Naval Facilities Engineering Systems Command (NAVFAC), and Air Force Civil Engineer Center (AFCEC) are responsible for administration of the UFC system. Technical content of UFC is the responsibility of the cognizant DoD working group. Defense Agencies should contact the respective DoD Working Group for document interpretation and improvements. Recommended changes with supporting rationale may be sent to the respective DoD working group by submitting a Criteria Change Request (CCR) via the Internet site listed below.

UFC are effective upon issuance and are distributed only in electronic media from the following source:

- Whole Building Design Guide website https://www.wbdg.org/ffc/dod.

Refer to UFC 1-200-01, *DoD Building Code*, for implementation of new issuances on projects.

CHAPTER 1 INTRODUCTION

1-1 REISSUES AND CANCELS.

This UFC reissues and cancels UFC 3-260-03, *Airfield Pavement Evaluation*, dated 15 April 2001.

1-2 PURPOSE AND SCOPE.

This document provides guidance in the structural evaluation of existing pavements. It incorporates recent and applied research that has resulted in improved reliability in evaluation results obtained with DoD engineering tools that address the purpose and scope of this UFC for all DoD Services.

UFC 3-260-03 presents criteria for evaluating the load-carrying capability of airfield pavements in terms of allowable traffic that a pavement can sustain for given loading conditions or the allowable load for a specified traffic mix, without producing unexpected or uncontrolled distress. It is not for use in contractor quality assurance or quality control (QA/QC). This document outlines procedures for nondestructive testing (NDT) and direct testing to gather data for use in conventional and layered elastic pavement analysis. The Pavement-Transportation Computer Assisted Structural Engineering (PCASE) application implements the pavement evaluation criteria in this document.

1-3 APPLICABILITY.

This document applies to evaluations of DoD airfields and heliports or those used by DoD aircraft or missions.

1-4 NATO AIRFIELDS AND OPERATIONS.

Comply with NATO STANAG 7131, *Aircraft Classification Number (ACN)/Pavement Classification Number (PCN)*, and NATO STANDARD AEP-46, *ACN/PCN*, when evaluating airfields used by NATO forces or NATO campaigns. Comply with TSPWG M 3-260-00.NS7210*, Standards for NATO Deployed Air Operations*.

1-5 PAVEMENT TYPES.

The pavement types considered in this UFC are the following.

1-5.1 Flexible Pavement.

A pavement with an asphalt concrete (AC) surface course and one or more supporting base or subbase courses, placed over a prepared subgrade.

1-5.2 Plain Concrete Pavement.

A single thickness of non-reinforced portland cement concrete (PCC) resting directly on a prepared subgrade, granular base course, or stabilized layer.

1-5.3 Rigid Overlay on Rigid Pavement.

A rigid overlay pavement placed on an existing rigid pavement. Placing a rigid overlay can include or exclude a bond-breaking course between the existing rigid pavement and the overlay. If the thickness of the bond-breaking course between the two rigid pavements is 4 inches (102 millimeters) or more, evaluate the entire pavement as a composite pavement (see paragraph 1-5.6 and paragraph 7-8).

1-5.4 Non-rigid Overlay on Rigid Pavement.

An AC surface layer or combination of AC layer and granular base course placed on an existing rigid pavement.

1-5.5 Rigid Overlay on Non-rigid Pavement.

A rigid overlay pavement placed on an existing non-rigid pavement.

1-5.6 Composite Pavement.

A composite pavement consists of a rigid overlay placed on an existing pavement that already has an existing flexible overlay on a rigid base slab. The existing flexible overlay may be asphalt for its full depth or a combination of asphalt and granular base course over the rigid base slab. When the thickness of the flexible overlay is less than 4 inches (102 millimeters), consider the entire pavement as an unbonded rigid overlay on rigid pavement. The asphalt overlay material is considered a bond-breaking course.

1-5.7 Reinforced Concrete Pavement.

A concrete pavement reinforced with deformed steel bar or welded-wire fabric. Measure the diameter and spacing of the steel in both the longitudinal and transverse directions to determine the percent steel.

1-5.8 Fiber Reinforced Concrete.

A concrete pavement reinforced with fibers. Previous evaluation manuals contained curves for evaluating concrete pavements with steel fibers. These curves are no longer used because there are no airfield pavements in DoD with steel fibers due to the fibers causing surface problems. Do not use steel fibers unless approved by the Pavements Discipline Working Group (DWG) or its designated representative. If using other types of fibers in pavements, do not reduce the pavement thickness requirement.

1-6 GLOSSARY.

Appendix F contains acronyms, abbreviations, and terms.

1-7 REFERENCES.

Appendix G contains a list of references used in this document. The publication date of the code or standard is not included in this document. Unless otherwise specified, the most recent edition of the referenced publication applies.

CHAPTER 2 EVALUATION CONCEPTS AND PROCESS

2-1 RELATIONSHIP OF DESIGN TO EVALUATION.

Pavement design requires selecting materials with the necessary strength and placing them at the proper thickness, density, and depth to construct a pavement capable of carrying the anticipated number of passes of a given load. Due to variations in material and placement conditions, the strengths and thicknesses of the as-constructed pavement may differ from the design. Over time, the strength of layers in the pavement structure will change. An evaluation determines the physical properties of a pavement as constructed and in its current condition to verify its aircraft load-supporting capability.

2-2 CONCEPTS.

The primary function of a pavement is to distribute the wheel loads over a larger area than the wheel contact area. Each airfield has its own natural soil and environmental conditions, and the in situ soils must ultimately sustain the stresses resulting from loads applied to the pavement. Since the strengths of native soils can vary widely from site to site, the ability to support loads also varies widely. In most cases, aircraft tire loads cannot be sustained directly on the native soils.

2-2.1 Pavement Structure.

A pavement design limits the tensile strain in an AC surface layer and tensile stress in a PCC surface layer to prevent excessive shear deformation (e.g., vertical strain) in the underlying unbound layers, including the subgrade. Flexible and rigid pavement structures are designed to limit tensile strains and stress for a defined mix of aircraft at specified loads and passes. Based on the magnitude of the applied surface load, contact pressure, and gear configuration, a pavement structure must distribute surface loads to that which the subgrade soil can accept for the aircraft mix. The evaluation process looks at load capability of an existing pavement in two ways. First, given a specified aircraft mix at a specified load, determine the allowable passes. Second, given a specified aircraft mix at a required number of passes, determine the allowable load.

Flexible pavements distribute load by broadening the effective area supporting the load, from the tire contact area on the surface to a wider area on the base, to a still wider area on the subbase, and so on. Each layer must be of sufficient quality to sustain the load intensity or stress and each must be thick enough to broaden or distribute the load and reduce intensity to that which its supporting layer can sustain without excessive permanent deformation. Rigid pavements are stiffer and have a “beam action” or flexural capability that spreads or distributes load more widely but must still have sufficient support to distribute the load and reduce flexural and tensile stresses in the slab.

2-2.2 Performance Models.

Performance models act as a “transfer function” between pavement response models and actual pavement performance. DoD uses several different pavement evaluation models, all of which are mechanistic-empirical models that associate an empirically derived pavement failure indicator (e.g., vertical stress) that defines the response with the required performance (e.g., coverages to failure). These performance models include the following:

- CBR-Alpha-Beta Hybrid model for flexible pavements that uses the California Bearing Ratio (CBR) as a strength index for base, subbase, and subgrade layers
- Westergaard Medium-Thick Plate Solution for rigid pavements that uses the modulus of subgrade reaction (k) as a strength index for layers supporting the slab
- CBR-Alpha model for unsurfaced and mat pavements that uses the CBR as strength index for all supporting layers
- Layered Elastic model for both rigid and flexible pavements that uses a material's Modulus of Elasticity (E) and Poisson's Ratio (*v*) values to characterize each layer

2-3 PAVEMENT EVALUATION PROCESS.

Pavement evaluation requires a structured approach to gather and organize information, perform testing and analysis, and generate report products for a variety of stakeholders to use in decision making. In addition to the structural evaluation process and procedures defined in this UFC, UFC 3-260-16, *O&M Manual: Standard Practice for Airfield Pavement Condition Surveys*, outlines the guidance for pavement condition index (PCI) inspections and UFC 3-270-08, *Pavement Maintenance Management*, provides guidance on using PCI and structural evaluation results in the overall pavement management process. The processes and procedures in all three of these documents are interrelated, follow the same general steps, and use the same inventory organization.

2-3.1 Evaluation Planning.

Gather and review information regarding the site and the pavement at the site from the sources outlined below. These data are used to determine the scope and validity of available data and develop a test plan. While this step in the process begins prior to any field work, it typically continues through the other phases of the evaluation as you contact people at the installation and get access to additional information.

2-3.1.1 Previous Evaluation Reports, Design, and Construction Documents.

Begin the planning process by gathering any previous evaluation reports. They typically have much of the background data needed for planning and conducting the evaluation. In addition to physical property and surface condition data, they contain site, construction history (also known as work history), and previous traffic information. Design and construction documents are another good source of information, including, but not limited to, the following:

- Pavement, base, and subbase layer thicknesses

- Asphalt physical properties such as mix design aggregate gradation and testing, binder properties, and asphalt mix properties such as density and voids
- PCC physical properties such as mix design, aggregate gradation, and slump
- Base and subbase strength and material properties
- Rigid pavement flexural strength
- Rigid pavement joint layout and load transfer devices or thickened edges

These data are particularly useful for forensic analysis when testing uncovers issues with existing pavements. This type of information is also available in the sources described below when no previous evaluations exist and is also used to validate and supplement information in previous reports.

2-3.1.2 Geographic Location and Mapping.

Determine the geographic location of the airfield and obtain mapping data. Geospatially correct mapping is normally furnished by the installation when performing an evaluation at a DoD installation or forward operating location with a current DoD mission. Obtain imagery and mapping from other sources such as the National Geospatial-Intelligence Agency (NGA) when not available from the installation or operating location.

2-3.1.3 Geological Data.

Identifying the general geology in the vicinity of the airfield is critical to determine the general type of soil deposition (e.g., alluvial, residual), the parent rock from which the soil derives, and other pertinent information. Soil type data is available in U.S. Geological Survey publications or Department of Agriculture soil maps as well as from state geological departments, state highway departments, subsurface exploration companies, and similar organizations, including NAVFAC and USACE construction offices. Soil boring or well logs from the installation and aerial photographs showing pertinent geologic features are also valuable data sources.

2-3.1.4 Drainage and Groundwater Conditions.

Identify the natural drainage pattern and general surface-drainage system for the area from contour maps published by the U.S. Geological Survey, the National Oceanic and Atmospheric Administration, or the NGA. Collect detailed information concerning drainage at the airfield, including descriptions of any drainage structures and shoulder slopes, and whether excessive vegetation or soil along the pavement edges ponds water on the pavements. Determine the depth to groundwater table near the airfield and at the airfield perimeter and note the presence of any perched water tables in the airfield subgrade. Obtain groundwater data and the location of springs and seeps from well logs, cuts, or borings in the vicinity. Also, identify and evaluate subsurface drainage systems.

2-3.1.5 Climatic Data.

The Pavement-Transportation Computer Assisted Structural Engineering (PCASE) application has a world index database with the average daily maximum and minimum temperatures for each month, average annual rainfall, and the freezing index. This, as well as other information such as the average humidity and description of the prevailing winds for the period of record, can be found in routine National Weather Service publications, from records of the airfield weather station, or from the U.S. Air Force 14th Weather Squadron (formerly Combat Climatology Center [AFCCC]) Asheville, NC.

2-3.1.6 Construction/Work History.

Having an accurate construction history is essential to analyze the pavement surface condition deterioration and is used for structural analysis if field testing cannot be conducted. Information on other work performed, such as dates for overlays, surface treatments, joint seals, patches, and other repairs, enhances analysis capability. Obtain detailed information on the construction and maintenance performed on each facility from the installation engineer organization responsible for base maintenance. The construction office responsible for construction on the installation (e.g., NAVFAC or USACE) may also be able to provide this information.

2-3.1.7 Traffic Data.

Collect data from airfield management on the type, gross weight, and typical operating weight of each type of aircraft regularly using the airfield on a day-to-day basis. Specific traffic data (type, weight, passes) for all fixed or rotary wing aircraft using each runway, taxiway, and apron system will enhance the evaluation accuracy if available. These data will be used to define future expected traffic loading and pass levels. Specific traffic analysis procedures are discussed in detail in Chapter 4.

2-3.2 Mapping and Inventory.

Having a geospatially correct map linked to areas of pavement with similar characteristics provides organization for pavement testing, analysis, and reporting. Mapping and inventory standards and procedures are described in detail in UFC 3-270-08. The following is a process summary.

2-3.2.1 Pavement Inventory.

Pavement inventory is the term used to describe all the airfield pavement on an installation. The pavement is divided into a hierarchy consisting of a network, branches, and sections. A site typically has one airfield network but can have more than one in some situations. Branches are divided based on pavement use (e.g., runways, taxiways, and aprons) and sections are areas of pavement with similar physical characteristics. Each of these entities has an ID and the combination of the network, branch, and section IDs is the pavement ID (PID). The PID is associated with the pavement evaluation data in the database and its respective polygon on the map. See UFC 3-270-08 for more detail.

2-3.2.2 Creating and Updating Maps.

Use a Geographic Information System (GIS) application such as ArcMap or AutoCAD 3D Map to create or update mapping. There is also the option to use the GIS application to update inventory data and work history associated with section polygons. When implementing this option, the inventory and work history data structure must follow the PAVER standard. Export the map to a shape (.shp) file or table and import that file to PCASE or PAVER for use in either application.

2-3.2.3 Importing Maps to PCASE or PAVER Applications.

The PCASE and PAVER applications both use the same database. When you import the map in PCASE, the updated map is available in PAVER and vice versa. Details on importing GIS/tabular data are available in the PCASE and PAVER user guides. The process is the same for both.

2-3.2.4 Creating and Updating Inventory in PCASE or PAVER.

When the map imported from the GIS application does not include inventory or work history data, it is updated in PCASE or PAVER using the Define Inventory tool. The updated section data is then assigned to the section polygons using the GIS Assignment tool. When starting with an empty inventory, add a network to the inventory, then add branches to the network and add sections to the branches.

2-3.2.5 Linear Segmentation.

Linear segmentation is the process of linking the pavement inventory to the corresponding facilities in the Real Property data structure. This linkage is created between the branch and the facility using the Real Property Unique ID (RPUID) such that a pavement network can have one or many facilities and a facility can have one or many branches. The objective of creating this linkage is to be able to report pavement management data in Real Property terms (facility) for use at the Service and Office of Secretary of Defense (OSD) level. See UFC 3-270-08 for more detail.

2-3.3 Test Plan.

Using the mapping, inventory structure, and data gathered from previous reports and other sources, develop a test plan that defines the types and estimated number of tests required as outlined in paragraph 3-1 to accurately characterize the pavement structure of each section in the inventory. This historical data provides an indication of the uniformity of the pavement structure for each section. It is used to identify gaps in the data or the need to validate the historical data with testing. Note that even data captured twenty, thirty, or more years ago remains valuable. Once a soil reaches an equilibrium moisture content, strength and thickness may not change significantly over time. Where moisture varies seasonally or frost issues exist, address these seasonal variations with appropriate testing described in Chapter 8 and Appendix A. When performing testing such as coring or using a dynamic cone penetrometer (DCP), develop a map with the approximate locations of these tests. The map is helpful to communicate the test plan to the installation engineers and airfield management. Depending on the Service, installation, and type of testing, a work clearance request may be required before the start of field work.

2-3.4 Perform Field Testing.

Conduct field testing based on the test plan to determine the pavement characteristics and structure of each section in the inventory, using one or a combination of the procedures below. Note that additional testing is often required to supplement the test plan when test results deviate from previous evaluation, design, or construction data. When no previous evaluation or construction data are available and there is significant variability in the test plan testing results, conduct additional tests as required. Finally, access time on the airfield may limit the number of tests that can be performed. In these cases, prioritize the tests. Details on the procedures below are included in Chapter 3.

2-3.4.1 PCI Inspection.

Conduct a PCI survey to determine the PCI for each section or validate the results from a previous inspection.

2-3.4.2 Coring or Test Pits.

Coring is used to determine the pavement thickness, get asphalt or concrete samples, and provide access for DCP testing and collecting soil samples. Test pits are rarely used due to operational restrictions but provide the capability to collect more samples and do more robust material testing.

2-3.4.3 Dynamic Cone Penetrometer (DCP).

Use the DCP or automated DCP (ADCP) to determine soil strengths and layer thickness.

2-3.4.4 Falling Weight Deflectometer (FWD).

Provides deflection data used to backcalculate the moduli for the layered elastic analysis procedure.

2-3.4.5 Ground-Penetrating Radar (GPR).

Use GPR to determine pavement layer thicknesses for each material type and the presence of anomalies in a structure.

2-3.4.6 Portable Seismic Pavement Analyzer (PSPA).

Uses wave propagation and elastic theory to determine structural properties for the layered elastic analysis procedure.

2-3.4.7 MIRA Ultrasonic Tomography.

Used to estimate the average thickness of the section.

2-3.5 Perform Laboratory Testing.

Perform laboratory testing on asphalt, concrete, and soil samples taken during field work. This step in the process is used less frequently than in the past, but when performed, is typically done after the initial field work data compilation, modeling, and analysis. It is used to validate the initial results and improve the level of detail and overall quality of the report.

2-3.6 Compile Evaluation Data.

Select representative layer thickness, strength, and material types for the pavement surface, base course, subbase course, and subgrade of each section from available data and summarize the data in the physical property data (PPD) or construction history table of the report. These layer structures are used in the modeling and analysis process, so it is important to document any assumptions or limitations made in compiling the data. For example, if limited time did not permit additional testing or when data was taken from a previous report.

2-3.7 Modeling and Analysis.

There are two approaches to pavement modeling and analysis based on the performance models described in paragraph 2-2.2. The first is commonly known as airfield pavement evaluation (APE) analysis and the second is layered elastic analysis. Either or both models may be used, depending on the situation. While all of these procedures use different models to compute stresses, they all compute allowable passes, allowable load, the pavement classification number (PCN), and overlay requirements when required for each analyzed section.

2-3.7.1 APE Analysis.

APE analysis uses the CBR-Alpha-Beta Hybrid model for flexible pavement, the Westergaard model for rigid pavements, and the CBR-Alpha model for unpaved and mat airfields. These models are implemented in the PCASE APE module, which is typically used for contingency evaluations at forward operating locations or when layered elastic analysis does not yield reasonable results (e.g., on low strength pavements). APE inputs include the layer structure, thickness, and strength (CBR or k). Layers may be combined in some complex structures to facilitate analysis (e.g., a multi-layer composite pavement).

2-3.7.2 Layered Elastic Analysis.

Layered elastic analysis uses the YULEA model for both flexible and rigid pavement analysis. Layered Elastic analysis is implemented in the PCASE Layered Elastic Evaluation Program (LEEP). Layered elastic analysis is more commonly used to evaluate main operating installations but is also used at forward operating locations with an enduring mission. LEEP inputs include the layer structure, thickness, and properties (E and v). Similar layers are typically combined to simplify the structure being analyzed (e.g., combine the subbase and subgrade when they have similar material properties). Once the layer structure is defined, select FWD deflection (basin) data that define the pavement's response to loading and use it to determine the pavement layer moduli by matching the deflection basin with an elastic layer model. This process is known as backcalculation. Finally, select a representative model from the backcalculation procedure for layered elastic analysis.

2-3.8 Report Generation.

Report format and content varies by Service and mission (e.g., the report format and content for a contingency evaluation is different than that for a main operating installation). In general, a pavement evaluation report for a main operating installation has the report elements listed below. Contingency evaluations focus on tabular summaries of data collected in the field, PCI and structural analysis results, and any limitations to the proposed mission. More detailed information on report content is outlined in Chapter 10 of this UFC, UFC 3-270-08, and TSPWG M 3-260-03.02-19.

- Discuss construction changes that have occurred since the last evaluation
- Discuss changes in the installation mission regarding aircraft traffic mixes and define the critical aircraft and required overlays for deficient sections
- Discuss field data collection efforts and provide a tabular summary of the data structure for each section
- Tabular summary of PCI ratings
- Tabular summary of analysis results, including allowable aircraft loads, allowable aircraft passes, and PCN ratings
- Color maps for the inventory, PCI, and structural condition (e.g., PCN or Structural Index [ACN/PCN] ratios)
- Discuss structural capacity and functional condition deficiencies
- Recommend localized and global preventive maintenance and repair (M&R) requirements
- Recommend major M&R requirements and alternatives to address deficiencies

CHAPTER 3 DATA COLLECTION

3-1 GENERAL.

Selecting representative physical characteristics for a pavement section requires a thorough study of all existing information as well as field and, in some cases, laboratory testing. Previous evaluations, and when available, design and construction control data, provide a starting point for the evaluation test plan described in Chapter 2 that identifies test requirements for the evaluation. These tests fall into two general categories: nondestructive testing (NDT) and direct sampling.

3-1.1 Nondestructive Testing (NDT).

As the name implies, NDT does not require taking physical samples. This category includes methods such as the falling weight deflectometer (FWD), ground penetrating radar (GPR), and the MIRA ultrasonic tomography device.

3-1.2 Direct Sampling.

Direct sampling includes methods such as coring, DCP, split tensile, and soil classification as well as methods conducted in test pits such as in-place CBR, plate bearing, and soil density testing. More robust laboratory testing can be performed on asphalt, concrete, and soil samples collected from test pits. This chapter outlines data collection requirements and procedures. More detailed information on sampling and testing methods are discussed in Appendix A.

3-1.3 Determining Testing Methods.

There are a several factors that dictate the testing methods for an evaluation, including the purpose of the evaluation, logistics limitations, and site-specific testing limitations.

3-1.3.1 Purpose of the Evaluation.

Pavement evaluations fall into two general categories based on the nature of the mission: permanent and contingency. Contingency evaluations are further categorized as expedient or sustainment. A third general category is special purpose, in which the evaluation is focused on a specific issue. All require the same basic procedures as outlined in this chapter but differ in amount of data used in the evaluation and, in turn, the reliability of the results and the level of detail in the report. The evaluation classification is driven primarily by the purpose and time allotted for field work and analysis.

- Permanent: Managing pavement maintenance and repair (M&R) and long-term aircraft operations
- Contingency: Managing pavement and aircraft operations at forward locations
    - Expedient (100 passes or initial surge of mission aircraft)
    - Sustainment (5,000 passes or throughout anticipated operation)

- Special purpose: Address specific issues (e.g., void detection)

3-1.3.2 Logistics Limitations.

The ability to get test equipment to a site, time available for the evaluation, and access to the pavements are all limiting factors that determine the approach to pavement evaluation testing and analysis.

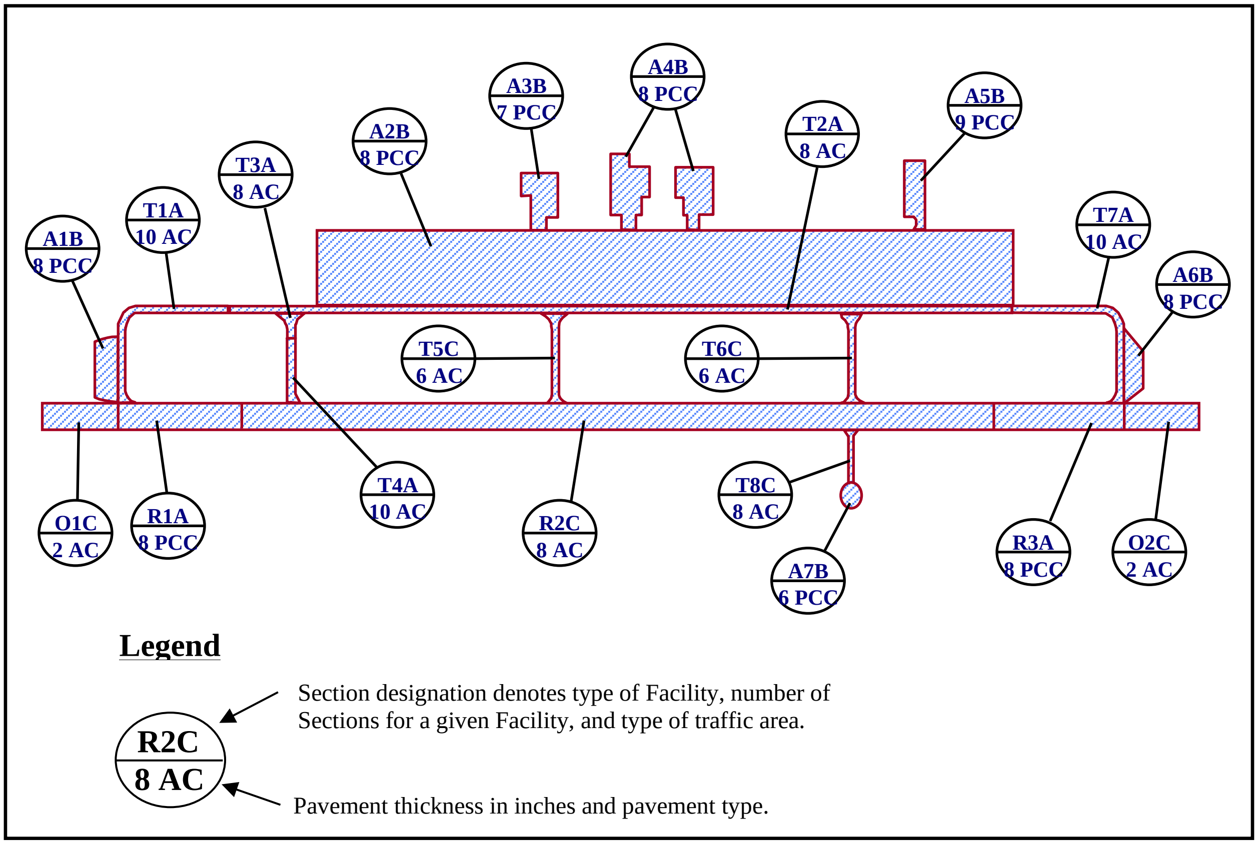
3-1.3.3 Site-Specific Testing Limitations.

The nature of the pavement or soils at the site can limit the reliability of the data. For example, FWD testing can provide unreliable results in certain soil types or when there is a high water table. DCP results can be unreliable in rocky soils. Research and understand the limitations of each test method to determine its suitability for the pavements or soils at each site. TSPWG 3-260-03.02-19, *Airfield Pavement Evaluation Standards and Procedures*, provides alternative testing procedures when site conditions limit the use of testing equipment.

3-2 MAPPING AND INVENTORY.

All testing described in this chapter is intended to determine representative physical characteristics at the pavement inventory section level as shown in Figure 3-1. It assumes that the mapping and inventory is established as outlined in paragraph 2-3.2, with specific details outlined in UFC 3-270-08. Note that Figure 3-1 is typical for a contingency evaluation. In an evaluation for a main installation, section IDs have a leading zero before the number (e.g., A01B and pavement thicknesses are typically rounded to the quarter inch, e.g., 8.25 AC).

Figure 3-1 Typical Airfield Section Map



3-3 PAVEMENT SURFACE CONDITION INSPECTION.

The Pavement Condition Index (PCI) is the standard measure of pavement surface condition used by DoD. PCI data are collected using the procedures outlined in UFC 3-260-16, which is the DoD equivalent of ASTM D5340, *Standard Test Method for Airport Pavement Condition Index Surveys*, with additional DoD-specific requirements. The PCI uses a scale from 0 to 100 to define the condition of the pavement as shown in Figure 3-2 and described in Table 3-1. Ideally a structural pavement evaluation includes a project-level PCI inspection (aka a PCI survey) but the situation may dictate a network-level inspection or even a cursory inspection, which is often the case in a contingency environment. The determining factors on the level of inspection are the intended use of the data and the time and manpower available.

Figure 3-2 PCI Rating Scale

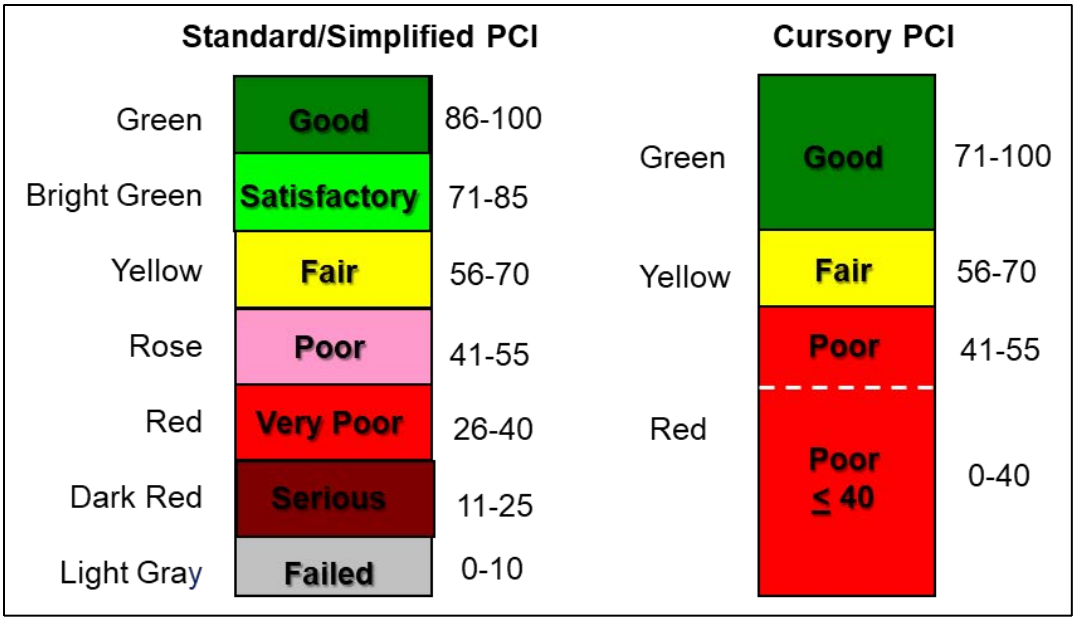


Table 3-1 PCI Rating Definitions

Rating	Definition
86–100	**GOOD:** Pavement has minor or no distresses and will require only routine maintenance.
71–85	**SATISFACTORY:** Pavement has scattered low-severity distresses, which should require routine maintenance.
56–70	**FAIR:** Pavement has a combination of generally low- and medium-severity distresses. Near-term maintenance and repair needs should be routine to major.
41–55	**POOR:** Pavement has low-, medium-, and high-severity distresses, which probably cause some operational problems. Near-term maintenance and repair needs should range from routine to reconstruction.
26–40	**VERY POOR:** Pavement has predominantly medium- and high-severity distresses causing considerable maintenance and operational problems. Near-term maintenance and repair needs will be intensive in nature.
11–25	**SERIOUS:** Pavement has mainly high-severity distresses, which cause operational restrictions; immediate repairs are needed.
0–10	**FAILED:** Pavement deterioration has progressed to the point that safe aircraft operations are no longer possible; complete reconstruction is required.

3-3.1 Project-Level PCI Inspection.

The project-level PCI is referred to as a standard PCI inspection in some contingency pavement evaluation material and in Figure 3-2 above. The PAVER pavement management application implements the inspection process outlined in UFC 3-260-16. It requires inspecting sufficient samples to achieve a 95 percent confidence level. Determine the samples to be inspected based on a systematic random sampling process. The formula for determining the number of samples is in UFC 3-260-16 but Table 3-2 provides a general idea of sampling requirements. Use the seven-tier PCI scale shown in Figure 3-2 and Table 3-1 when reporting results. Use project-level inspections when the data is used to develop project management plans for main installations or to meet a specific requirement for a higher confidence level. PAVER uses the same database structure as the Pavement-Transportation Computer Assisted Structural Engineering (PCASE) application, so PCI inspection data are also accessible in PCASE for use in structural analysis.

Table 3-2 Project-Level Sampling Requirements

PCC Sampling			
Total # of SU	Survey #	Total # of SU	Survey #
1-10	ALL	50-55	22
11-13	10	56-61	23
14-15	11	62-70	24
16-17	12	71-79	25
18-19	13	80-91	26
20-22	14	92-105	27
23-24	15	106-122	28
25-27	16	123-145	29
28-31	17	146-175	30
32-35	18	176-217	31
36-39	19	218-280	32
40-43	20	281-330	33
44-49	21	>= 331	10%

ACC Sampling	
Total # of SU	Survey #
1-7	ALL
8-11	7
12-15	8
16-19	9
20-24	10
25-32	11
33-44	12
45-64	13
65-104	14
105-150	15
≥151	10%

3-3.2 Network-Level PCI Inspection.

The network-level PCI is referred to as a simplified or contingency pavement condition survey in some contingency pavement evaluation references. It is also conducted in accordance with UFC 3-260-16 but requires a lower sample rate than a project-level PCI, as shown in Table 3-3. Another difference between the project and network-level PCI is that the network-level PCI requires representative rather than random samples. The inspector must determine the typical distress types in the section and inspect samples that are typical of the entire section. Place emphasis on structural or foreign object damage (FOD) -related distresses. Use the seven-tier PCI scale shown in Figure

3-2 and Table 3-1 when reporting results. The network-level inspection is typically used for contingency evaluations at forward or en-route operating locations but may also be used at sites such as auxiliary fields when there is not a specific requirement for a higher confidence level.

Table 3-3 Network-Level PCI Sampling Requirements

Section Size (Total Samples)	Sample Units to Survey
1 to 5	1
6 to 10	2
11 to 15	3
16 to 40	4
Greater than 40	10%

3-3.3 Cursory Pavement Condition Inspection.

In a cursory pavement condition inspection, the number of inspected sample units may be less than the minimum requirements for a network-level inspection. Use the same process outlined in UFC 3-260-16 when time permits or, when time is limited, conduct a visual assessment noting the primary distresses with a focus on distresses that cause limitations or mission impacts to aircraft. Mission-critical PCI values typically occur when the value is less than 40 or 25. In either case, report the results of a cursory survey as a qualitative assessment of the pavement surface condition using the Cursory three-color scale in Figure 3-2. When a cursory condition survey is conducted using the simplified evaluation procedures, the evaluation is considered "expedient" and valid for limited or immediate use only. Cursory inspections are typically used in contingency pavement evaluations.

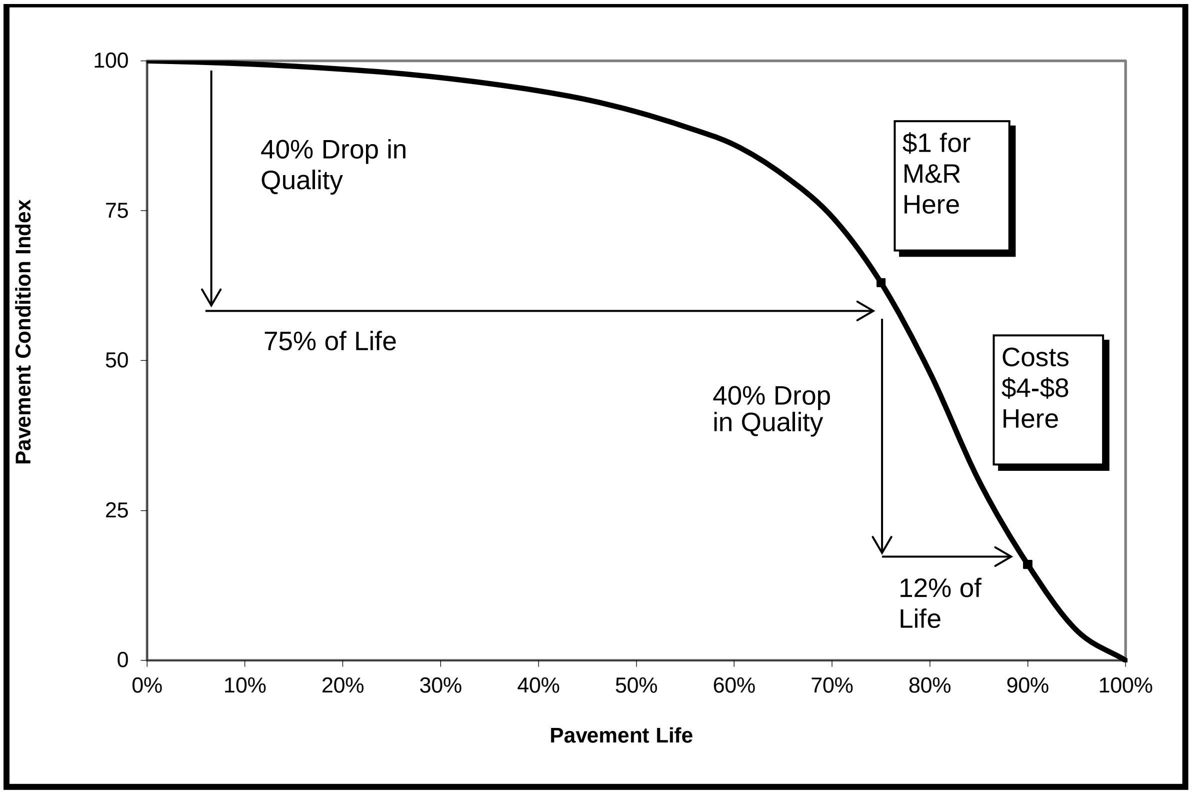
3-3.4 Using PCI Inspection Results.

The PCI of a pavement plays a critical role in determining localized and global preventive as well as major M&R requirements in pavement management plans. It is also used in all the structural evaluation pavement analysis procedures.

3-3.4.1 PCI Use in Pavement Management.

The PCI is used to determine the rate of deterioration of the surface condition and predict the future condition of the pavement. The predicted PCI is used to plan appropriate cost-effective M&R actions. When a pavement deteriorates to a condition where it is no longer cost-effective to do localized or global M&R (known as the critical PCI), major M&R is triggered to address issues before the pavement deteriorates to the point that reconstruction is required (see Figure 3-3). While each Service establishes PCI levels that trigger major M&R and reconstruction based on their respective missions, the general principles remain the same: invest in localized and global M&R to extend the service life of GOOD pavement and invest in major M&R at the appropriate time to delay the need for reconstruction.

Figure 3-3 Typical Pavement Life Cycle (APWA,1983)



3-3.4.2 PCI Use in Pavement Structural Analysis.

The pavement condition can adversely affect aircraft operations because some distresses generate foreign object debris (FOD) that poses a risk to aircraft operations. It can also help identify potential structural problems (e.g., structural distresses that indicate the pavement is overloaded or at the end of its service life). When the PCI is 40 or lower, reported allowable gross loads (AGL) are reduced by 25 percent. In addition, the PCI is used to compute the structural condition index (SCI). The SCI is like the PCI but only considers the load-related distresses. The SCI is used as the failure criteria for rigid pavement when doing layered elastic analysis and used to determine the condition factors Cb and Cr that determine the equivalent thickness of existing overlays on rigid pavements or new overlay requirements when an existing pavement is not capable of supporting the evaluation traffic.

3-3.5 Additional Contingency Evaluation Considerations.

The amount of time available to conduct PCI surveys impacts the number of sample units inspected. The evaluator’s most important task is to accurately identify the correct distress type and severity level as described in UFC 3-260-16. Acceptable errors in distress quantity will have less of an impact on the PCI value and FOD risk to mission aircraft. Typically, medium- and high-severity distresses create the highest FOD potential that may cause operational limitations or impacts to the mission aircraft. While the PCI value may provide an indirect measure of subsurface deficiencies, it is important to consider both the surface condition (e.g., PCI) from a function perspective and structural evaluation results. A pavement surface may rate GOOD (PCI 71 to 100) but have underlying pavement or soil conditions that could result in pavement failure under repeated aircraft operations. On the other hand, a pavement may be structurally sound, but the surface condition may be hazardous for aircraft traffic (e.g., FOD).

3-4 NONDESTRUCTIVE PAVEMENT TESTING.

Paragraph 3-1.1 describes three nondestructive pavement testing techniques currently in use, the FWD, GPR, and the MIRA device. Each is used to determine different pavement characteristics are used in conjunction with each other or in conjunction with direct sampling testing.

3-4.1 Falling Weight Deflectometer (FWD).

The falling or heavy-weight deflectometer (FWD/HWD) is an impulse loading device that measures the response of a pavement system to a falling dynamic load that simulates a moving vehicle or aircraft wheel. FWD is the generic term for the device, with the HWD capable of applying a heavier load than other FWDs, but the terms are used synonymously. The heavier load of the HWD is preferred on thick AC and PCC airfield pavement structures. The objective is to apply the maximum load possible to simulate aircraft loading without overloading the FWD sensors. ASTM D4694, *Standard Test Method for Deflections with a Falling-Weight-Type Impulse Load Device*, provides detailed guidance on the FWD and HWD test procedures.

3-4.1.1 FWD Description.

The load on the pavement (impulse force) from an FWD is created by dropping weights from different heights onto a rubber or spring buffer system. The standard loading plates used to transmit the applied force to the pavement are either 12 inches (300 millimeters) or 18 inches (450 millimeters) in diameter, with the 12-inch plate being most commonly used for AC or PCC pavement surfaces while the 18-inch load plate used for unbound aggregate layers and stabilized subgrades. The drop height is varied to produce an impact force up to 56,000 pounds (25,401 kilograms), depending on the HWD. Other FWD models are limited to lower loads more typical of road traffic.

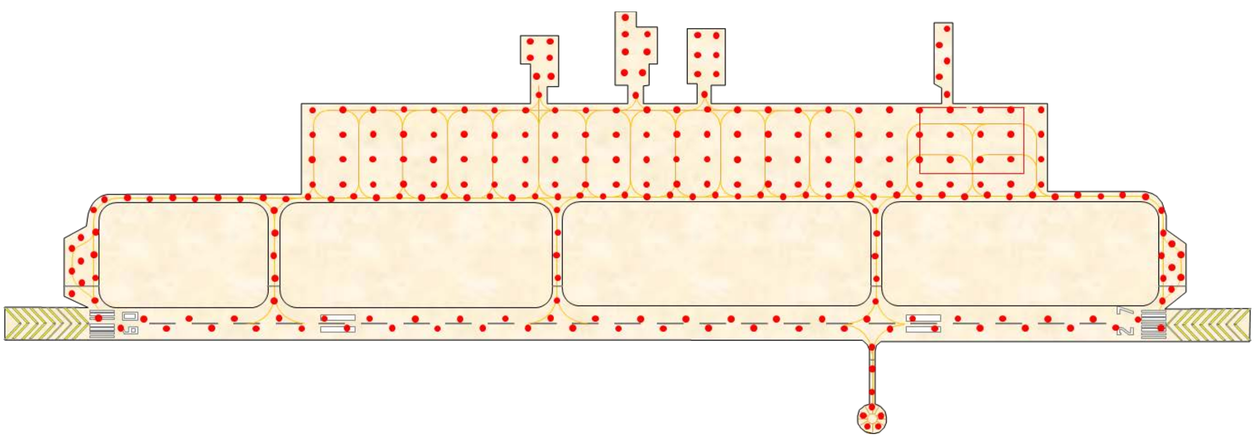
3-4.1.2 Measuring Pavement Response.

The FWDs currently in use by DoD use geophones, which are velocity transducers that convert ground movement (velocity) into voltage to measure the pavement response to the applied load. The load is measured by a load cell integral to the FWD load system and the pavement response is captured by the pavement deflection which is obtained by integrating the surface velocity measured by the velocity transducers. Other systems use seismometers but both are typically referred to as sensors. Seven sensors are preferred, with a sensor located at the center of the load plate and the remaining sensors at 12-inch (300-millimeter) intervals, with the outermost sensor (farthest from the falling weight load application) at 72 inches (1829 millimeters). There may be instances when fewer sensors are used but in no case should the outermost sensor be less than 48 inches (1219 millimeters) from the load.

3-4.1.3 Test Location and Density.

The time required to measure the deflection basin at each testing location is short (one to two minutes), allowing for many tests in a short period of time. Conduct FWD testing at 100-foot (30-meter) intervals on runways and taxiways. Alternate tests on either side of the centerline at an offset that is within the main gear wheel paths of aircraft that frequently use the airfield or are based at the site. The centerline offset is usually 10 to 12 feet (3 to 4 meters) for flexible pavements. Adjust this offset distance for rigid pavements as required to accommodate joint layouts and PCC slab size. Conduct FWD tests on apron areas in a grid pattern at 100- to 200-feet (30- to 61-meter) spacing. As seen in Figure 3-4, the procedure outlined above establishes longitudinal profiles along the runways, taxiways, and aprons to produce a test density that gives a comprehensive assessment of subgrade, base, and pavement structural condition. The uniformity of results will dictate whether test spacing can be increased or whether additional tests should be conducted when there are large variations in pavement response. When failed areas or areas of excessive pavement distress are encountered, locate enough FWD and other tests in the failed or distressed areas to determine the cause of the failure or distress. Conduct a minimum of five FWD tests on all pavement sections.

Figure 3-4 FWD Test Locations



3-4.1.4 Performing the FWD Test.

Position the FWD equipment at each test location and initiate the test sequence through the FWD application provided with the system. Test sequences require a minimum of three drops (loads) and use of the same drop heights (e.g., 2-4-4) throughout a given section. The first loading is at a lower drop height and is considered a seating load and results are not typically used in backcalculation. The second and third loadings are set to maximize the magnitude of the loading without exceeding the geophone limitations. They should produce similar results and are used for the analysis. If inconsistencies are observed in either of these test sequences (e.g., high errors or inconsistent basin shape), select the better of the two drop sequences for analysis. The load is applied for each drop in the sequence, the resulting surface deflections are determined at each geophone location, and the results are stored in a data file. There are several data file formats, but a formatted text file with a .fwd or .hwd file extension is typically used by DoD. Import the .fwd file (or other chosen format) into PCASE for analysis.

3-4.1.5 FWD Testing for Asphalt.

The modulus of bituminous concrete is temperature dependent. There are relationships between the temperature and the modulus used in backcalculation and analysis as described in Chapter 5. The relationship for backcalculation requires the mean pavement temperature at the time of testing. This datum can be captured by measuring the temperatures with thermometers installed 1 inch (25 millimeters) below the pavement surface, 1 inch (25 millimeters) above the bottom of the AC layer, and at mid-depth of the bituminous layer, but this procedure is seldom used. The standard approach is to collect data on the average (mean) air temperature for the five-day period prior to the day of testing and adding it to the measured pavement surface temperature, which is captured by the FWD at the time of the test to determine the mean pavement temperature using the relationship described in Chapter 5.

3-4.1.6 FWD Testing for Concrete.

Perform tests on rigid pavements near the center of the PCC slabs but at a minimum of 3 to 6 feet (1 to 2 meters) away from the joints and linear cracks that may exist within the slab. When a slab width or length is less than 20 feet (6 meters), center the entire sensor array on the slab, keeping the outer sensor at least 3 feet (1 meter) from the joint.

3-4.1.7 FWD Testing for Joint Load Transfer.

Rigid airfield pavements are commonly designed to transfer at least 25 percent of the load on a slab to adjacent slabs. FWD testing is used to verify that the load is being transferred across the joint. Figure 3-5 shows the test configuration with the plate (and sensor 1) on the loaded slab and the second sensor on the unloaded slab. The deflection ratio of the unloaded slab to the loaded slab is the deflection ratio used to determine the joint load reduction factor using the relationship shown in Figure 3-6 to define joint transfer efficiency. If the joint load transfer is poor, the load-carrying capacity of the PCC slabs is reduced, with a corresponding decrease in the pavement service life.

Joint testing policy varies. In some cases, joint testing is always done and in other cases it is only done when there are indications that there is poor load transfer such as longitudinal cracking in the wheel path on multiple slabs in a section. In either case, determine the number of center slab tests, take 20 percent of that number and perform joint tests on that number of slabs. Joint load transfer is temperature dependent; testing in the morning can yield different results in the afternoon as slabs heat up and expand. While not always feasible, it is best to perform NDT work in the spring or fall to avoid high temperatures in the summer and cold temperatures in the winter that may not represent typical load-transfer for a pavement system. If NDT work must be performed in the summer, consider early-morning testing when temperatures are typically cooler than in the afternoon. This is especially relevant if joint load transfer exists primarily from aggregate interlock because no dowel bars exist in the jointed PCC pavement. Reference point tests can establish a relationship between air temperature and the deflection ratio from NDT such that adjustments are made to test results collected over a wide range of temperatures. Select a reference slab within each section to be tested on a given day. Conduct joint tests on each reference slab at one- to two-hour intervals throughout the testing period, or at closer intervals if the testing period is less than four hours on a given section.

Figure 3-5 NDT Configuration for Determining PCC Joint Load Transfer

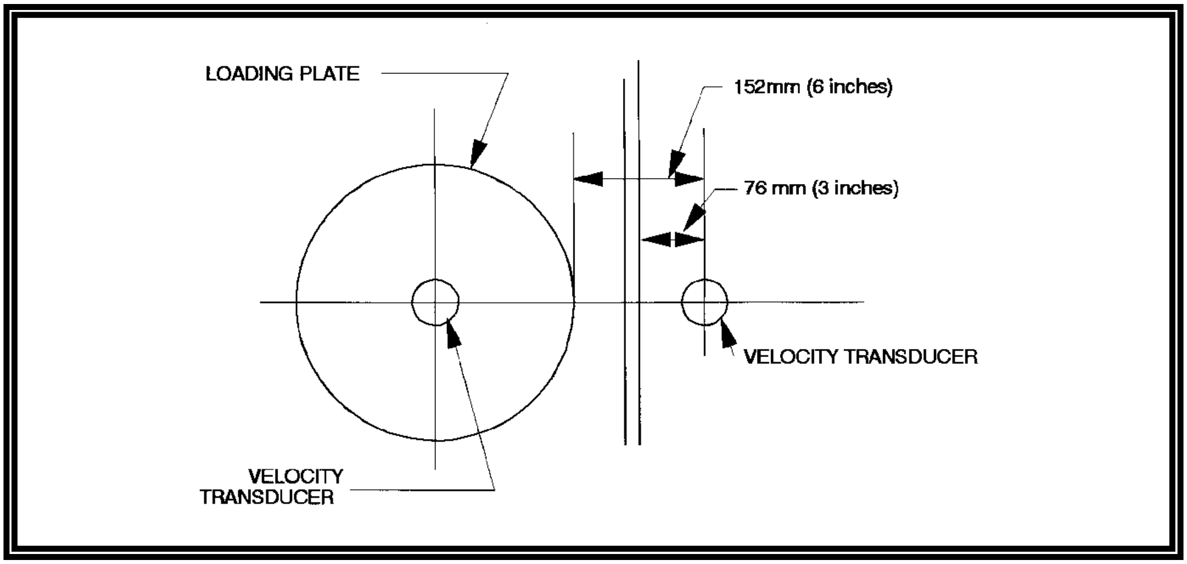


Figure 3-6 Joint Load Reduction Factor

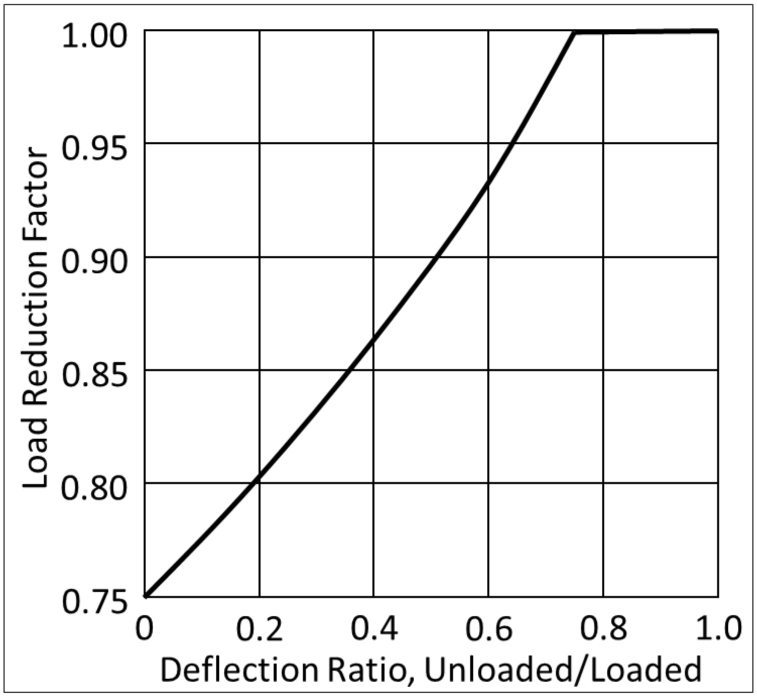


3-4.2 Ground Penetrating Radar (GPR).

The primary benefit of GPR is that it can collect large amounts of detailed data in a short time. Use GPR to determine pavement layer thicknesses for each material type and the presence of anomalies in a structure. There are air-coupled and ground-coupled GPR variants that use electromagnetic radiation, usually in the range of 10 MHz to 2.6 GHz. Higher frequencies do not penetrate as far as lower frequency antennae but may provide better resolution. A GPR transmitter emits electromagnetic energy into the structure. When the energy encounters a buried object or a boundary between materials having different permittivity, it is reflected, refracted, or scattered back to the surface. The receiving antenna records the variations in the return signal.

GPR is sensitive to specific site conditions. The material types encountered will dictate the ability of the GPR to evaluate the layered structure. Dry, sandy soils or materials such as granite or limestone tend to be resistive rather than conductive and can penetrate up to 49 feet (15 meters). Moist or clay-laden soils and materials with high electrical conductivity can limit penetration to as little as a few inches. Materials with similar dielectric constants will limit the ability to discern layer changes. Before testing, calibrate the GPR system (see Figure 3-7) at each site using cores and a steel plate. Take measurements along FWD testing paths on each side of the centerline for taxiways and runways and along the FWD testing path on aprons. The data collection system records the voltage and time history of the signal and GPS location and camera images for use in post-processing. Post-process the data to determine layer thickness by comparing voltage peaks (amplitude) and the time between peaks to estimate the layer thickness and use these data to determine the average layer thicknesses for each section. Use the procedure outlined in Appendix B for void detection.

Figure 3-7 Air Coupled GPR

3-4.3 MIRA Ultrasonic Tomography.

The MIRA ultrasonic tomography device is used to determine concrete pavement thickness. The standard procedure is to take measurements near each FWD test location with the objective of achieving a 95 percent confidence level that the average value reported for each section is within 0.5 inch (13 millimeters) of the true value. Round the computed average value to the nearest 0.25 inch. While coring has the benefit of providing a sample that can be measured and tested for flexural strength, the MIRA can test more locations to determine an average thickness without the need to repair core holes. Figure 3-8 shows a MIRA device being used for testing.

Figure 3-8 MIRA Ultrasonic Tomography

3-5 DIRECT SAMPLING.

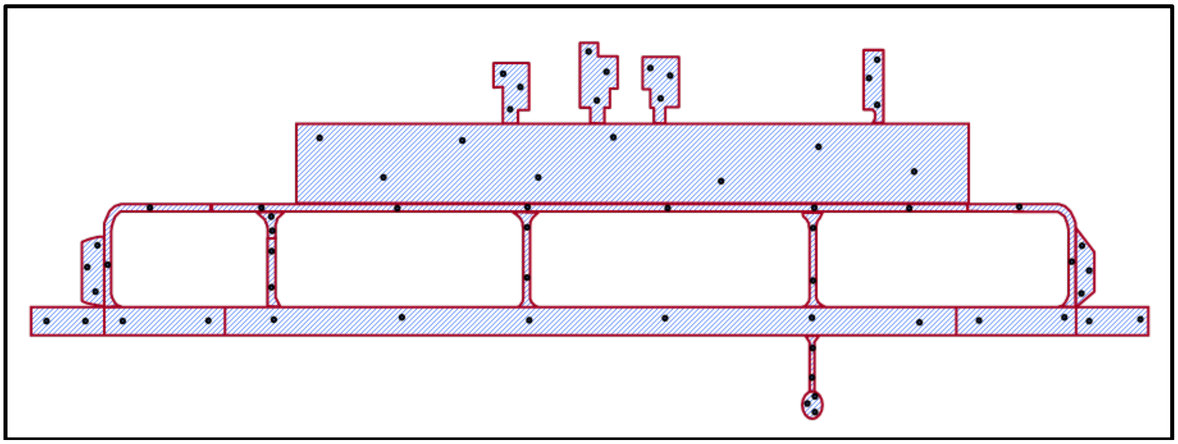
3-5.1 Pavement Coring and Drilling.

Pavement coring or drilling is used to collect pavement and soil samples, verify the pavement thickness, and provide access to the subsurface layers for DCP testing.

3-5.1.1 Coring or Drilling Locations.

When there were previous evaluations at a site, select locations that were not previously tested and use the data from both the previous and new evaluation to define the representative pavement structure. For rigid pavements, core in the center of the slabs to avoid thickened edges. Recording new location GPS coordinates can assist in preparing GIS maps. For contracted coring or drilling work, obtain GPS data for each location if the airfield owner allows GPS data collection. When coring or drilling is done in conjunction with FWD testing, use the FWD data to identify locations for additional testing where there are anomalies or changes in strength. The size and uniformity of the section dictates the number of tests required but test at least three locations for any new pavement not previously tested. Perform tests in the aircraft wheel paths on alternating sides of the centerline and in any weak areas. Conduct additional tests to verify the boundaries of these areas. When test time is limited, prioritize runway and taxiway tests. Figure 3-9 shows a typical test plan for coring or drilling.

Figure 3-9 Typical Coring/Drilling Test Plan



3-5.1.2 Pavement Coring.

Figure 3-10 shows a typical coring operation. The core drill uses 4- to 8-inch (102- to 203-millimeter) -diameter, diamond-tipped coring barrels (6-inch [152-millimeter] is the norm) to cut through asphalt or concrete pavements. This type of pavement coring system can cut through pavements to depths greater than 36 inches (914 millimeters) using a technique known as double dipping to remove the core in sections. Measure the cores to the nearest 0.25 inch and inspect them in the field for evidence of defects such as alkali-silica reaction (ASR).

Figure 3-10 Typical Coring Operation

3-5.1.3 Pavement Drilling.

Impact or rock drills are commonly used for contingency pavement evaluations because they have a smaller logistics footprint. Drill 1- to 1.25-inch (25- to 32-millimeter) -diameter holes through bound materials or any layers impenetrable by a DCP. Pavement thickness is measured to the nearest 0.25 inch in the drill hole.

3-5.2 Dynamic Cone Penetrometer (DCP).

The DCP is a device used to determine the thickness and strength of the soil layers in a pavement structure. There are manual, semi-automated, and automated DCP variants but all apply the same principles to measure the depth of penetration for a known applied load to determine a DCP index (in. or mm / blow). The DCP index is empirically correlated to CBR, k, or modulus.

3-5.2.1 DCP Description.

The four main components of the DCP are the 0.79-inch (20-millimeter) -diameter 60-degree cone, the rod, the anvil, and the 17.6-pound (7.98-kilogram) hammer, as described in ASTM D6951, *Standard Test Method for Use of the Dynamic Cone Penetrometer in Shallow Pavement Applications*. The cone is driven into the ground by raising and dropping a hammer 22.6 inches (575 millimeters) against the anvil. The manual hand-held version shown in Figure 3-11 is portable, requires the hammer be lifted manually, and the depth of penetration measurements be taken manually using an incremented measuring stick. The correct number and length of extensions in the field must account for the thickness of all bound layers or materials that cannot be penetrated by the DCP. The semi-automated version requires lifting the hammer manually but the depth of penetration is measured automatically using a magnetic rule, string potentiometer, or similar device, and the blow count and depth of penetration are saved in a data file.

The automated DCP (ADCP) has a mechanism for lifting the hammer to the prescribed height and releasing it, then recording the blow count and depth of penetration, which are saved in a data file. Figure 3-12 shows an example of a system that has both a core drill and an ADCP.

Figure 3-11 Schematic of DCP

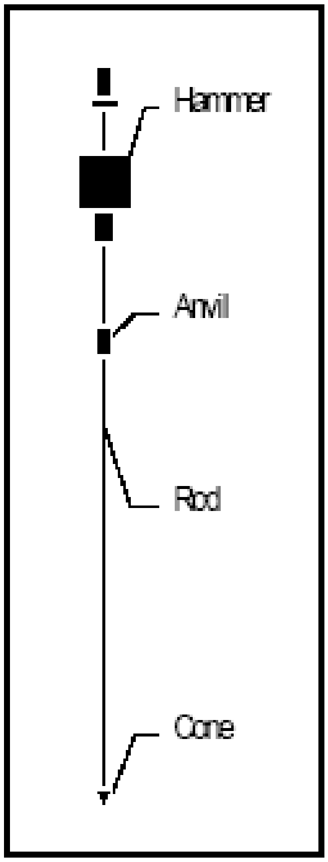


Figure 3-12 ADCP

3-5.2.2 DCP Test Procedure.

A 1-inch (25-millimeter) or 6-inch (152-millimeter) -diameter hole is drilled or cored through the pavement until the top of the base or subgrade is encountered. The rod with the cone attached is placed in the hole until it is in contact with the soil, then the hammer is raised and dropped and the depth of penetration recorded. The standard test is designed to penetrate soils to a depth of 48 inches (1219 millimeters) from the top of the pavement, although extension kits can go deeper, with a maximum recommended depth of 6.5 feet (2 meters). Testing is normally done to 36 inches (914 millimeters) in contingency evaluations. Once the DCP test is completed, the DCP is removed from the hole and soil samples for lab testing can be taken using a hand auger. Detailed test procedures and correlations for using the DCP and ADCP are provided in TM 3-34.48-2, *Theater of Operations: Roads, Airfields, and Heliports - Airfield and Heliport Design*.

3-5.3 Test Pits.

Test pits are seldom used for evaluations due to the number of tests required to characterize an entire airfield and the time it takes to open the pit and conduct testing, both of which typically have a significant impact on the mission. They are used more frequently for geotechnical work associated with a project or when doing forensic analysis to determine the cause of a pavement failure. Test pits provide greater opportunity to collect more pavement samples and larger soil samples for testing. An alternative to test pits is a minimum of three core holes up to 8 inches (203 millimeters) in diameter to permit in-place small aperture CBR tests and obtain samples for laboratory tests. The size of the test pits and some test procedures vary between flexible and rigid pavements. Following are descriptions for both pavement types.

3-5.3.1 Test Pits for Flexible Pavements.

Test pits for flexible pavements are approximately 4 feet (1 meter) wide by 5 feet (1.5 meters) long. Whether doing a full test pit or core holes for small aperture CBR testing, record the general condition of the pavement and a visual classification of materials from each test pit or core hole. Take several measurements around the perimeter of the test pit or core hole to determine the representative pavement thickness to the nearest 0.25 inch. For each test pit, perform CBR and field density tests on the base and collect disturbed and undisturbed soil samples of the base material for laboratory testing. Remove the remaining base material and measure the thickness of the base at several locations around the perimeter to determine the representative base thickness to the nearest 1 inch. Repeat this process for each subbase and the subgrade. Describe each soil course, noting color, in situ conditions, texture, and a visual classification. Sampling procedures, test descriptions, and testing references are included in Appendix A.

3-5.3.2 Test Pits for Rigid Pavements.

Test pits for rigid pavements are a minimum of 4 feet by 5 feet (1 meter by 1.5 meters), although the size of the test pits for rigid pavements depends, in part, on the thickness of the pavement because the length of the beams for flexural strength tests cut from the slab must be at least three times the pavement thickness, except when 6-inch by 6-inch (152-millimeter by 152-millimeter) beams are cut from the top and bottom of the slab for a three-point beam test. Record the general condition of the pavement and a visual classification of materials from each test pit. Take several measurements around the perimeter of the test pit to determine the representative pavement thickness to the nearest 0.25 inch. For each test pit, perform a plate bearing test, field density tests and, in some cases, CBR testing on the base. Collect disturbed and undisturbed soil samples of the base material for laboratory testing. Remove the remaining base material and measure the thickness of the base at several locations around the perimeter to determine the representative base thickness to the nearest 1 inch. Repeat this process (without the plate bearing test) for each subbase and the subgrade. Describe each soil course, noting color, in situ conditions, texture, and a visual classification. Sampling procedures, test descriptions, and testing references are included in Appendix A.

CHAPTER 4 TRAFFIC

4-1 TRAFFIC DEFINITION.

A fundamental component of pavement evaluation is the traffic concept. Traffic is the mix of different aircraft types, loads, and number of passes used for the evaluation analysis. This group of aircraft defines the anticipated applied stress and number of stress repetitions the pavement will experience. Traffic is applied in the analysis procedures in different ways, depending on the Service and mission. Following is a summary of traffic terms and concepts and the various ways traffic is defined in an evaluation.

4-1.1 Traffic Pattern.

Traffic pattern is a term used to describe one or more aircraft or ground vehicles, with the weight and number of passes defined for each. The term traffic pattern is often used interchangeably with traffic mix and aircraft group when the loads and passes are defined for the aircraft in the group.

4-1.2 Traffic Mix.

Traffic mix is a term used to describe one or more aircraft or ground vehicles with the weight and number of passes defined for each. The term traffic mix is often used interchangeably with traffic pattern and for aircraft group when the loads and passes are defined for the aircraft in the group.

4-1.3 Aircraft Group.

An aircraft group is a collection of one or more aircraft organized by a specific criterion (e.g., pavement effect, gear type, or mission). When the load and passes are defined for each aircraft in the group, the term is synonymous with the term traffic pattern or traffic mix.

4-1.4 Representative Aircraft.

An aircraft in an aircraft group that is representative of the group based on a specified criterion such as gear configuration, weight, or a combination of these that defines the effect on the pavement for that group.

4-1.5 Controlling Aircraft.

The controlling aircraft is used in a mixed traffic analysis. In design, it is the aircraft in the traffic mix that requires the greatest pavement thickness. In evaluation, it is the aircraft with the fewest allowable passes.

4-2 AIRCRAFT PASSES.

Passes are defined as the number of aircraft movements across an imaginary transverse line placed within 500 feet (152 meters) of the end of the runway. Since touch-and-go aircraft operations will not pass this line, they are not counted. For taxiways and aprons, passes are determined by the number of aircraft movements across a line on the primary taxiway that connects the runway and the parking apron. At single-runway airfields with a parallel taxiway, the pass levels for the runway, taxiway, and apron could be the same, but passes can vary based on the airfield configuration as shown in Figures 4-1 through 4-4.

Figure 4-1 Takeoff and Land in Same Direction with No Back Taxiing

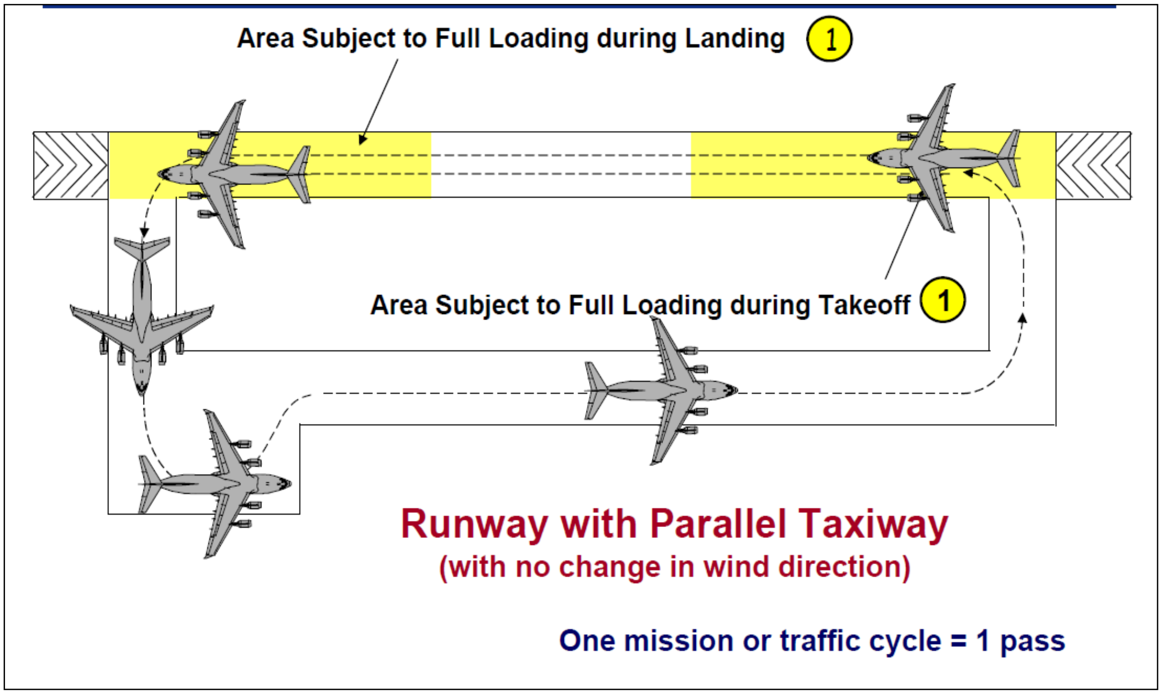

Figure 4-2 Takeoff and Land in Opposite Directions with No Back Taxiing

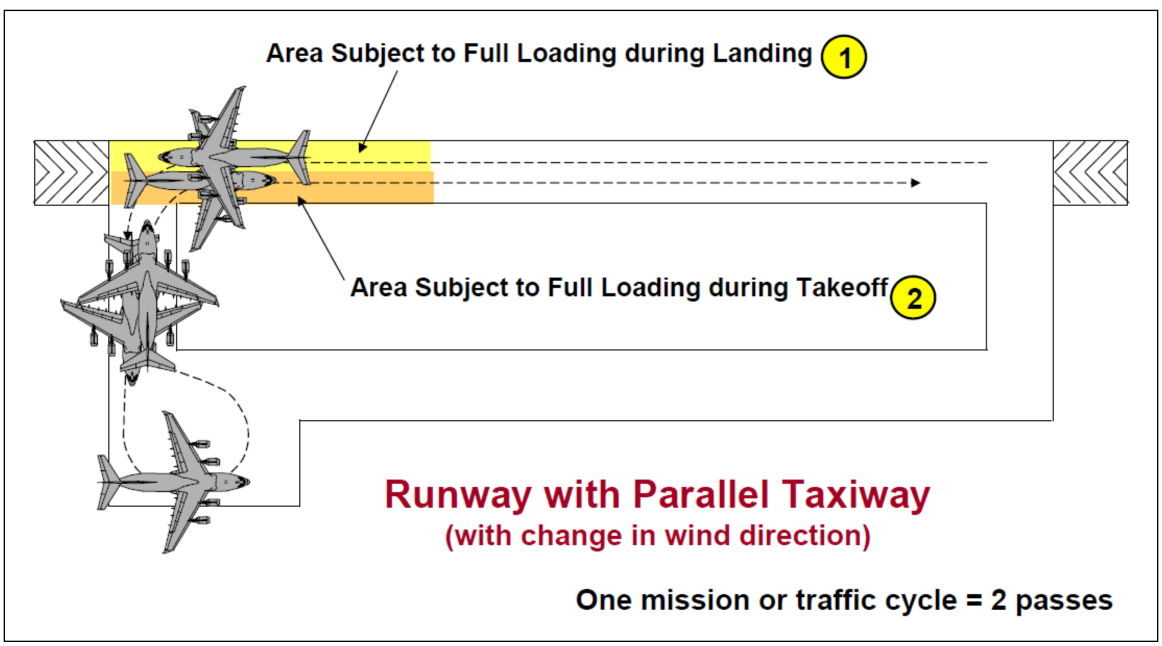

Figure 4-3 Takeoff and Land in Same Direction with Back-Taxiing

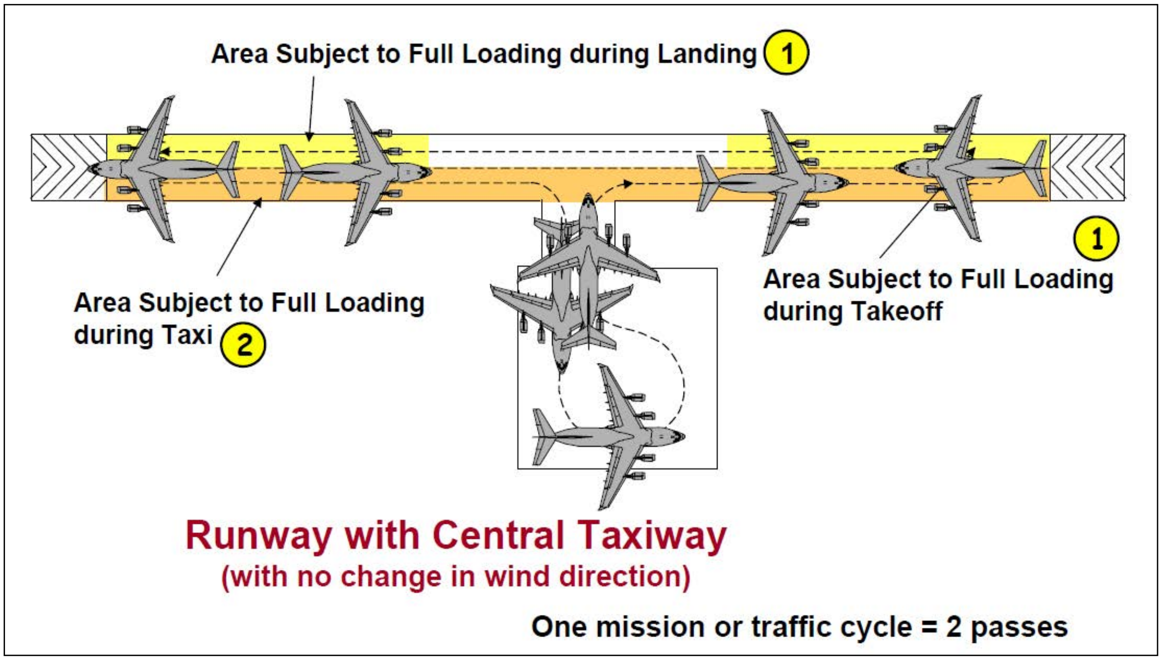

Figure 4-4 Takeoff and Land in Opposite Directions with Back-Taxiing

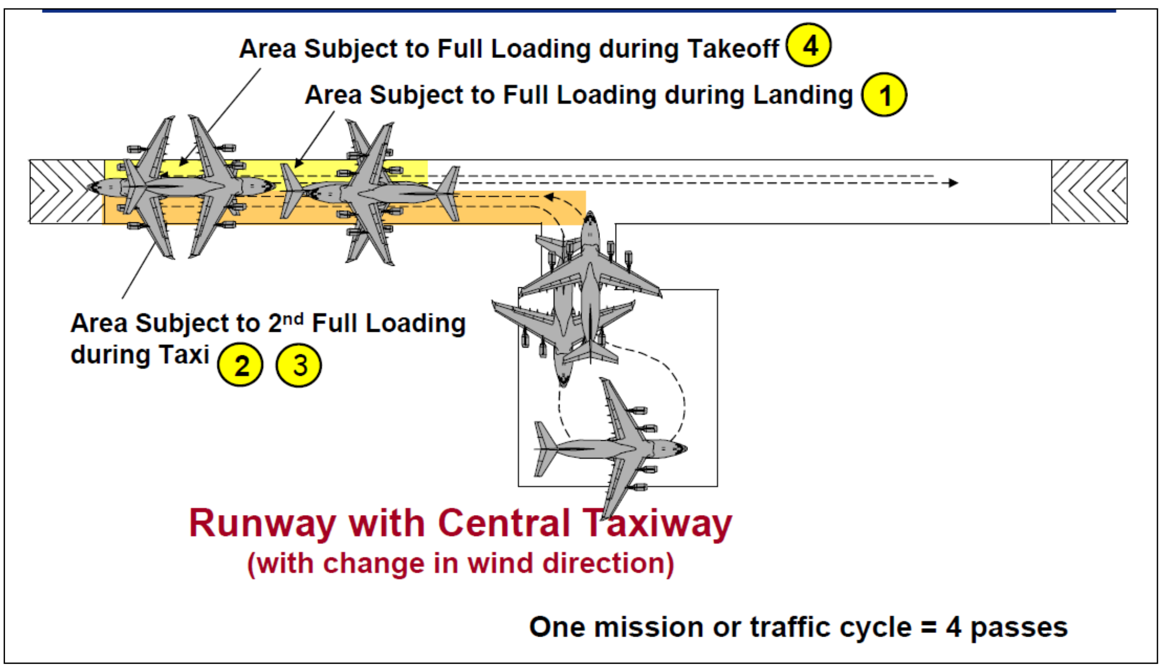

4-3 AIRCRAFT COVERAGES.

Passes are converted to coverages for analysis. Coverage is a term used to define the number of maximum stress repetitions that occur in a pavement due to aircraft operations. For flexible pavement, a coverage occurs when every point on the pavement surface within the traffic lane has been subjected to one application of maximum stress by operating aircraft. For rigid pavement, a coverage occurs when each point in the pavement within the limits of the traffic lane has been subjected to a maximum stress by operating aircraft. Maximum stress is the stress induced in the pavement by the aircraft wheels when the aircraft is operating at its maximum gross weight. An important point is that the surface criteria (AC and PCC) are based on coverages to failure, while the subgrade criteria are based on repetitions to failure. The lateral distribution of traffic has a greater effect on the number of maximum stress applications that occur at a point near the surface than for a point deep within the pavement structure (ERDC Miscellaneous Paper S-73-56, *Lateral Distribution of Aircraft Traffic*). A coverage is a function of gear configuration and tire width as well as the traffic area, so the pass/coverage (P/C) ratio varies for each aircraft and for each traffic area. The Pavement-Transportation Computer Assisted Structural Engineering (PCASE) application implements the P/C ratio concept for rigid and flexible pavement design and evaluation. These ratios are shown in TSPWG M 3-260-03.02-19.

4-4 TRAFFIC AREA.

The traffic area defines the wander width and load condition on specific portions of the airfield.

4-4.1 Wander Width.

Wander width is defined by whether aircraft traffic is close to the centerline of the runway or taxiway or whether they tend to deviate from the centerline. The first scenario is known as channelized traffic and is used when 75 percent of traffic occurs within ±35 inches (889 millimeters) from the center line for a runway or taxiway (a 70-inch [1778-millimeter] wander width). The second scenario is known as unchannelized traffic, which is used when 75 percent of traffic occurs within ±70 inches (1778 millimeters) from the centerline of a runway, taxiway, or apron (a 140-inch [3556-millimeter] wander width). The pass-to-coverage ratio for a given aircraft is lower for channelized traffic than for unchannelized traffic.

4-4.2 Load Condition.

An aircraft is typically fully loaded as it moves from the apron onto the taxiway and to the runway end. As the aircraft takes off, the wings provide lift and the interior portion of the runway is not typically experiencing the full aircraft weight. As an aircraft lands, the wings are still providing lift until the aircraft comes to taxi speed at the end of the runway, onto the taxiway and then to the apron. When the airfield configuration requires back-taxiing, as seen in Figures 4-3 and 4-4, the pavement will experience the full weight of the aircraft.

4-4.3 Traffic Area Designations.

Table 4-1 summarizes the wander width and load condition of the different traffic areas. Details are available in UFC 3-260-02, *Pavement Design for Airfields*.

Table 4-1 Traffic Area Summary

Traffic Area	Load Condition	Distribution	Usage
A	Full weight	Channelized	Runway ends and primary taxiways
B	Full weight	Unchannelized	Aprons
C	75% weight	Unchannelized	Runway interiors and secondary taxiways
D	75% weight	Unchannelized and 1% of passes	Overruns

4-5 STANDARD VERSUS MISSION AIRCRAFT TRAFFIC.

There are three approaches to defining the traffic mix used in an evaluation: standard aircraft traffic groups, mission aircraft traffic groups, and representative/mission aircraft groups. One or more of these approaches may be used for any given evaluation, depending on the Service and mission.

4-5.1 Standard Aircraft Groups.

In this approach, the Service defines a standard mix of aircraft types, weights, and passes for a standard aircraft traffic group based on its mission and operations. They are used for both design and evaluation, although these groups are different for each. Standard groups are used in design when the Service wants to address future uncertainty. For example, it is often difficult to predict future mission changes, aircraft loads and passes, and potential maintenance and repair (M&R) funding constraints over the design life of the pavement. Using a standard aircraft group reduces this risk. The same concept applies to evaluation and has the benefit of better evaluation results comparison between installations. Standard groups may be supplemented with specific aircraft for use in an area of operations or specific mission and often include the same aircraft at different loads.

4-5.1.1 Standard Aircraft Group by Aircraft Effect and Pass Level.

The standard 14-aircraft group in Table 4-2 has aircraft with a similar load effect on the pavement grouped together. This load effect is termed an index and each group has a designated controlling aircraft based on its gear configuration and load. Note that a given group can have more than one gear configuration as shown in Table 4-3. Each group has a minimum weight based on the unloaded weight of the lightest aircraft in the group and a maximum weight based on the fully loaded weight of the heaviest aircraft in the group. This standard aircraft group is used in an individual analysis procedure described in paragraph 4-6. Each of the 14 groups is analyzed at each pass intensity level. The primary benefit of this approach is that it can be used to consider the impact of a wide array of aircraft at different pass intensity levels and can be used to compare the capability of different installations for specific aircraft groups.

Table 4-2 14-Aircraft Group Index Table

Aircraft Group Index

Group	1	2	3	4	5	6	7	8	9	10	11	12	13	14

4-5.1.2 Standard Aircraft Group for Contingency Evaluation.

Table 4-4 shows an example of a standard aircraft group with aircraft that might operate at a forward operating location or en-route airfield. Each Service will have their own pattern, dependent on the mission requirements. The primary objective of this approach is to determine the allowable passes for each aircraft at the defined load. Note that the C-17 at 585,000 pounds is evaluated for 50,000 passes. In this example standard aircraft group, the C-17 is evaluated for 50,000 passes and the resulting allowable gross load (AGL) is used to determine the PCN. This concept is further discussed in Chapter 9.

Table 4-4 Contingency Evaluation Traffic Group

Aircraft	Load (lb)	Passes
C-5	840,000	1,000
E-3A	325,000	1,000
F-15D	68,000	1,000
KC-10	590,000	1,000
KC-135R/T	322,500	1,000
MV-22	60,500	1,000
C-130J	135,000	1,000
C-130J	155,000	1,000
C-130J	175,000	1,000
C-17	450,000	1,000
C-17	500,000	1,000
C-17	585,000	50,000

4-5.1.3 Standard Aircraft Group by Gear Type.

Table 4-5 shows a standard aircraft group categorized by gear types, with a defined representative aircraft for each group. This standard traffic group assumes the maximum load for the aircraft in each group but differs from the previous groups in that there are no predefined pass levels. This group is typically used in conjunction with the mission aircraft group for a specific location using the procedure described in paragraph 4-5.3.

Table 4-5 Aircraft Gear Type Groups

Single Tricycle	Dual Tricycle	Single-Tandem Tricycle	Dual-Tandem Tricycle	Triple Tandem Tricycle

T-44				
U-6				
UC-35				
Note 1: Designated representative aircraft for each group.				

4-5.2 Mission Aircraft Groups.

Mission aircraft groups are used for both design and evaluation and are based on the anticipated aircraft traffic at the specific airfield over the design life of the pavement, which is currently 20 years as defined in UFC 3-260-02. Note that different sections on an airfield can have different mission aircraft groups depending on the aircraft that use that specific section. It is not unusual to have two or more mission aircraft groups for any given airfield as shown in the example from a specific airfield in Table 4-6. The primary benefit of a mission aircraft group is that it gives a higher level of fidelity for managing pavements at that specific location but does not serve as well as the standard group when trying to compare evaluation results between installations. Mission aircraft groups are typically used with a mixed traffic analysis.

Table 4-6 Mission Aircraft Group Example

Aircraft	Gross Weight (lb)	20-year Projected Aircraft Passes	20-Year Equivalent PCC Passes	20-Year Equivalent AC Passes
Fixed-Wing Pavements				
C-9A	108,000	600	49	1
C-12J	16,600	1,100	1	1
C-130H	155,000	10,000	42	52
C-17A	585,000	6,300	6,300	6,300
C-23	24,600	800	1	1
C-26	16,500	340	1	1
Equivalent C-17 Passes at 585,000 lb			9,436	6,356
Rotary-Wing Pavements				
UH-60	16,300	6,700	283	3,954
AH-64	18,000	4,720	160	1,929
CH-47	50,000	4,820	4,820	4,820
MH-60	16,300	1,340	57	791
Equivalent CH-47 Passes at 50,000 lb			5,321	11,494
Fixed-Wing and Rotary-Wing Pavements				
CH-47	50,000	9,600	1	1
C-17	585,000	2,000	2,000	2,000
AH-64	18,000	19,000	1	1
C-130H	155,000	800	5	9
Equivalent C-17 Passes at 585,000 lb			2,475	2,011

4-5.3 Mission/Representative Aircraft Group.

The goal of this traffic approach is to determine the equivalent passes of the mission aircraft group in terms of each of the five representative aircraft gear-type groups listed in Table 4-5. The first step in achieving this goal is defining the aircraft and pass levels in the mission aircraft group for the specific location using the procedure in paragraph 4-5.2, then append this traffic mix with each representative aircraft from Table 4-5 that is not already included in the mission aircraft group, with each aircraft at full load and one pass. The next step is to use a mixed traffic analysis to determine the controlling aircraft in the group. Next, manually set the first representative aircraft gear type as the controlling aircraft and determine the equivalent passes. Repeat the process for each representative aircraft shown in Table-4-5.

This approach results in equivalent passes for each of the five representative aircraft. The equivalent passes will vary by section depending on the pavement type, subgrade category, and traffic area as described in paragraph 4-6.2. The load and equivalent passes for each of these patterns are used in the structural analysis procedure for each section. The intent of this approach is to get the fidelity of the mission traffic approach while facilitating comparison between installations. There may be specific instances where aircraft not represented in Table 4-5 would also be presented this way and there may also be sections or sites whose missions support aircraft significantly lighter than the representative aircraft. In these instances, only add the appropriate representative aircraft (up to three) that do not overload the pavement.

4-6 INDIVIDUAL VERSUS MIXED TRAFFIC ANALYSIS.

Both standard and mission traffic patterns can be used in an individual or mixed traffic analysis although a mixed traffic analysis is typically used for a mission traffic pattern. Individual or mixed traffic analysis can be used for either a conventional (APE) or layered elastic (LEEP) analysis.

4-6.1 Individual Traffic Analysis.

In an individual traffic analysis, each aircraft in the group is analyzed individually. The allowable passes for the specified aircraft load and the allowable load for the specified evaluation passes are computed irrespective of the other aircraft.

4-6.2 Mixed Traffic Analysis

In a mixed traffic analysis, the controlling aircraft is determined based on the pavement type (rigid or flexible), traffic area (defined above), subgrade category (see Table 4-7), and number of passes. The equivalent passes of each aircraft in the mix are determined in terms of the controlling aircraft and the equivalent passes for all aircraft are added together. The result is a controlling aircraft at a specified weight and number of equivalent passes that is used in analysis.

Table 4-7 Subgrade Category

Subgrade Category	Rating	Flexible (CBR %)	Representative CBR	Rigid (k pci)	Representative k
A	High	CBR ≥ 13	15	k ≥ 442	452.6
B	Medium	8 < CBR < 13	10	221 < k < 442	294.7
C	Low	4 < CBR ≤ 8	6	92 < k ≤ 221	147.4
D	Ultra Low	CBR ≤ 4	3	k ≤ 92	73.7

4-7 GEAR CONFIGURATIONS.

Early aircraft were primarily supported on two main landing gear wheels, referred to as “single” wheels. With the large increases in aircraft gross weights, landing gear have changed to twin (two per strut) wheel loadings, to twin-tandem (four wheel) loadings, and to more complex (16 and 24 main-gear wheels, extra “belly” gear) wheel support systems. The two main wheels of single-wheel aircraft are generally spaced far enough apart that there is no significant overlap of the distributed loads for even very thick pavement structures protecting weak subgrades. For twin wheels, however, and closely spaced tandem wheels or complex wheel groups, the patterns of distributed surface loadings at and near the bottom of pavement structures overlap so the intensities (pressures or stresses) combine between adjacent wheels. This combining effect of load intensities is greater as the adjacent wheels become closer. The aircraft gear configurations and nomenclature used by the Services are shown in Appendix C.

4-8 TIRE PRESSURE.

The intensity of stress at a given point in a flexible pavement is affected by the tire contact pressure, which, for large aircraft tires, is roughly equivalent to the inflation pressure. The major difference in stress intensities caused by variation in tire pressure occurs near the surface; consequently, the pavement surface and upper base-course layers are most seriously affected by high tire pressures. Current evaluation criteria outlined in this UFC and implemented in PCASE are based on constant tire pressure. Previous versions of UFC 3-260-03 had criteria based on constant contact area. This difference does result in changes to evaluation results.

4-9 MANAGING AIRCAFT TRAFFIC.

The goal in defining the anticipated load and passes for the aircraft in a traffic mix is to determine whether each pavement section can structurally support the traffic to accomplish the mission, typically for a defined period. When the evaluation determines the pavement is not structurally capable, there are several options for managing the traffic:

- Reducing the departure weights of one or more aircraft in the traffic mix
- Reducing the number of daily operations of some aircraft in the mix
- Decreasing the pavement service life and programming repairs

The first two options typically focus on large, heavy aircraft that can generate unacceptable amounts of structural damage. Structural damage is often sensitive to changes (5 percent or less) in the aircraft gross loads for heavier aircraft, so it is often more advantageous to restrict the operations of one to three heavy aircraft that typically cause 90 percent of the pavement fatigue damage rather than limiting day-to-day operations. Whether the focus is on using up the service life and performing timely repairs for each inadequate section or managing the traffic as in the first two options, color-coded structural and condition maps convey this information. Chapter 10 describes these report products in more detail.

CHAPTER 5 LAYERED ELASTIC PAVEMENT EVALUATION

5-1 PERFORMANCE CRITERIA.

5-1.1 Flexible Pavement Performance Criteria.

The flexible pavement structural evaluation procedure considers two performance criteria: cracking in the asphalt surface course by limiting values of the tensile strain at the bottom of the AC layer and rutting due to deformation in the subgrade by limiting values of the vertical strain at the top of the subgrade. The limiting performance criterion is typically the vertical strain at the top of the subgrade. There are cases where the tensile strain controls the allowable number of passes or allowable gross load (AGL) for thin asphalt surfaces (e.g., less than 3 inches [76 millimeters]), but this scenario could also exist for thicker AC layers when there are no bases or subbases, or these layers are weak.

5-1.2 Rigid Pavements Performance Criteria.

Performance criteria for rigid pavements are based on limiting the tensile stress in the PCC slabs such that failure occurs only after the pavement with has sustained many load repetitions. Failure is based on a SCI of 50 or 0, as discussed in paragraphs 3-3.4.2 and 5-3.9.1.3.

5-2 PAVEMENT RESPONSE MODEL.

The YULEA linear elastic modeling subroutine computes the pavement responses that implement the performance criteria in the Pavement-Transportation Computer Assisted Structural Engineering (PCASE) Layered Elastic Evaluation Program (LEEP) module. The following assumptions apply in YULEA.

5-2.1 Pavement Structure.

Pavement is a multilayered structure, with each layer characterized by its thickness, modulus of elasticity, and Poisson’s ratio. Layers are assumed to be homogeneous, isotropic, and extend infinitely in the horizontal direction.

5-2.2 Layer Interface.

The interface between layers is continuous, meaning the friction resistance between layers is greater than the developed shear force.

5-2.3 Bedrock Layer.

The bedrock layer is located 20 feet (6 meters) from the surface and is of infinite thickness. When geotechnical information indicates the depth to the bedrock layer is less than 20 feet (6 meters), adjust the depth to bedrock to the known depth.

5-2.4 Loads.

All loads are static, circular, and uniform over the contact area.

5-3 LAYERED ELASTIC EVALUATION PROCEDURE.

The layered elastic evaluation procedure is based on a layered linear elastic model that characterizes multilayer pavement systems as outlined above. It applies to flexible, plain concrete, plain concrete overlays, and non-rigid overlays on plain concrete pavements. Layered elastic criteria are not currently available for reinforced or fibrous pavements. Refer to Chapter 7 for methods to evaluate reinforced pavements. It uses layer properties determined from in situ measurements (at the time fieldwork is conducted) to compute allowable loads for a selected number of aircraft passes, allowable passes at a specified load, and the Pavement Classification Number (PCN). When the pavement structure cannot support the defined pass level and aircraft load, PCASE can determine overlay requirements to strengthen the pavement. More detailed information on the following procedure is available in the PCASE User Manual.

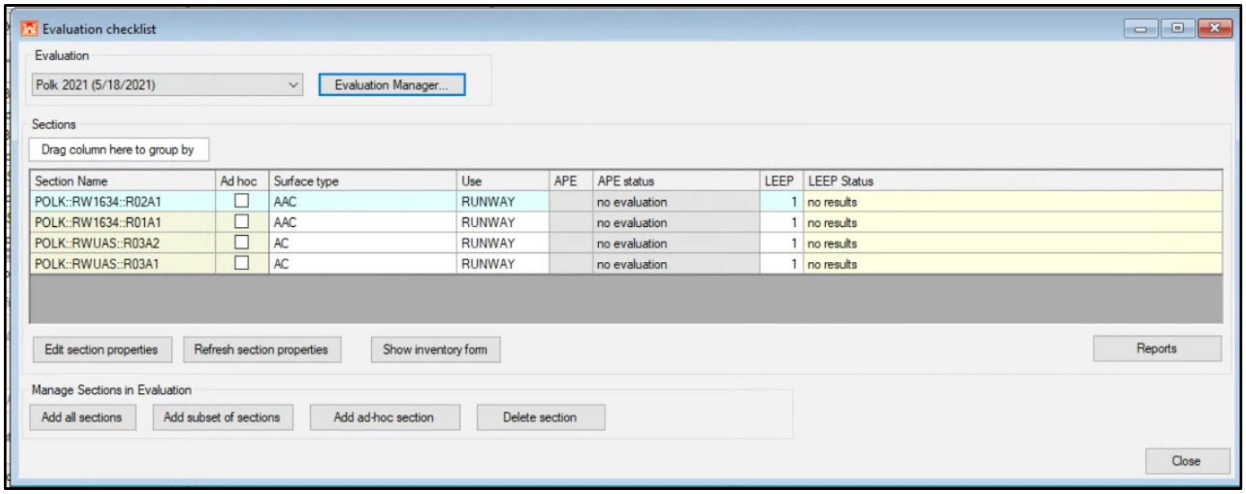
5-3.1 Layered Elastic Evaluation Using PCASE.

The Services use the PCASE application for design and evaluation of pavements (see Appendix E). Use the PCASE LEEP module to compute allowable loads, allowable passes, and PCNs using layered linear elastic evaluation criteria.

5-3.2 Step 1 – Create a New Evaluation.

Open the PCASE Evaluation Checklist to create a new evaluation using the Evaluation Manager. Define the Service, climate data, evaluation traffic, and rigid failure criteria for the evaluation, then assign the inventory sections to be included in the evaluation.

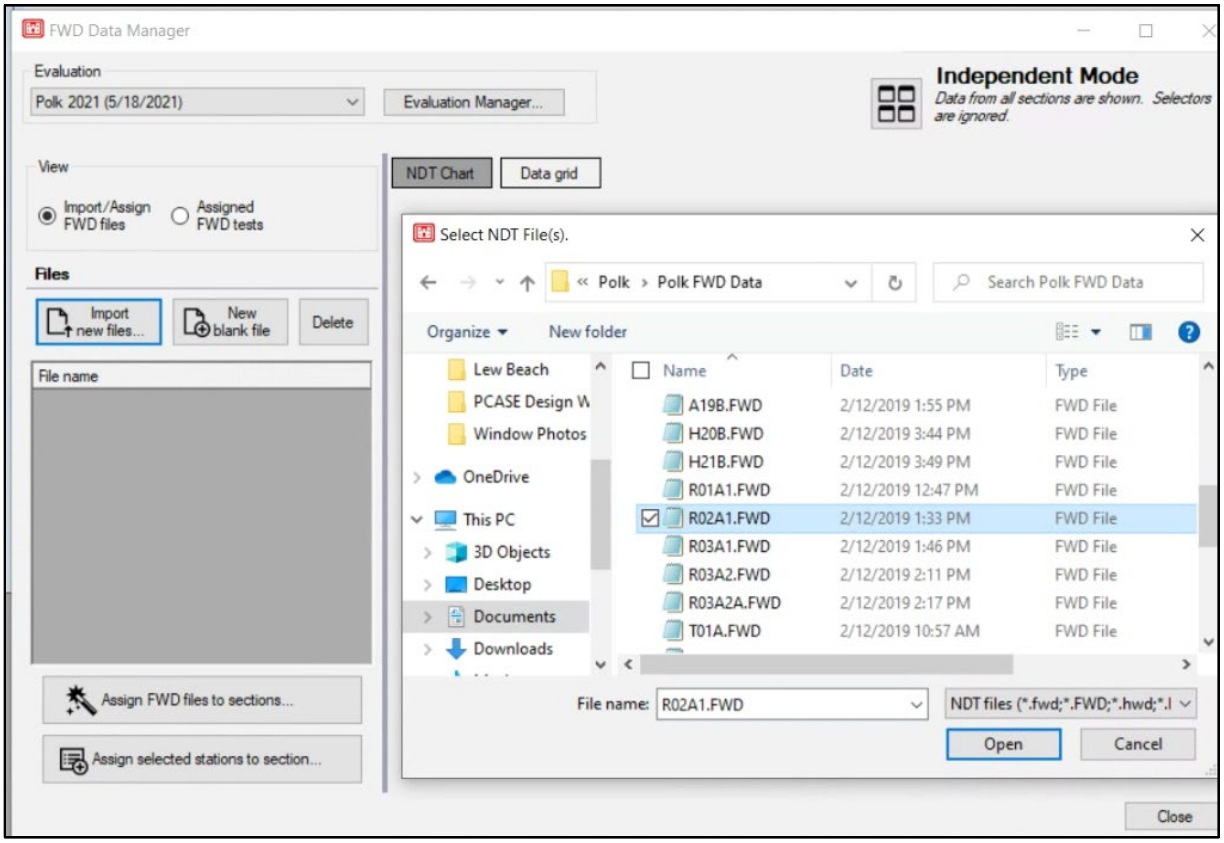
Figure 5-1 Evaluation Checklist



5-3.3 Step 2 – Import HWD Test Data.

Use the FWD Module to import the NDT files created during FWD testing (as described in Chapter 3) into PCASE.

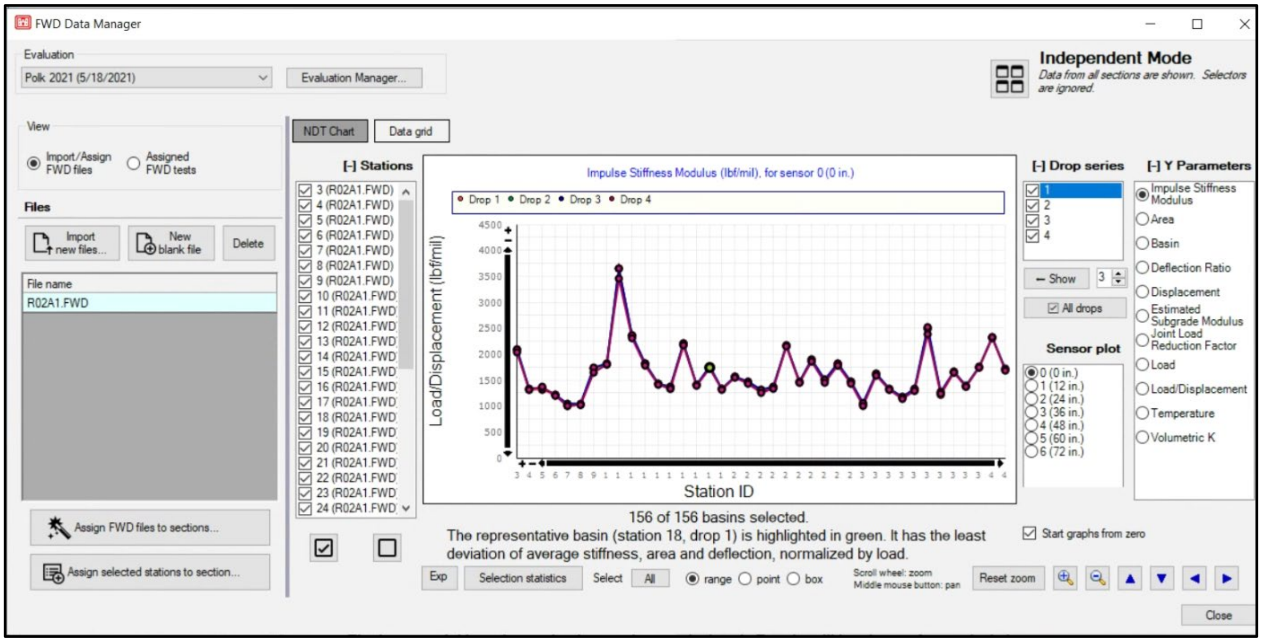
Figure 5-2 FWD Data Import



5-3.4 Step 3 - Assign Basins to Sections.

Each FWD test (each drop at each station) defines a deflection basin, which is viewed in PCASE as a two-dimensional plot, as shown in Figure 5-3. When the HWD file has data for an entire branch (e.g., an entire runway), use the FWD tool to “Assign selected stations to sections.” When all the stations in an HWD file were collected for a specific section, use the “Assign FWD files to sections” option.

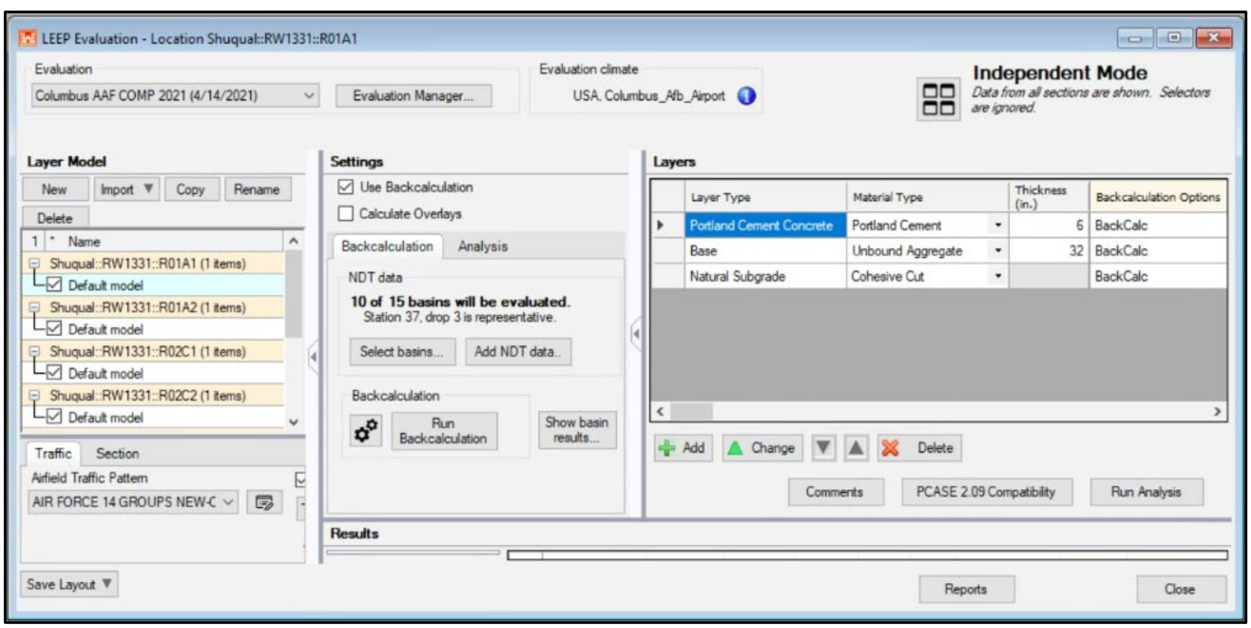
Figure 5-3 Assign FWD Files to Sections



5-3.5 Step 4 – Select Basins for Backcalculation.

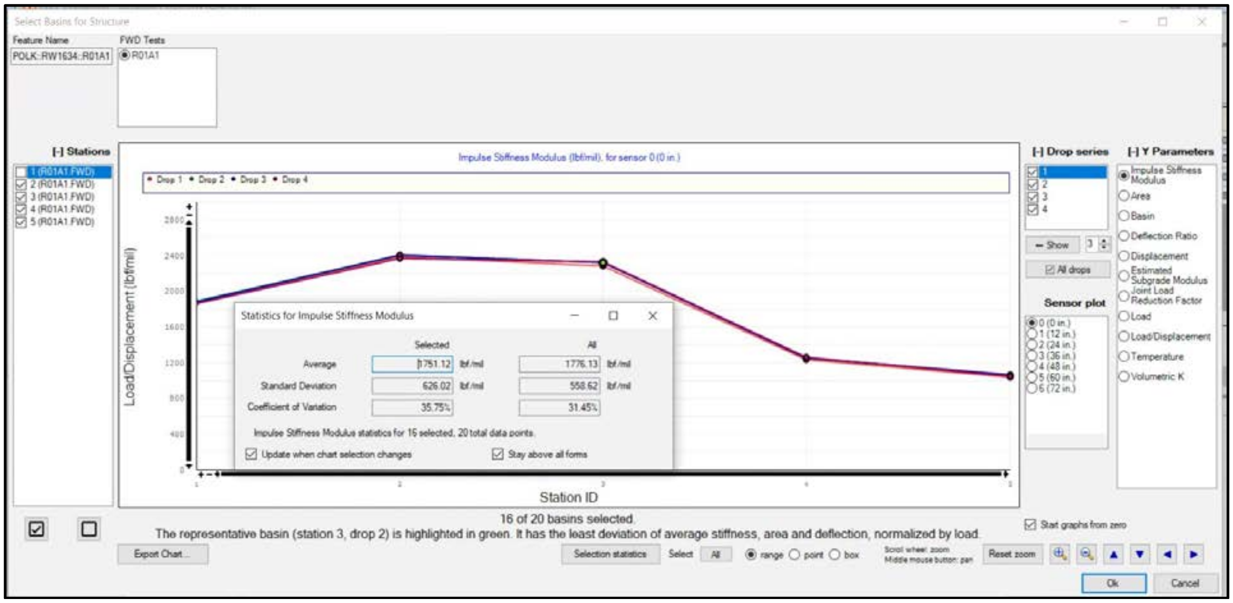
Open the LEEP module and use the Select Basins tool on the Settings tab to define the basins used in backcalculation.

Figure 5-4 Select Basins for Backcalculation



The Select Basins tool is like the NDT tool but only displays the basins for the section that is the current focus. Use the Selection Statistics tool to determine which basins to include or exclude from backcalculation. This tool displays statistics on the impulse stiffness modulus by default. Other views of the basin data are available including Area, Basin, Displacement, Estimated Subgrade Modulus, Load, Load Displacement, Temperature, and Volumetric K, Deflection Ratio, and Joint Load Reduction Factor (testing rigid pavement joints) as shown in Figure 5-5 and described in the following paragraphs.

Figure 5-5 FWD Analysis Parameters



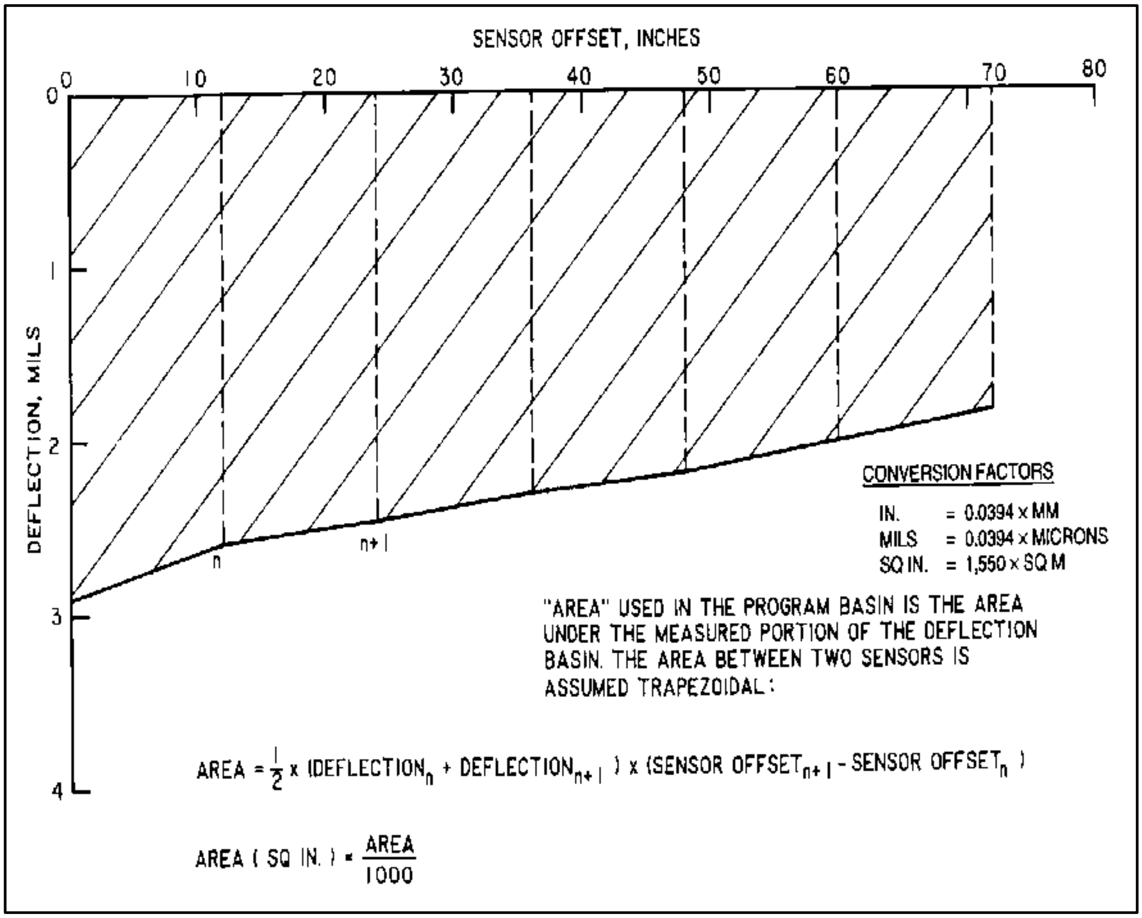
5-3.5.1 Impulse Stiffness Modulus.

The impulse stiffness modulus (ISM) is defined as the FWD force or load in kips divided by the deflection measured at the center of the load in inches. ISM values computed for the load-plate sensor (geophone) represent the overall strength of the pavement structure. These ISMs provide a quantitative stiffness comparison between test points and between pavement sections. The ISM values are plotted on the Y axis for each station (test point) in the section. This data is used to visually determine if a change in strength exists and define where sections change when the FWD file has basin data from multiple sections. Even when a pavement section has the same pavement type and construction, the ISMs measured in one area of the section can be statistically different from those in another area of the section. In this case, consider splitting the section. Ideally the Coefficient of Variation of the selected basins within a section should be less than 20 percent. PCASE also displays ISM values for the other sensors that can be used to compare the relative strength of the base, subbase, or subgrade at each NDT location.

5-3.5.2 Basin Area.

The AREA parameter displays the area of each deflection basin determined using the procedure illustrated in Figure 5-6. Only the hatched area (under the measured portion of the basin) is considered in this computation, and the area between two sensors is assumed trapezoidal. Selection Statistics for AREA displays the average deflection basin area for the section.

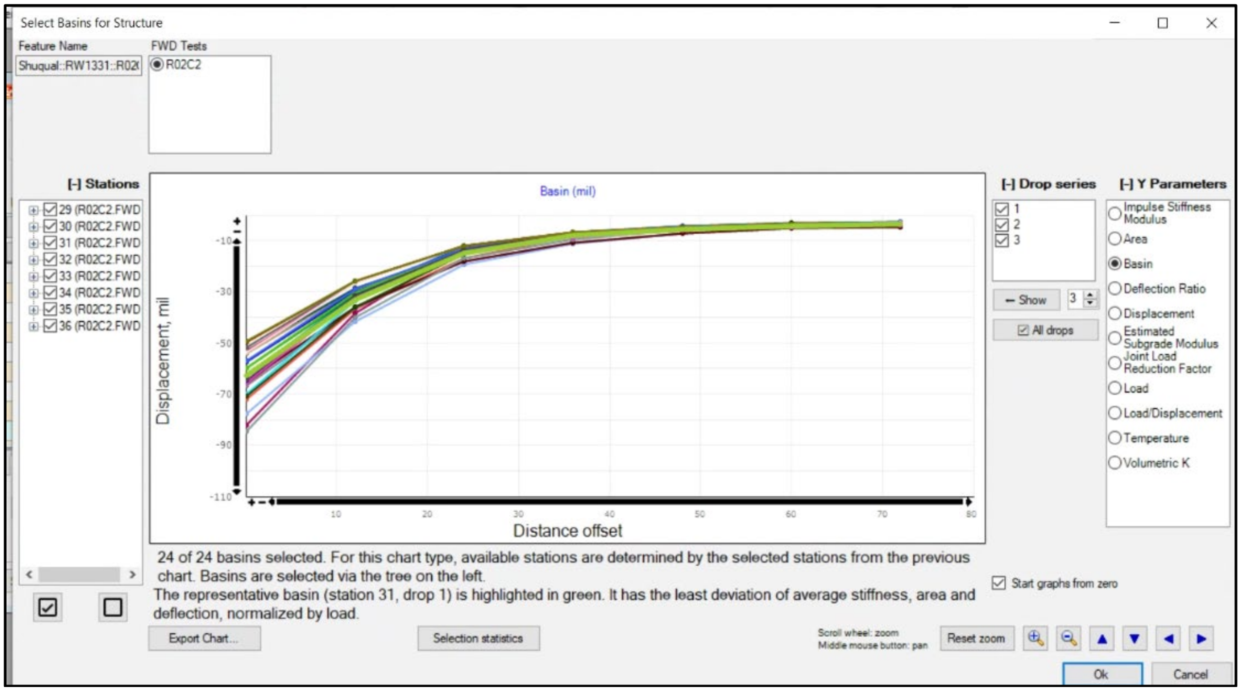
Figure 5-6 Determining AREA Beneath Deflection Basin



5-3.5.3 Basin.

The basin plot displays the deflection (in mils) on the Y axis for each sensor at its respective offset distance on the X axis. The plot provides a visual indication of the quality of the basin data. When the lines in the plot are well organized, as in the Figure 5-7 example, the data is likely good. When there are discontinuities in the data, such as varying basin shapes and crossing lines, the quality of the data is questionable.

Figure 5-7 Basins



5-3.5.4 Displacement.

Displacement plots show the sensor deflection (in mils) for each drop in the test series on the Y axis for each station on the X axis. Like the basin plot, this plot provides a visual indication of the quality of the data. Discontinuities such as lines crossing can indicate anomalies such as voids or delamination or indicate data quality issues.

5-3.5.5 Estimated Subgrade Modulus.

The estimated subgrade modulus is displayed on the Y axis for each drop in the series for each station in the section. The estimate is computed in Equation 5-1 using the deflection measured at the 72-inch (1829-millimeter) offset. These values are also used as the seed moduli for the subgrade layer in the backcalculation procedure.

Equation 5-1. Estimated Subgrade Modulus

$$E = 59{,}304.82\,(D72)^{-0.98737}$$

Where:

E = *subgrade modulus, psi*

D72 = *deflection measured at 72 inches (1829 millimeters) from the NDT load normalized to 25,000 pounds (11,340 kilograms)*

5-3.5.6 Load.

Load plots show the load (in lbf or kN/μm) for each drop in the test series on the Y axis for each station on the X axis. This plot provides a visual indication of the quality of the data. Discontinuities such as lines crossing can indicate data quality issues.

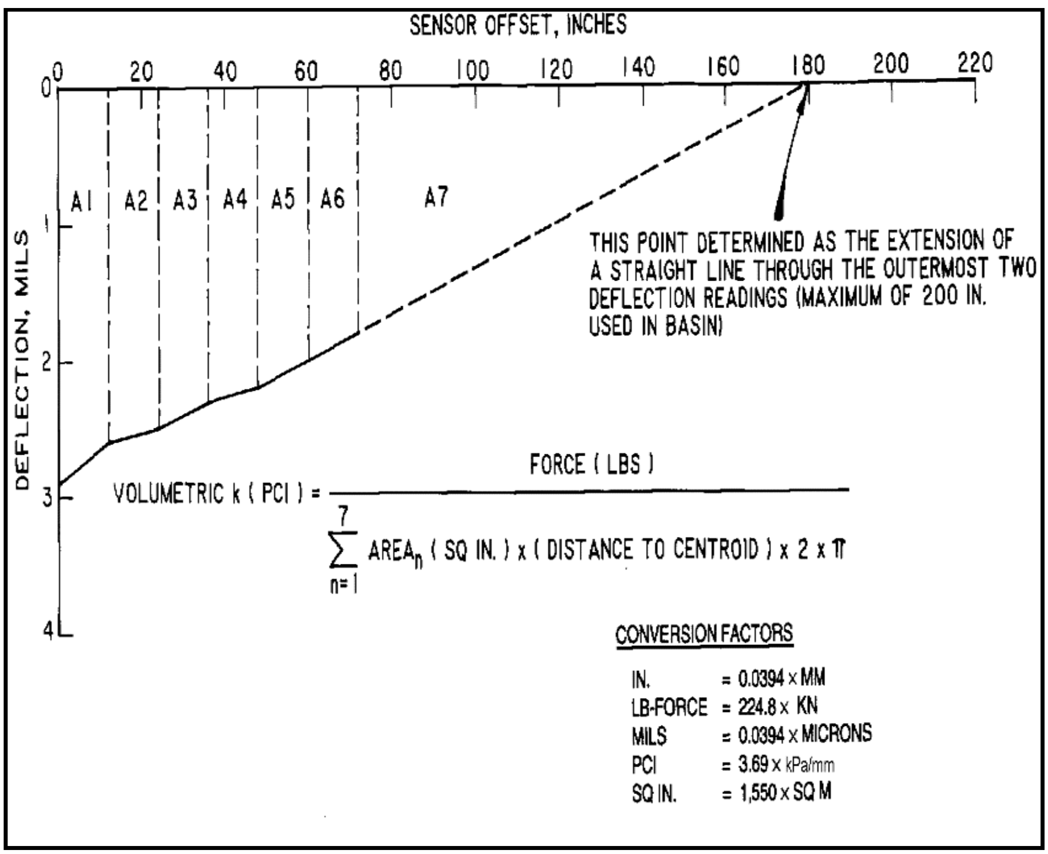
5-3.5.7 Temperature.

Temperature plots show the temperature (in °F or °C) on the Y axis for each drop in the test series for each station on the X axis. The air and the surface temperature are captured at the time of testing and the pavement temperature (at depth) is calculated.

5-3.5.8 Volumetric Estimation of k Value.

This procedure estimates the modulus of subgrade reaction, k, beneath rigid pavement, or rigid pavement with a flexible overlay. It computes the volume of the deflection bowl as illustrated in Figure 5-8. The k value obtained in this manner is only an approximate value that can be used for comparison with results from other test procedures such as plate bearing or dynamic cone penetrometer (DCP) tests used to determine k values. When no other test data to determine k is available, use the volumetric k in an airfield pavement evaluation (APE) analysis for comparison with the layered elastic analysis results. Note that volumetric k values are not typically sufficiently accurate to compute allowable aircraft loads and PCN values.

Figure 5-8 Determining Volumetric k (Estimate of Modulus of Subgrade Reaction)



5-3.5.9 Deflection Ratio.

The layered elastic rigid pavement analysis procedure assumes a 25 percent load transfer by default. Validate this assumption by testing joints with the FWD as described in more detail later in this chapter. The result of this test is used to compute the joint deflection ratio and, when results indicate, reduce the percent of load transfer. PCASE can also compute the deflection ratio between other sensors, but this capability is not typically used at this time.

5-3.5.10 Joint Load Reduction Factor.

The deflection ratio is used to determine and, when appropriate, adjust the load transfer percentage between slabs for the analysis. The Joint Load Reduction Factor is equal to one whenever the joint deflection ratio is greater than or equal to 0.76.

5-3.6 Step 5 – Layer Model and Backcalculation Options.

LEEP populates a default layer model for each section based on the pavement type, but the user must update the layer structure as shown in Figure 5-9 based on the data collected during fieldwork, including the type and thickness of each layer and the flexural strength (for PCC). In addition, the user can select different backcalculation options and edit the seed moduli used to initiate the backcalculation procedure as well as the lower (min) and upper (max) limits used in the procedure. Following are the backcalculation options for the various layer types.

Figure 5-9 Layer Model for Backcalculation

Layers

Layer Type	Material Type	Thickness (in.)	Backcalculation Options	Seed Modulus (psi)	Min Modulus (psi)	Max Modulus (psi)	Apply Limit
Portland Cement Concrete	Portland Cement	6	Flexural Strength	5,000,000	2,500,000	10,000,000	☑
Base	Unbound Aggregate	32	BackCalc	60,000	5,000	150,000	☑
Natural Subgrade	Cohesive Cut		BackCalc	9,132	4,132	14,132	☑

5-3.6.1 Backcalculation Option.

The Backcalculation option can be selected for any layer type. It uses estimated initial modulus values, a minimum, and a maximum modulus that are set for each layer but the number of backcalculated layers cannot exceed the number of measured deflections. Table 5-1 provides an example of typical default values used in PCASE that can be edited when test data is available. When the Apply Limit box is checked, the backcalculation routine keeps the solution within the limits and when it is unchecked, the backcalculation routine is not restricted by the limits for that layer.

Table 5-1 WESDEF Default Modulus Values (psi)

Material	Range		Initial Estimate	Poisson's Ratio
	Minimum	Maximum		
Asphalt concrete	100,000	2,500,000	350,000	0.35
Portland cement concrete	2,500,000	10,000,000	4,000,000	0.15
High-quality stabilized base	500,000	2,500,000	1,000,000	0.20
Base-subbase, stabilized	100,000	1,000,000	650,000	0.25
Base-subbase, unstabilized	5,000	150,000	61,000	0.35
Subgrade	1,000	75,000	15,000	0.40

5-3.6.2 Subgrade Seed Modulus.

The seed modulus for the subgrade is determined differently than other layer types. It is estimated using the deflection measured at the 72-inch (1829-millimeter) offset from the load using Equation 5-1. The maximum and minimum moduli are set to ±5,000 psi (34 MPa) respectively. This relationship is not valid when bedrock is present near the pavement surface (< 20 feet [6 meters]). In this case use the depth to bedrock estimation tool (for asphalt pavements) or other geotechnical information to adjust the depth to bedrock and determine a reasonable subgrade seed modulus.

5-3.6.3 Flexural Strength Option.

The Flexural Strength option uses Equations 5-2 and 5-3 to estimate the modulus value based on the flexural strength of the pavement.

Equation 5-2. Compressive Strength

$$C = 0.4036 * {M_R}^{1.4281}$$

Equation 5-3. PCC Layer Modulus

$$E = 57{,}000 * C^{0.5}$$

Where:

C = *Compressive strength, psi*

M_R = *Flexural strength, psi*

E = *Modulus of elasticity, psi*

5-3.6.4 Backcalculation Temperature Option.

This option adds the surface temperature at the time of testing to the previous five-day mean air temperature to determine the pavement temperature at depth as shown in Figure 5-10. Use this mean calculated mean pavement temperature to estimate the AC modulus using the relationship in Figure 5-11. The FWD or HWD device normally produces a load frequency at or near 20 Hz. The curves in Figure 5-11 are extrapolated from laboratory relationships for new AC mixes; therefore, predicted values may not always agree with actual field values.

Figure 5-10 Determining Mean Pavement Temperature

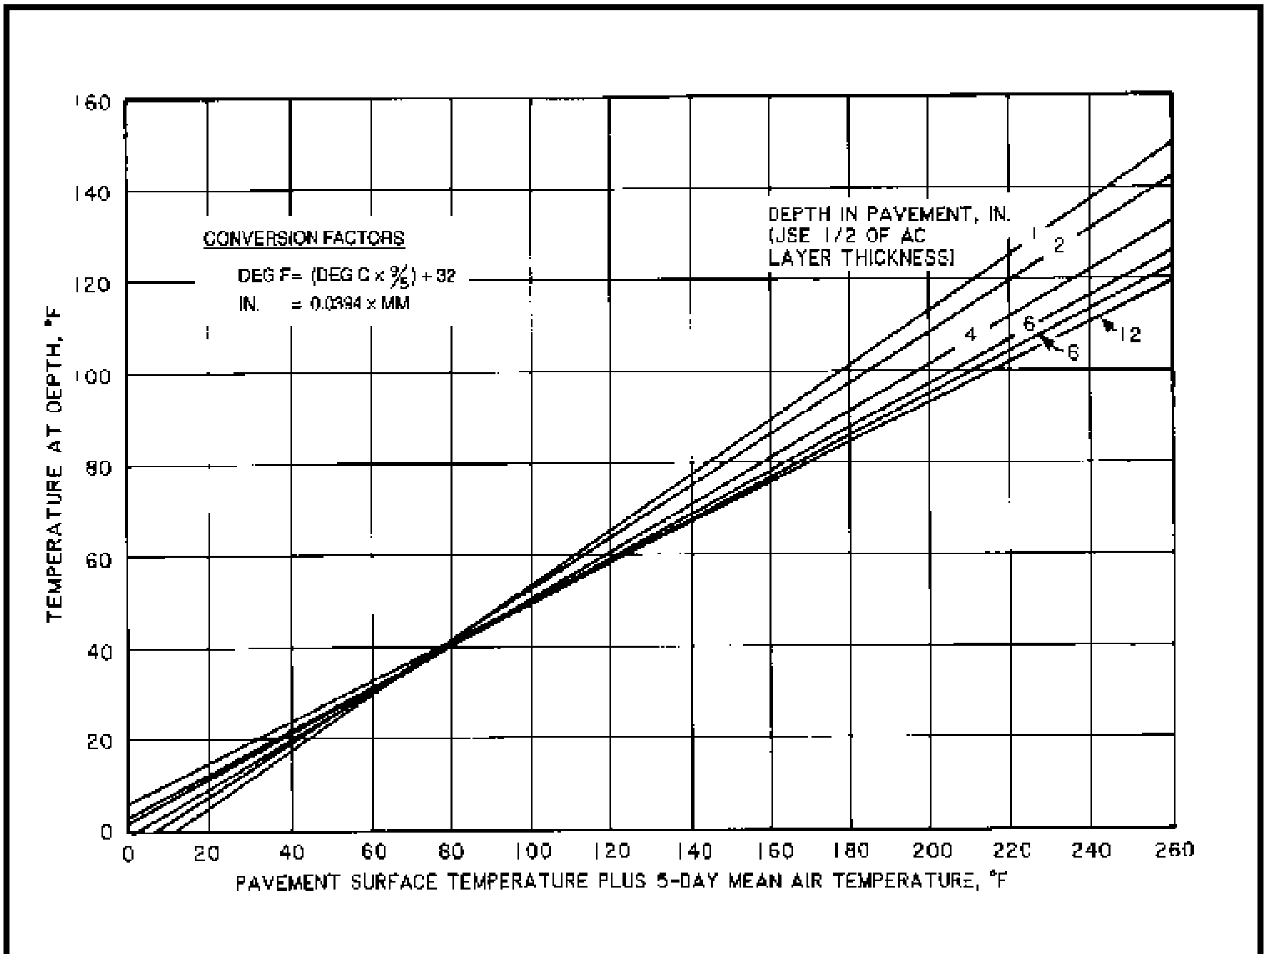


Figure 5-11 Predicting AC Modulus for Asphalt Layers

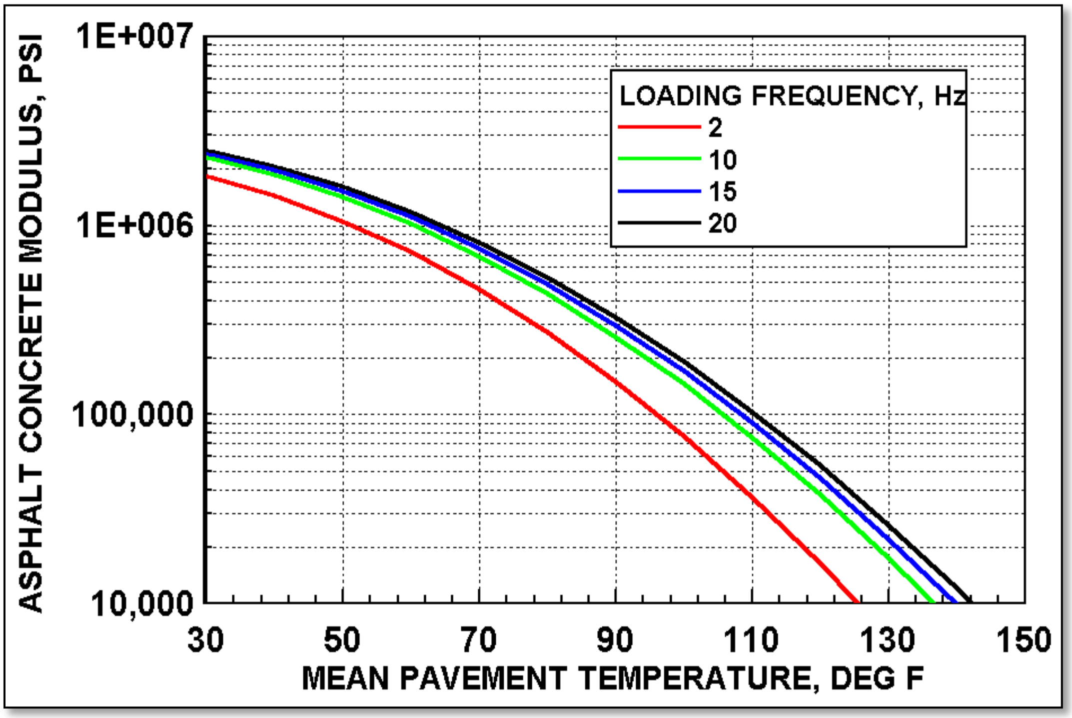


5-3.6.5 En+1 Option.

The E_{n+1} option uses the modulus of the layer below to estimate the base or subbase modulus using Equation 5-4 for base course and Equation 5-5 for subbase layers:

Equation 5-4. Base Course

$$E_{n+1} = E_n * (1.0 + 10.52 \log t - 2.1 \log E_n * \log t)$$

Where:

E_{n+1} = Modulus of base layer with a maximum value of 100,000 psi

E_n = Modulus of subbase or subgrade layer

t = Thickness of base layer

Equation 5-5. Subbase Layer

$$E_{n+1} = E_n * (1.0 + 7.18 \log t - 1.56 \log E_n * \log t)$$

Where:

E_{n+1} = Modulus of subbase layer with a maximum value of 40,000 psi

E_n = Modulus of subgrade layer

t = Thickness of subbase layer

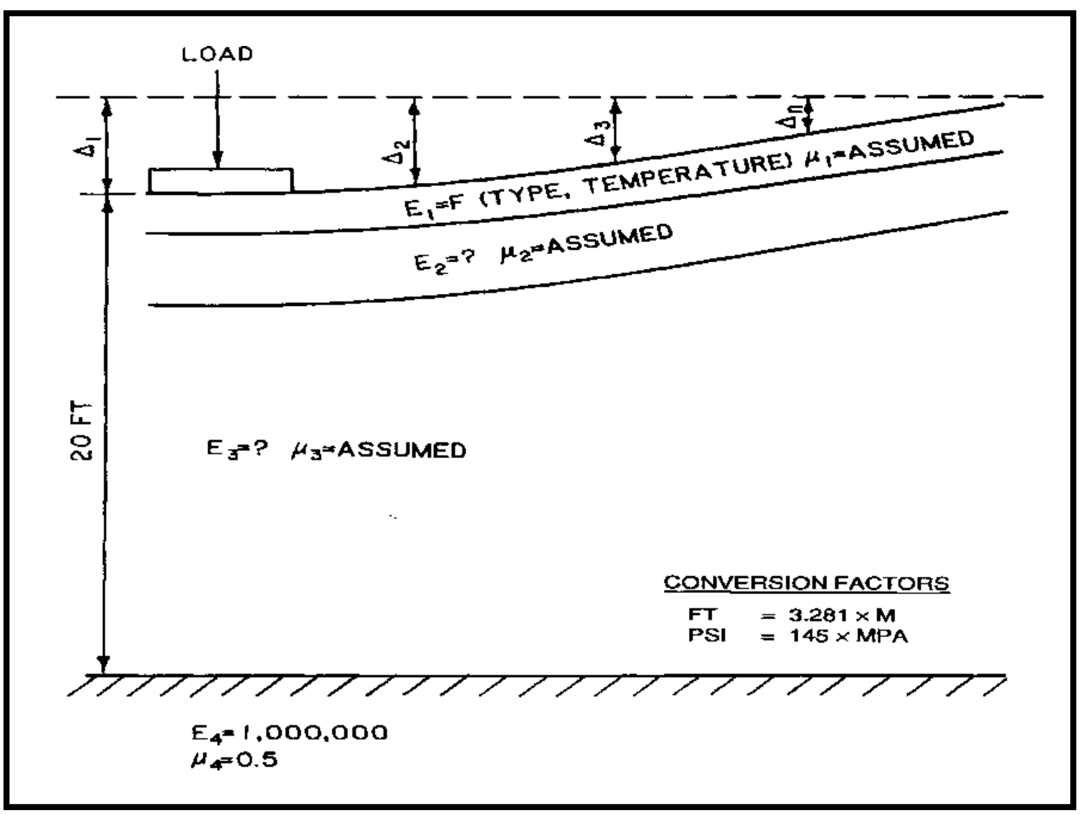
5-3.6.6 Manual Option.

Typically, the modulus of any layer can be backcalculated; however, when backcalculated results are erratic, assigning a modulus value to a base or subbase layer based on its material type or other tests (e.g., DCP) can resolve backcalculation issues. In general, use the backcalculation, flexural strength, or temperature options for surface layers. If the results are reasonable for all unbound layers but not surface layers, adjust the surface layer modulus in analysis rather than in backcalculation. Modulus values developed from the portable seismic pavement analyzer (PSPA) are also used for the surface layer modulus in analysis when this testing is performed.

5-3.7 Step 6 – Backcalculate Layer Modulus Values.

The deflection basin produced by applying a load to the pavement with an NDT device gives input parameters to the system analysis that are used to derive the relative strength parameters of the pavement layers. To determine modulus values, model the pavement structure as a layered system like that illustrated in Figure 5-12. PCASE uses the YULEA module to determine a set of modulus values that provides the best fit between a measured and a computed deflection basin when given an initial estimate of the elastic modulus values, a range of modulus values, and a set of measured deflections. The following paragraphs summarize the layered elastic modulus backcalculation routine.

Figure 5-12 Layered Pavement Structure



5-3.7.1 Backcalculation Objective.

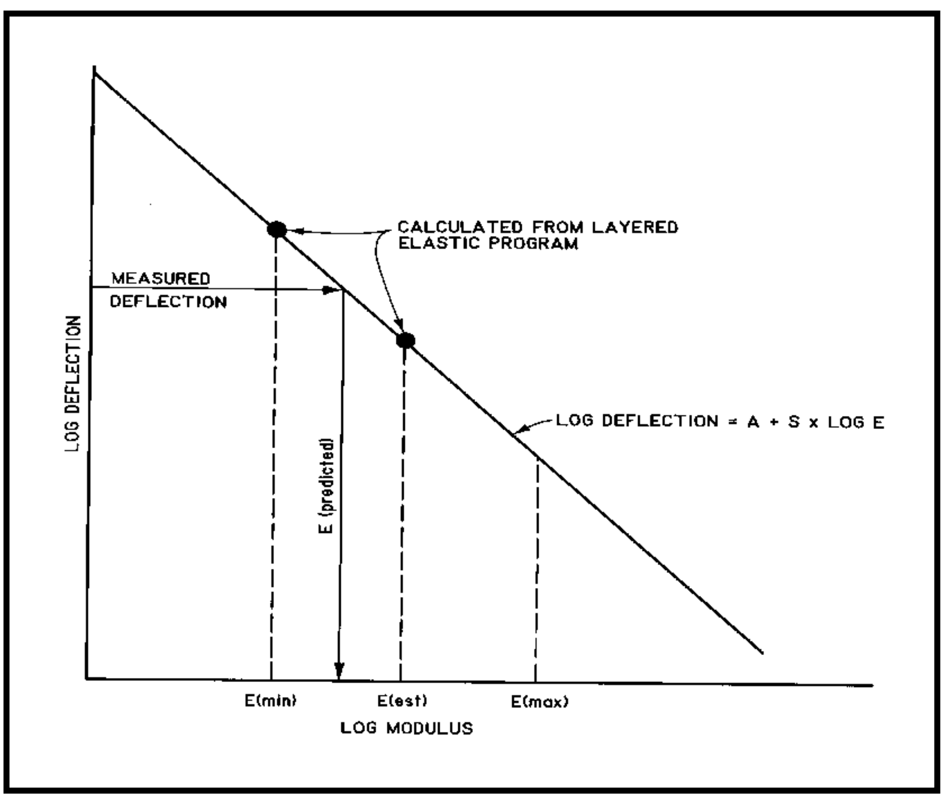
Consider the pavement system where:

- The modulus is unknown for a number of layers (NL).
- The deflection due to an NDT load is measured at a number of deflection sensors (ND).
- The number of deflection sensors (ND) is greater than the number of layers (NL).
- The objective is to determine the set of elastic moduli values that minimizes the error between the computed deflection (CD) and the measured deflection (MD).

5-3.7.2 Elastic Modulus Backcalculation from NDT Data.

Assume a set of E values and compute the deflection at the sensor location corresponding to the measured deflection. Vary each unknown E individually and compute a new set of deflections for each variation. Figure 5-13 presents a simplified description of how the deflection basins are matched. This illustration is for one deflection and one layer. For multiple deflections and layers, obtain the solution by developing a set of equations that defines the slope and intercept for each deflection and each unknown layer modulus using Equation 5-6.

Figure 5-13 Simplified Description of Matching Deflection Basins in YULEA (One Deflection and One Layer)



Equation 5-6. Backcalculated Layer Modulus

$$Deflection_j = A_{ji} + S_{ji}(\log E_i)$$

Where:
A = *intercept*
S = *slope*
j = *1 to the number of deflections*
i = *1 to the number of layers with unknown modulus values*

5-3.7.3 Depth to Bedrock Estimation.

PCASE assumes a stiff layer having a modulus of elasticity of 1,000,000 psi (6,895 MPa) and Poisson's ratio of 0.5 below the subgrade layer. This stiff layer defaults to a 20-foot (6-meter) depth and is infinitely thick. When modulus values for the subgrade seem excessively high for the material type, adjust the depth to bedrock using geotechnical information such as boring logs or the PCASE Depth to Bedrock tool for asphalt pavements that uses Equations 5-7 through 5-10 to estimate the depth of bedrock for each station and then uses equation 5-11 to determine the average depth to bedrock (see Report No. FHWA/TX-91/1123-3, *Modulus 4.0: Expansion and Validation of the Modulus Backcalculation System*)

Equation 5-7. Depth to Bedrock, Asphalt Thickness < 2 in.

$$\frac{1}{B} = 0.0362 - 0.3242r_0 + 10.2717r_0^2 - 23.6609r_0^3 - 0.0037BCI$$

Equation 5-8. Depth to Bedrock, Asphalt Thickness > 2, ≤ 4 in.

$$\frac{1}{B} = 0.065 + 0.1652r_0 + 5.42898r_0^2 - 11.0026r_0^3 - 0.0004BDI$$

Equation 5-9. Depth to Bedrock, Asphalt Thickness > 4, ≤ 6 in.

$$\frac{1}{B} = 0.0413 + 0.9929r_0 - 0.0012SCI + 20.0063BDI - 0.0778\log(BCI)$$

Equation 5-10. Depth to Bedrock, Asphalt Thickness > 6,

$$\frac{1}{B} = 0.0409 + 0.5669r_0 + 3.0137r_0^2 + 0.0033BDI - 0.0665\log(BCI)$$

Where:
$r_0 = {}^1\!/_r \ intercept\ by\ extrapolating\ the\ steepest\ section\ of\ the$
$\quad {}^1\!/_r\ vs.deflection\ curve\ \left({}^1\!/_{ft.}\ units\right)$
$SCI = D_0 - D_1\ (Surface\ Curvature\ Index)$
$BDI = D_1 - D_2\ (Base\ Damage\ Index)$
$BCI = D_2 - D_3\ (Base\ Curvature\ Index)$
$D_i = Surface\ deflection\ (inches\ 10^{-3})\ normalized\ to\ 9{,}000\ lb.load$
$\quad at\ an\ offset\ i\ in\ feet.$

Equation 5-11. Average Depth to Bedrock

$$D = \left[\frac{n}{\sum_{i=1}^{n} \frac{1}{B_i}}\right]$$

Where:

D = *Average depth to an apparent rigid layer in feet*
B_i = *Depth to the apparent rigid layer for the ith deflection bowl*
n = *Number of deflection bowls within one standard deviation of the mean 1/*B_i

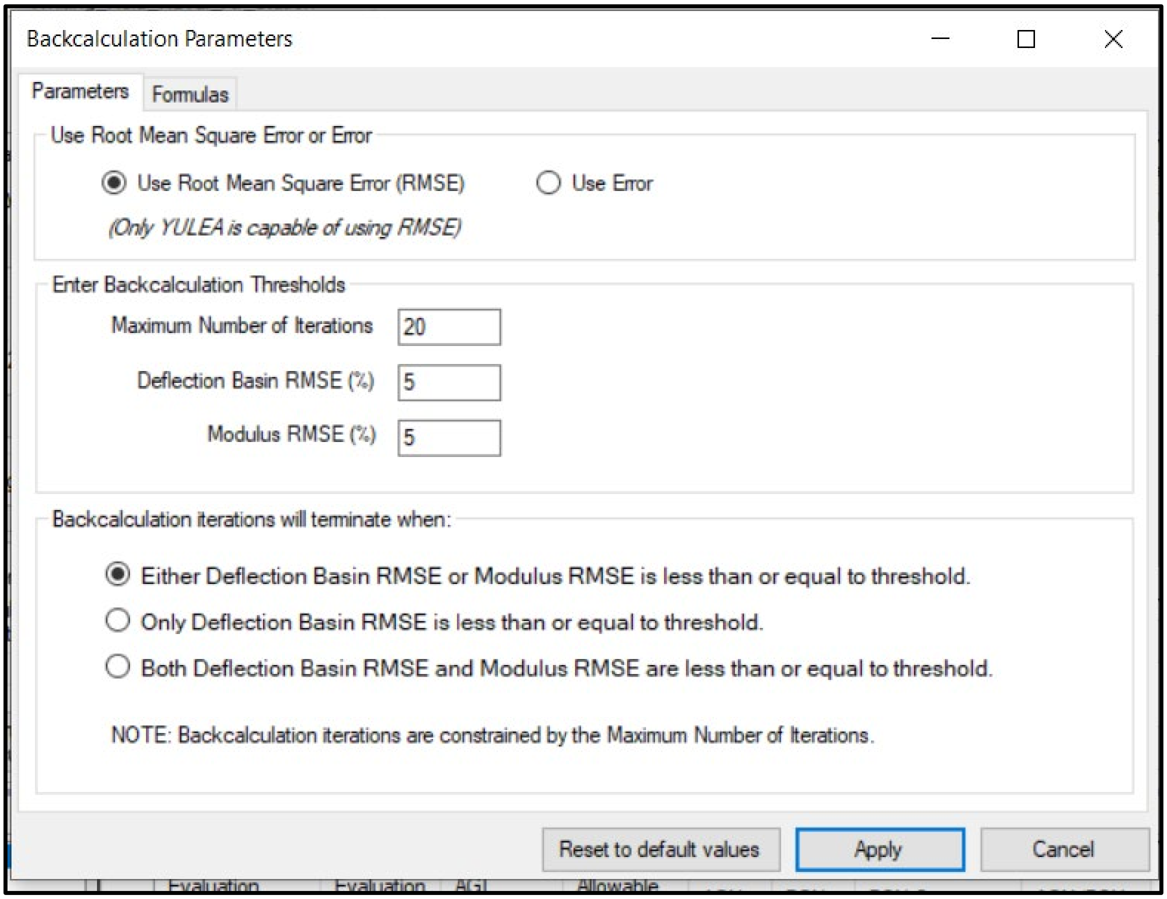
5-3.7.4 Layered Elastic Interface Conditions.

YULEA can accommodate multiple loads and variable interface conditions. For a given layer (n) and underlying layer (n + 1), set the interface value to "Fully Bonded" for complete adhesion between the layers or "Partially Bonded" for almost frictionless bond between the layers. The procedure assumes a partially bonded condition at the bottom of a PCC layer and a fully bonded interface condition for all other layers.

5-3.7.5 Backcalculation Procedure Closure.

PCASE allows the user to define the backcalculation procedure closure parameters. The user can choose whether the to use the Error (historically used by DoD) or Root Mean Square Error (RMSE) which is more commonly used in industry. The user can define the maximum number of iterations and the closure parameters, including the percent error (or RMSE) for the deflection basin (Equation 5-12) and the percent error (or RMSE) for the modulus (Equation 5-13). There are also options for defining the backcalculation termination parameters, including when both the basin and modulus error (or RMSE) are less than or equal to the thresholds, only the basin error (or RMSE) is less than or equal to the threshold, or either the basin or modulus error (or RMSE) is less than or equal to the threshold. The latter is the default setting. The maximum iterations defaults to 20, and both the basin and modulus error defaults to five percent as shown in Figure 5-14. When the backcalculation results meet the parameters for each basin, the procedure closes and presents the results. The targeted error for deflection basin and modulus is less than 3 percent after one or two iterations. Compare the results from the basin and modulus backcalculation methods to obtain optimum results with low standard deviations and low coefficients of variation. A coefficient of variation that is less than 15 percent is good but this statistic depends heavily on the variability of the pavement layer thicknesses, material types, and strength.

Figure 5-14 PCASE Backcalculation Closure Options



Equation 5-12. Basin RMSE

$$RMSE_{Deflection\ Basin} = 100 * \sqrt{\frac{\sum_i^n \left(\frac{D_{measured} - D_{computed}}{D_{measured}}\right)^2}{n}}$$

Where:

$RMSE_{Deflection\ Basin}$	= *Deflection basin root mean square error*
i	= *ith Sensor*
n	= *Total number of sensors*
$D_{measured}$	= *Measured deflection at sensor i*
$D_{computed}$	= *Computed deflection at sensor i*

Equation 5-13. Modulus RMSE

$$RMSE_{Modulus} = 100 * \sqrt{\frac{\sum_{i}^{n}\left(\frac{E_{i-1,j} - E_{i,j}}{D_{i-1,j}}\right)^{2}}{n}}$$

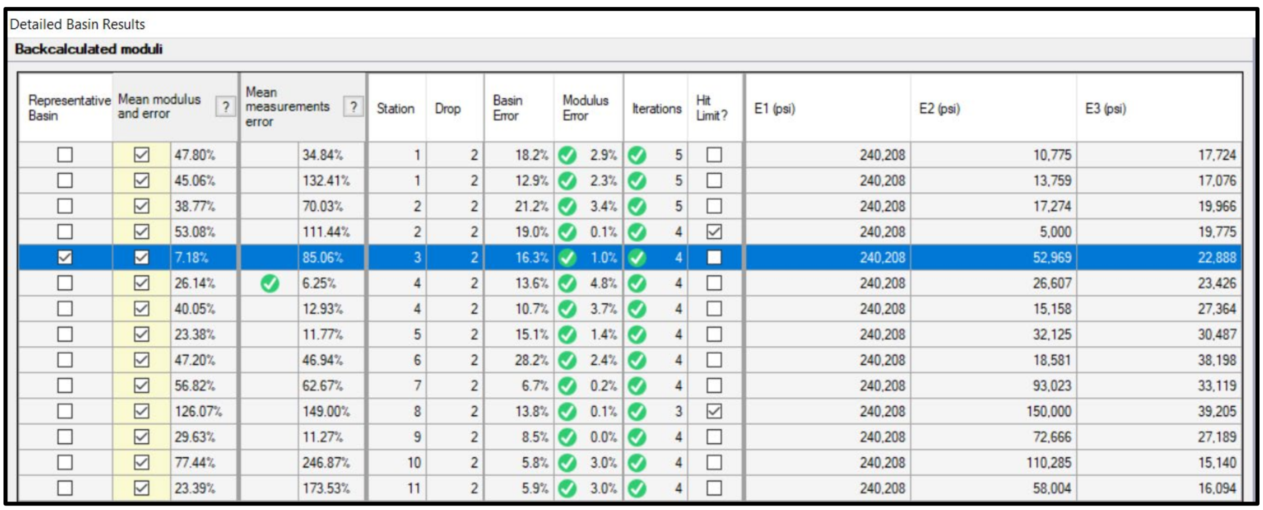
Where:

$RMSE_{Modulus}$ = *Modulus root mean square error*
i = *ith Iteration*
j = *jth Layer*
n = *Total number of layers*
$E_{i-1,j}$ = *Modulus from previous iteration for layer j*
$E_{i,j}$ = *Modulus for current iteration for layer j*
$D_{i-1,j}$ = *Deflection from previous iteration for layer j*

5-3.8 Step 7 – Select Layer Model for Analysis.

In addition to the basin and modulus error closure procedure described above and shown in Figure 5-15, PCASE provides several other statistics to aid in selecting a basin for layered elastic analysis. These include the representative basin (mean modulus error) (Equation 5-15) and the mean measurement error (Equation 5-16).

Figure 5-15 Detailed Basin Results



Detailed Basin Results
Backcalculated moduli

Representative Basin	Mean modulus and error ?		Mean measurements error ?		Station	Drop	Basin Error	Modulus Error		Iterations		Hit Limit?	E1 (psi)	E2 (psi)	E3 (psi)

5-3.8.1 Representative Basin.

PCASE determines the representative basin using Equation 5-14. It highlights the row for the basin with the lowest mean modulus error, which is based solely on the backcalculation results. The basin with the lowest error is sent to LEEP for analysis unless the user selects another basin (e.g., the basin with the lowest mean measurement error).

Equation 5-14. Mean Modulus Error

$$Error_k = \sum_{i=1}^{NL} \left(\frac{\bar{E}_i - E_i}{\bar{E}_i} \right)^2$$

Where:

$\bar{E}_i$	*= Average of the modulus of the i-th layer among all the basins 1 to k*
k	*= basin number*
NL	*= number of layers*

5-3.8.2 Mean Measurement Error.

The mean measurement error is computed using Equation 5-15 and is based solely on the FWD data, not the backcalculation results. The basin with the lowest error is indicated by a green circle with a white checkmark in the mean measurements error column as shown in Figure 5-15.

Equation 5-15. Representative Basin

$$Error_k = \left(\frac{\overline{ISM} - ISM_k}{\overline{ISM}} \right)^2 + \sum_{1}^{ND} \left(\frac{\overline{DF} - DF_k}{\overline{DF}} \right)^2 + \left(\frac{\overline{AREA} - AREA_k}{\overline{AREA}} \right)^2$$

Where:

ISM	*= computed ISM*
DF	*= measured deflection*
AREA	*= computed area*
k	*= basin number*
ND	*= number of deflection sensors*
$\overline{\mathrm{ISM}}$	*= average ISM*
$\overline{\mathrm{DF}}$	*= average deflection*
$\overline{\mathrm{AREA}}$	*= average basin area*

5-3.8.3 Basin Selection for Analysis.

Ideally, we want the basin and modulus error of closure (paragraph 5-3.7.5) to be below five percent, but there can be situations when one or both values exceed this threshold. In addition, having low errors for any of the statistics outlined above does not guarantee modulus values for the layers are reasonable. When results are not reasonable, adjust the model or backcalculation parameters as outlined in the following paragraphs and run backcalculation again. Select a basin with reasonable results for the material type even if the error is higher. Simply taking the average of each deflection reading from each FWD sensor and computing engineering properties from an “average deflection basin” is not a best-practices procedure. Each FWD test within a section represents a unique pavement response (e.g., deflection basin) for a unique pavement cross-section.

5-3.8.4 Backcalculation Analysis Guidelines.

Contributing factors that affect the reasonableness of results include errors between measured and calculated values, compensating adjacent layer E-values, or assigning inappropriate E-values. To overcome these issues, first identify the cause of the issue and do not make random changes to the structure. The following backcalculation guidelines are helpful in determining layer moduli.

- If modulus values are against the limits, turn off the limits and backcalculate again or modify the limits to include the computed elastic modulus. Results can come back within the original boundary conditions.
- Fix the modulus of an AC or PCC surface layer using the Temp or Flex option or based on tests conducted with the PSPA or on material type and condition at the time of testing rather than computing the modulus.
- Combine base and subbase into one layer and compute a composite modulus or divide the base course into two layers.
- Fix the subgrade modulus based on results of a preliminary run or on the deflection of sensor #7. In some cases, subdividing the subgrade into two layers is warranted.
- When a rigid pavement has a base and/or subbase, best practice is to include them in the model. However, if results are not reasonable, use a two-layer model with a composite modulus for the combined base and subgrade. Note that this can impact the PCN subgrade category in analysis.
- Do not attempt to compute the modulus of layers less than 3 inches (76 millimeters) thick. Assign the modulus of a thin layer based on material type, temperature, etc., or combine a thin layer with an adjacent layer with similar material properties to determine a composite modulus.
- Exercise caution when using modulus values outside the default ranges. Because the ranges are quite broad, values outside these limits can be unrealistic.

5-3.9 Step 8 – Layered Elastic Analysis.

The PCASE LEEP module uses YULEA to compute load-carrying capabilities and required overlay thicknesses for the defined traffic pattern (e.g., aircraft gear configuration, load, pass intensity level) on an existing pavement structure using layer moduli obtained through backcalculation or assigned based on one of the other previously described options. YULEA computes stresses (rigid and non-rigid overlay on rigid pavement) and strains (flexible pavement) that occur in the pavement system. Next, it calculates the limiting stress or strain values from empirically developed layered elastic values. LEEP compares the predicted stress or strain to the limiting value and outputs the allowable load for the defined pass level and allowable passes for the defined traffic (aircraft) load. The specific criteria and methodology are outlined below.

5-3.9.1 Analysis Criteria.

Maximum stresses and strains within a pavement system are computed using the controlling wheels of the design aircraft. The location of the maximum stress and strain value is influenced by factors such as pavement structure, wheel load, and wheel spacing. For a single wheel aircraft, the maximum stress and strain always occurs directly underneath the wheel. For other more complicated gear configurations, compute stresses and strains at several positions to determine the critical values. The PCASE LEEP module uses YULEA to determine the limiting values of stress/strain for a particular pavement type using the following.

5-3.9.1.1 AC Pavement Analysis Criteria.

The horizontal tensile strain at the bottom of the AC layer and vertical subgrade strain at the top of the subgrade are considered when evaluating flexible pavements. The limiting AC strain criterion (shown graphically in Figure 5-16) is as follows:

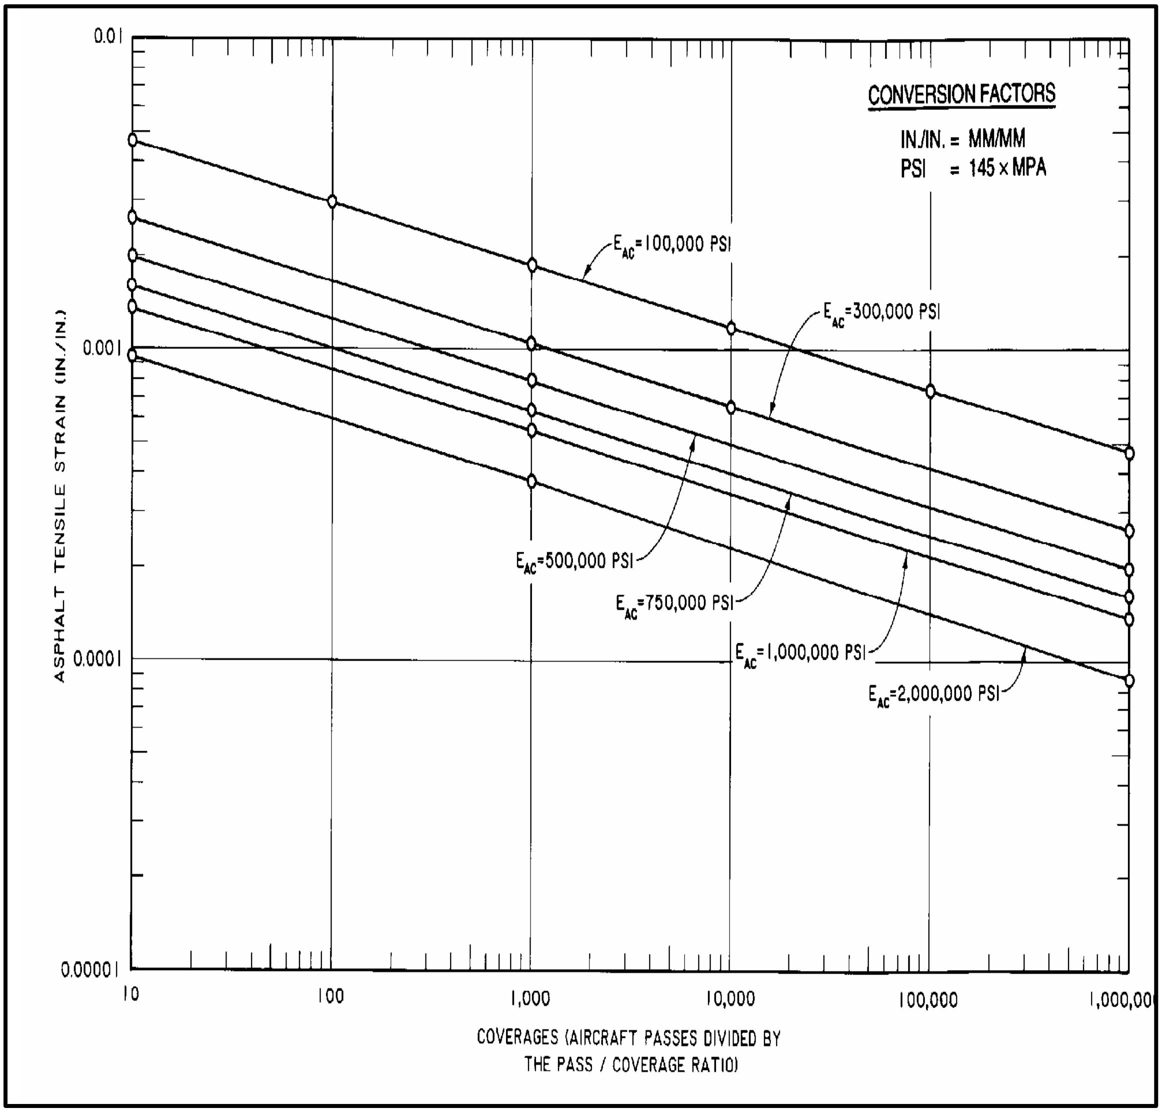
Equation 5-16. Allowable AC Strain

$$ALLOWABLE\ STRAIN_{AC} = 10^{-A}$$

Where:

ALLOWABLE STRAIN$_{AC}$ *= allowable tensile strain at the bottom of the asphalt layer, inches/inches*

Figure 5-16 Limiting Horizontal Tensile Strain Criteria for an AC Layer



The allowable subgrade strain criterion (shown graphically in Figure 5-17) is calculated using Equation 5-17.

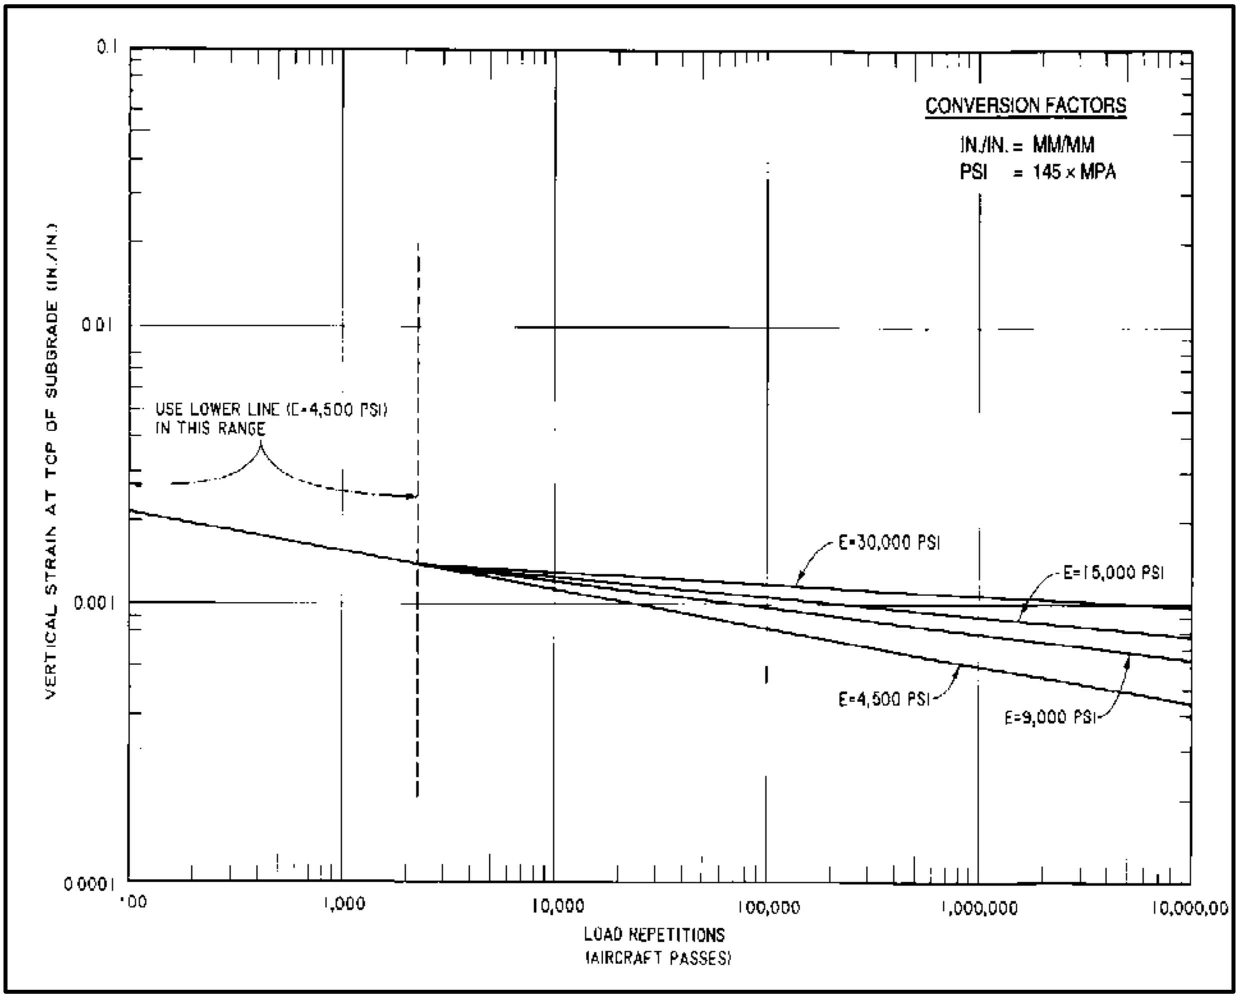
Equation 5-17. Allowable Subgrade Strain

$$ALLOWABLE\ STRAIN_{SG} = \left(\frac{10{,}000}{N}\right)^{1/B} A$$

Where:

ALLOWABLE STRAIN$_{SG}$	*= allowable vertical strain at the top of the subgrade, inches/inches*
N	*= aircraft repetitions (passes)*
A	*= 0.000247 + 0.000245 LOG(E_{SG})*
B	*= 0.0658 (E_{SG})$^{0.559}$*
E_{SG}	*= subgrade modulus, psi*

Figure 5-17 Limiting Vertical Subgrade Strain Criteria for Flexible Pavement



5-3.9.1.2 Asphalt Design Modulus.

While the backcalculation procedure uses the surface and five-day mean to determine a modulus, the analysis procedure uses the design air temperature that is the average of the hottest month's mean and maximum temperatures. The LEEP module pulls this data from the world index (climate) database to determine the design pavement temperature using the relationship in Figure 5-18. The design pavement temperature is then used in the relationship shown in Figure 5-19 to determine the asphalt modulus for the specific load frequency. Use the 10 Hz load frequency for runways and the 2 Hz load frequency for taxiways and aprons.

Figure 5-18 Design Pavement Temperature

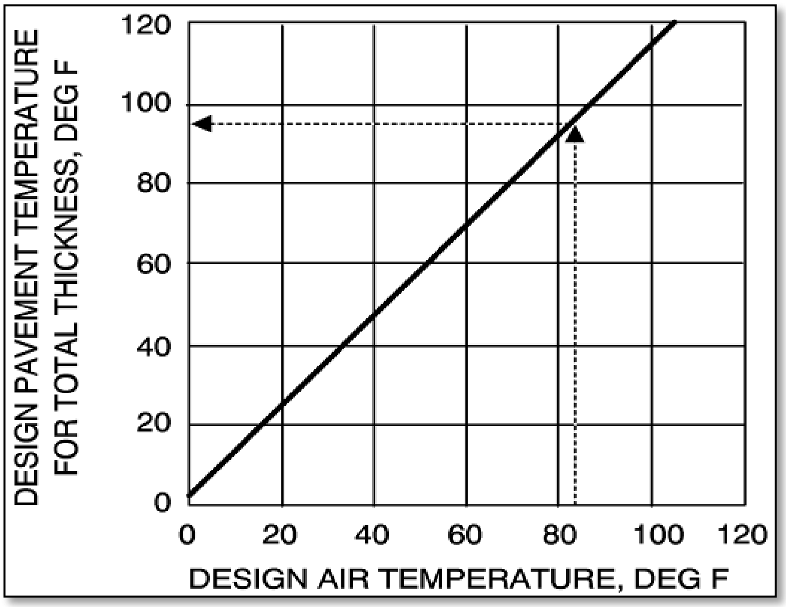


Figure 5-19 Asphalt Concrete Modulus

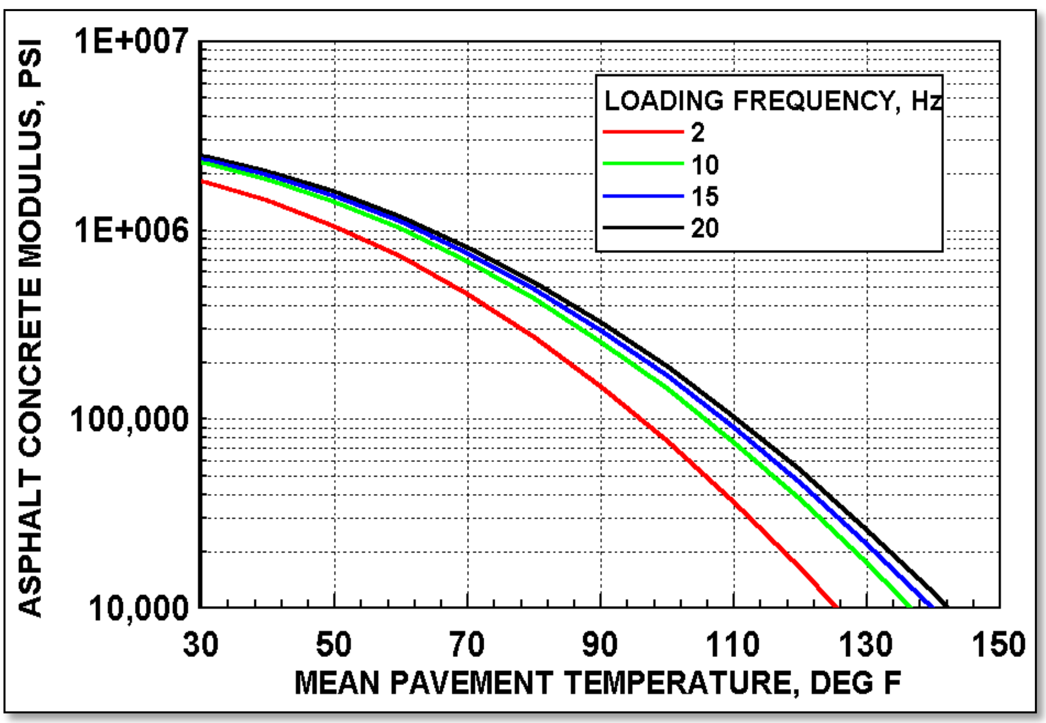


5-3.9.1.3 PCC Pavement Analysis Criteria.

LEEP assumes that an AC over PCC structure is a rigid pavement unless the backcalculated modulus of the PCC layer is less than 1,000,000 psi (6,895 MPa), then evaluate it as a flexible pavement. Rigid and non-rigid overlays of rigid pavements are evaluated based on the tensile stress at the bottom of the PCC slab and the predicted pavement deterioration in terms of the Structural Condition Index (SCI) as defined in Equation 5-18.

Equation 5-18. Structural Condition Index

$$SCI = 100 - A * (\,sum\ of\ structural\ deducts)$$

A is an adjustment factor based on the number of distress types with load-related PCI deduct values greater than five points as determined from the PCI survey procedure. The load-related PCI distresses are established and computed in the PAVER software program. These structural deducts are a function of distress types, severities, and densities associated with repeated aircraft and vehicle loads. The SCI prediction is based on a relationship between design factor and stress repetitions as related to crack formation in the PCC slabs due to load. An SCI of 50 corresponds well to the formation of one or more cracks per slab in 50 percent of the trafficked slabs (first crack failure criteria) and an SCI = 0 correlates approximately to a shattered-slab condition. The design factor, DF, is the concrete flexural strength divided by the flexural stress in a PCC slab.

Equation 5-19 shows the SCI-based equation for determining the DF. Using the PCC flexural strength, determine the allowable PCC slab flexural stress using Equation 5-20.

Equation 5-19. Design Factor

$$DF = A + B\ LOG\ \ C$$

Where:
DF = *design factor*
A = *0.2967 + 0.002267 (SCI)*
B = *0.3881 + 0.000039 (SCI)*
C = *coverage level at selected SCI*
SCI = *structural condition index*

Equation 5-20. Allowable PCC Slab Flexural Stress

$$ALLOWABLE\ STRESS_{PCC} = \frac{R}{DF}$$

Where:
$ALLOWABLE\ STRESS_{PCC}$ = *allowable tensile stress at the bottom of the slab, psi*
R = *PCC flexural strength, psi*

5-3.9.2 PCC Joint Load Transfer Efficiency Using NDT Tests.

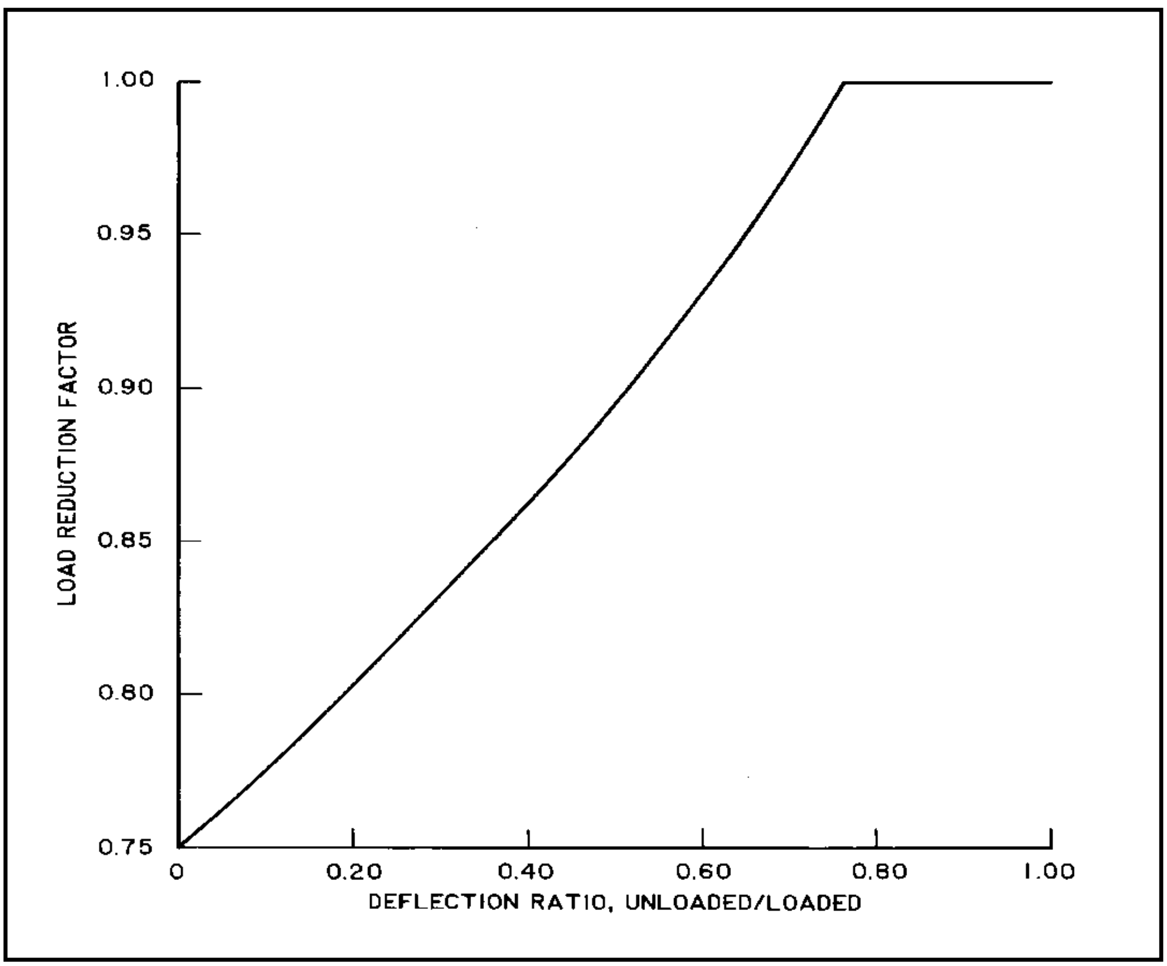
Rigid pavement analysis assumes 25 percent load transfer between slabs. The allowable loads determined at the slab centers can be reduced for poor joint transfer using load reduction factors shown in Figure 5-20. So, when there is evidence that there is a lack of load transfer (e.g., longitudinal cracking along the length of a section), test the joint load transfer as outlined in paragraph 3-4.1.7 and use the PCASE FWD module to compute the deflection ratio and load transfer efficiency as follows:

Equation 5-21. Deflection Ratio and Load Transfer Efficiency

$$DEFLECTION\ RATIO\ = \frac{DEFLECTION\ OF\ UNLOADED\ SLAB}{DEFLECTION\ OF\ LOADED\ SLAB}$$

The relationship in Figure 5-20 was developed using finite element programs to compute edge stresses for a range of pavement thicknesses and subgrade moduli and k values to relate the deflection ratio to the percent maximum edge stress. The maximum edge stress condition is a free edge with no load transfer. The edge stress is reduced as more load is transferred across a PCC joint from the loaded to the unloaded slab. For a load reduction factor of 1.0 (e.g., 100 percent of the aircraft design load), the deflection ratio is at least 76 percent as shown in Figure 5-20. As the deflection ratio falls below 76 percent, the load factor and corresponding design load decrease. The load reduction factor varies from 0.75 to 1.00, with a minimum load reduction factor of 75 percent when the deflection ratio is zero. This procedure is also used for both rigid and non-rigid overlays of rigid pavements.

Figure 5-20 Load Reduction Factors for Load-Transfer Analyses

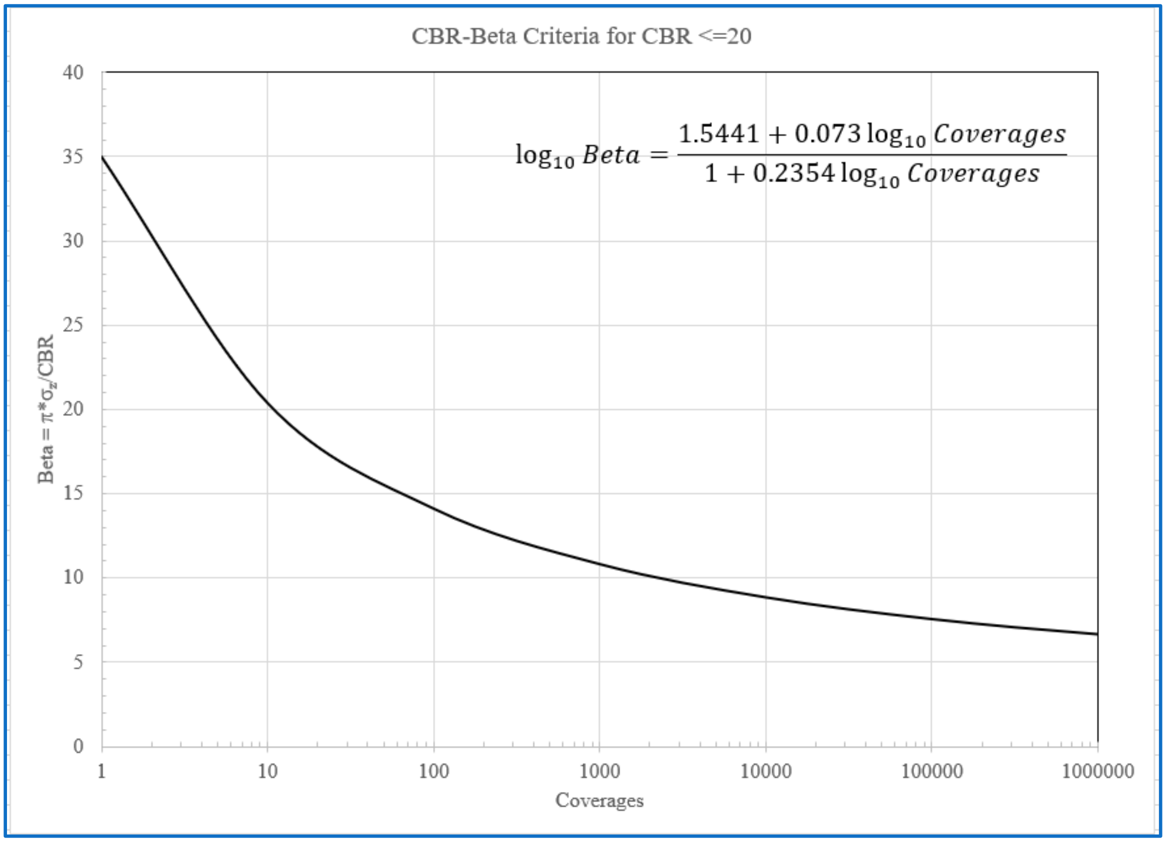


CHAPTER 6 FLEXIBLE PAVEMENT EVALUATION – CBR PROCEDURE

6-1 PERFORMANCE CRITERIA.

This flexible pavement structural evaluation procedure is a mechanistic-empirical approach known as the Alpha-Beta hybrid procedure which uses the California Bearing Ratio (CBR) as a measure of strength to analyze the vertical stress at the top of each layer and determine the allowable load and passes for an existing structure. Figure 6-1 shows the CBR Beta Performance model, which is based on the test points gathered in multiple full-scale test sections. The CBR Beta model is used when the CBR of a layer is less than or equal to 20. When the CBR of a layer is greater than or equal to 30, the CBR Alpha model is used for analysis, and when the CBR is greater than 20 and less than 30, the Alpha-Beta Hybrid model is used for analysis. The term CBR procedure is commonly used to describe the alpha-beta hybrid procedure. The details of this procedure are outlined in Appendix D and ERDC/GL TR-12-16, *Reformulation of the CBR Procedure*.

Figure 6-1 CBR-Beta Performance Criteria



6-2 FACTORS LIMITING LOAD-CARRYING CAPABILITY.

Structural failure criterion for a flexible pavement is based on a 1-inch (25-millimeter) rut. The load-carrying capability of a flexible pavement is limited by its critical or controlling layer, either the pavement surface, base, subbase, or subgrade.

6-2.1 Controlling Layer.

The ability of a given subsurface layer to withstand the loads imposed on it depends on the thickness and strength of material above it and its strength in its weakest condition. The critical or controlling layer is the layer that will support the least allowable load. To be realistic, an evaluation must consider possible future changes in moisture content and density as well as the effects of freezing and thawing.

6-2.2 Surface Condition.

A flexible pavement is assumed to have lost some structural capability when the PCI is less than or equal to 40 (VERY POOR, SERIOUS, or FAILED). When this occurs, a 25 percent load reduction is imposed on the section.

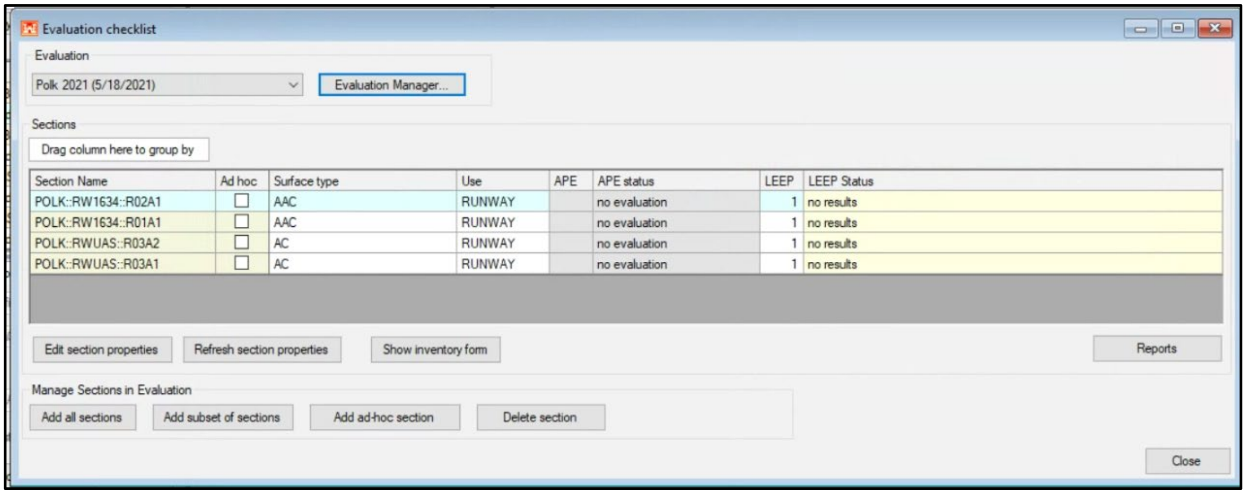
6-3 FLEXIBLE PAVEMENT (CBR) EVALUATION PROCEDURE.

The CBR evaluation procedure applies to flexible pavements. It analyzes the shear stress at the top of each layer using the CBR as a measure of the shear strength. It uses layer properties determined from in situ measurements to compute allowable loads for a selected number of aircraft passes, allowable passes at a specified load, and the Pavement Classification Number (PCN). When the pavement structure cannot support the defined pass level and aircraft load, determine overlay requirements to strengthen the pavement when desired. Following is a step-by-step procedure for evaluating a pavement section. Repeat Steps 2 through 4 of this process for each section being evaluated. The Pavement-Transportation Computer Assisted Structural Engineering (PCASE) Airfield Pavement Evaluation (APE) module implements the CBR criteria. More detailed information on using PCASE is available in the PCASE *User Manual*.

6-3.1 Step 1 – Create a New Evaluation.

Open the PCASE Evaluation Checklist to create a new evaluation using the Evaluation Manager. Define the Service, climate data, evaluation traffic, and rigid failure criteria for the evaluation, then assign the inventory sections to be included in the evaluation.

Figure 6-2 Evaluation Checklist



6-3.2 Step 2 - Input Pavement Layers and Thickness.

Open the APE module, edit the default layer structure, and enter the pavement thickness for each section. Determine the in-place thicknesses of asphaltic concrete to the nearest 0.25 inch and underlying unbound layers to the nearest inch by testing or from construction data when testing is not possible. Layer thickness testing can include measurements from coring, DCP, soil boring, GPR, or a combination of these tests. The number of tests required will vary based on the area and use of the pavement as well as the uniformity of the structure. When the layer thicknesses vary for a given section, evaluate the section using different models that replicate what was seen in the field, but only report the controlling evaluation for the facility.

6-3.2.1 Equivalency Factors.

When the measured thickness of a layer exceeds the required minimum thickness as defined in UFC 3-260-02, the excess measured thickness is converted to an equivalent thickness of base course and added to the existing base thickness. Then, any excess base-course thickness is converted to an equivalent thickness of subbase and added to the subbase thickness. This adjusted section is then used for evaluation. The equivalency factors for converting asphalt to base and subbase are 1.15 and 2.3 respectively, and for converting base course to subbase is 2.0, as shown in Table 6-1. This means that 1 inch (25.4 millimeter) of asphalt is equal to 1.15 inches (29 millimeters) of base and 2.3 inches (58 millimeters) of subbase, and 1 inch (25.4 millimeter) of base course is equal to 2 inches (51 millimeters) of subbase. The following example illustrates the use of equivalency factors.

Table 6-1 Equivalency Factors

Material	Base Equivalency Factor	Subbase Equivalency Factor
Unbound crushed stone	1.00	2.00
Unbound subbase*	-	1.00
Asphalt-stabilized and all-bituminous concrete	1.15	2.30
GW, GP, GM, GC	1.00	2.00
(SW, SP, SM, SC)*	-	1.50
Cement-stabilized		
GW, GP, SW, SP	1.15	2.30
GC, GM	1.00	2.00
(ML, MH, CL, CH)*	-	1.70
(SC, SM)*	-	1.50
Lime-stabilized		
(ML, MH, CL, CH)*	-	1.00
(SC, SM, GC, GM)*	-	1.10
Lime-, cement-, fly ash-stabilized		
(ML, MH, CL, CH)*	-	1.30
(SC, SM, GC, GM)*	-	1.40

*** Note:** Material is not to be used as a base layer.

6-3.2.2 Equivalent Thickness Example.

Evaluate a runway touchdown section for C-130 operations. The measured thickness of the pavement section and the equivalent thickness used to evaluate the pavement are shown in Table 6-2. The C-130 requires a minimum surface thickness of 4 inches (102 millimeters) and a minimum base thickness of 6 inches (152 millimeters). The base is unbound crushed stone.

Table 6-2 Equivalent Thicknesses

Layer	Measured Thickness (in.)	Equivalent Thickness of Base (in.)	Equivalent Thickness of Subbase (in.)	Evaluation Thickness (in)
Asphalt surface	5	5" - 4" min = 1" excess	-	4
Base	7	8.15 = 7.0 +1 x 1.15)	8.15" – 6" min = 2.15" excess	6
Subbase	10	-	14.30 = 10 + 2.15 x 2	14.3
Subgrade	-	-	-	-

6-3.2.3 Stabilized Layer Equivalent Thickness.

Stabilized layers are incorporated in the design of pavement sections to make use of locally available materials that cannot otherwise meet the criteria for base or subbase courses. Materials must meet the requirements in UFC 3-250-11, *Soil Stabilization and Modification for Pavements*. In design, the equivalency factors shown in Table 6-1 are assigned to the stabilized material and result in a thickness reduction as compared with an unbound base course or subbase course. These same equivalency factors result in an increase in thickness of the layer in evaluation. If no information is available on the condition and strength of the stabilized layer, it should be treated as a high-quality granular layer. If DCP results indicate the layer is well stabilized (refusal for DCP), then consider the layer for the equivalency factors.

6-3.2.4 Stabilized Layer Equivalent Thickness Example.

Assume that an Air Force pavement structure consists of a 4-inch (102-millimeter) asphaltic concrete, an 8-inch (203-millimeter) bituminous concrete base, and an 8-inch (203-millimeter) cement-stabilized gravelly clay subbase with an unconfined compressive strength of 700 psi (4.83 MPa). From Table 6-1, the 8-inch (203-millimeter) bituminous concrete base equivalency factor is 1.15, which increases the thickness of the stabilized base for evaluation to 9.2 inches (234 millimeters). Table 6-1 shows that the 8-inch (203-millimeter) cement-stabilized subbase has an equivalency factor of 2.0, which increases the thickness of the stabilized subbase for evaluation to 16 inches (406 millimeters).

6-3.3 Step 3 - Soil Layer Strength Values.

Enter the CBR for the subgrade and overlying subbase and base courses. Both in-field and laboratory CBR tests are described in CRD-C654, *Standard Test Method for Determining the California Bearing Ratio of Soils*. Field DCP tests are described in Appendix A and TM 3-34.48-2, Appendix G. Use construction data in conjunction with testing or when testing is not possible. The CBR test results from an individual test pit or from multiple DCP tests are seldom uniform. Therefore, analyze the data carefully as described in Chapter 3 to determine reasonable CBR values to use for an evaluation.

6-3.3.1 Base Course CBR.

Base course CBR or DCP testing can produce inaccurate CBR values when performing in-place tests or for laboratory tests due to inherent difficulties in processing samples. For example, DCP test results may show a 100 CBR for a Poorly Graded Gravel however, it is likely the DCP encountered large aggregates that skewed the test results. In this case, assign CBR values based on the material's typical behavior, as shown in Table 6-3.

Table 6-3 Assigned CBR values for Base Course Materials

Aggregate Base Course	Assigned CBR
Graded crushed aggregate	100
Aggregate	80
Limerock	80
Coral	80
Shell Rock	80

6-3.4 Step 4 – Flexible Pavement Analysis.

6-3.4.1 Alpha-Beta Hybrid (CBR) Evaluation Procedure.

Once the thickness and CBR values are selected for each of the layers, use these values to determine the shear stress at the top of each layer based on the stress-based CBR Alpha-Beta hybrid procedure assuming constant tire pressure. The objective of the analysis is to determine the allowable load and allowable passes for the structure. Note that results using the current criteria will differ from the CBR Alpha criteria and constant contact area assumption used in past versions of this UFC. PCASE automates the analysis procedure outlined in this chapter and in Appendix D. The procedure for generating aircraft curves using the current criteria is included in TSPWG M 3-260-03.02-19.

6-3.4.2 Procedure for Determining Allowable Gross Load (AGL).

The inputs for this analysis are the traffic mix with the load and number of passes for each vehicle in the mix defined, the pavement structure, and the traffic area. Determine the controlling/representative vehicle and equivalent passes based on one of the traffic analysis procedures outlined in Chapter 4. Perform the allowable coverages calculation using the Alpha-Beta Hybrid procedure in which limiting (vertical) stress is calculated for each layer in the pavement structure based on load of the controlling/representative vehicle load. Compute the cumulative damage factor (CDF). If the CDF is less than 1, increase the gross load and repeat the analysis procedure. If the CDF is greater than 1, decrease the load and repeat the analysis procedure. When CDF equals 1, use that value for the AGL. See Appendix D for details on this procedure.

6-3.4.3 Procedure for Determining Allowable Passes.

The inputs for this analysis are the traffic mix with the load and number of passes for each vehicle in the mix defined, the pavement structure, and the traffic area. Determine the controlling/representative vehicle and equivalent passes based on one of the traffic analysis procedures outlined in Chapter 4. Perform the allowable coverages calculation using the Alpha-Beta Hybrid procedure in which limiting (vertical) stress is calculated for each layer in the pavement structure based on load of the controlling/representative vehicle load. See Appendix D for details on this procedure.

6-3.4.4 Load, Tire Pressure, and Contact Area Relationship.

Typically, the relationship between weight on a tire, tire pressure, and contact area is:

Tire Contact Area = Load on Tire/Constant Tire Pressure

This relationship is good for AGLs up to approximately the maximum aircraft load. At that point, contact area begins increasing to unrealistic values to the extent that the limiting stress is not reached. Therefore, a solution for allowable load is not achievable. To resolve this issue, the following relationship is used for the allowable loads above the maximum aircraft loads.

Equation 6-1. Tire Pressure Relationship

$$T_p = T_{pml} + \frac{D}{T_{ca}\left[1 + \left(\frac{AGL}{D}\right)^3\right]}$$

where

$T_p = Tire\ pressure\ used\ for\ calculations$

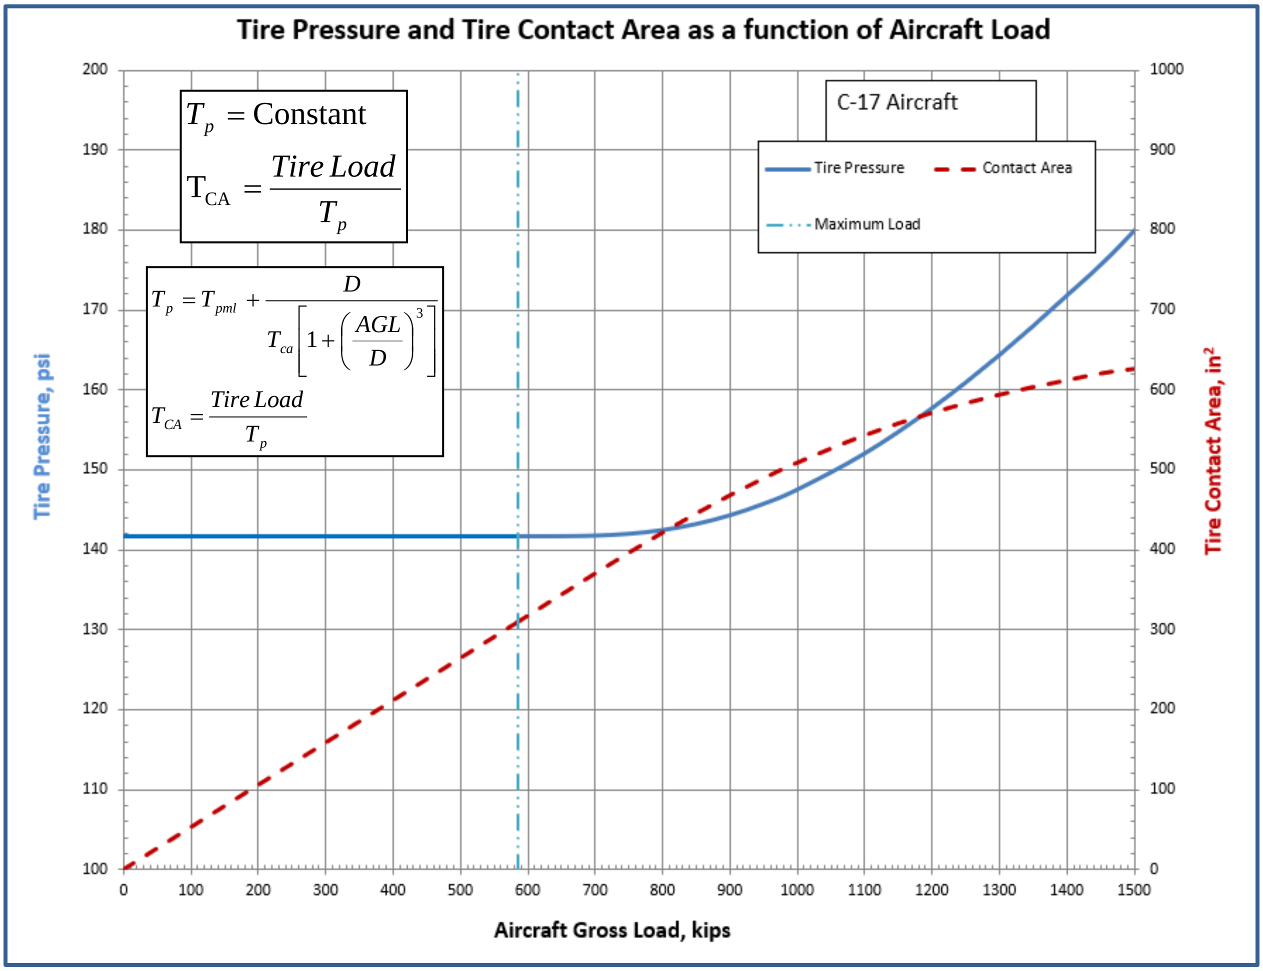
$T_{ca} = Tire\ contact\ area\ at\ MaxLoad$

$T_{pml} = Tire\ pressure\ at\ MaxLoad$

$D = AGL - MaxLoad$

An example of this relationship for the C-17 is shown in Figure 6-3.

Figure 6-3 Tire Pressure/Contact Area vs. AGL



6-3.5 Pavement Classification Number (PCN).

The process described above is used to calculate the allowable load which is then used to compute the PCN. Comparing the aircraft classification number (ACN) to the PCN of a pavement section is an expedient way to determine if it can support a particular aircraft. Chapter 9 presents the PCN procedure.

6-4 OTHER FLEXIBLE PAVEMENT EVALUATION CONSIDERATIONS.

The structural analysis procedure above assumes the quality of the materials and construction procedures used to construct a flexible pavement meet the criteria outlined in UFC 3-260-02 and the various Unified Facility Guide Specifications (UFGS). When field and laboratory testing indicate that this assumption is not valid, adjust evaluation inputs or at least fully document any anomalies in the report. The following paragraphs discuss evaluation issues that should be considered.

6-4.1 Ability to Support Traffic.

The type and gradation of the aggregate, the amount of bitumen in the mix, and the compaction of the mix all affect the ability of a mix to support traffic of a given load. Mixes with rounded aggregates are less stable than those with crushed-face aggregates. Mixes with aggregates of irregular grading are less stable than those with well-graded aggregates. A bitumen deficiency produces a pavement that may ravel, but too much bitumen produces a pavement that may rut and shove. Compare the test data from the laboratory recompacted core sample specimens taken during the evaluation with the design criteria in UFC 3-260-02. The condition of surface or binder course pavement at the time of sampling can be an indication of future behavior under additional traffic. Table 6-4 shows the prediction of behavior from tests on cores and on laboratory recompacted surface course specimens. Assume the thickness and aggregate gradation are satisfactory.

Table 6-4 Example Test Data

Tests	Field Cores	Recompacted Sample - 50 Blows*	Recompacted Sample - 75 Blows
Unit weight (density), pcf	144.2	149.7	150.9
Unit weight, percent of 50-blow laboratory compaction	96	-	-
Unit weight, percent of 75-blow laboratory compaction	95	-	-
Stability (pounds)	1,883	2,929	3,276
Flow (1/100 inch)	15	16	16
Voids total mix, percent	8.5	4.5	3.7
Voids filled, percent	57.2	72.1	75.8

***Note:** For shoulders and overruns

The test data from recompacted specimens shown above indicates the current density (field cores) is relatively low, the flow is approaching the upper limit, and the void relations are outside the acceptable ranges, but the stability is satisfactory. This means that additional compaction from traffic will likely increase the stability but also cause some rutting of the pavement. Therefore, the pavement should be able to withstand heavier loads than it sustained in the past and is satisfactory under traffic having up to 200 psi (1.4 MPa) tire pressure. At 75 blow laboratory compaction, the voids total mix value is below the midpoint of the acceptable range and the flow is at the upper limit, indicating a mix slightly rich of optimum. However, no danger from flushing is expected.

6-4.2 Ability to Withstand Fuel Spillage.

Fuel dripping on a given area at frequent intervals or a pervious pavement mix that allows considerable penetration of the fuel will cause pavement distresses because asphaltic cements are readily soluble in fuels. The voids in the total mix control the rate at which penetration occurs. Fuel will penetrate very little into pavements with 3 percent voids but will rapidly penetrate pavements with high (over 7 percent) voids. Therefore, an AC layer with higher density will typically increase the pavement's resistance to jet fuel penetration and weathering. Pavements about one year or older usually perform better in this respect than new pavements. Evaluate the surface course characteristics for resistance to jet fuel. Table 6-5 serves as a guide for evaluating asphalt pavements regarding fuel spillage for use in different areas of the airfield.

Table 6-5 Surface Course Fuel Resistance

Pavement Type	Texture	Satisfactory for
Asphaltic concrete	Dense	Runway interiors and areas of taxiways where aircraft do not warm up or stop frequently
Asphaltic concrete	Open	Runway interiors or any high-speed areas

6-4.3 Ability to Withstand Jet Blast.

Tests have shown that about 300 °F (149 °C) is the critical temperature for asphaltic concrete. Field tests simulating pre-takeoff checks at the ends of runways indicate that the maximum temperatures induced in the pavements when afterburners are not used are less than 300 °F (149 °C). Maximum temperatures induced in pavement tests simulating maintenance checkups are 315 °F (157 °C). When afterburners are turned on after the aircraft has begun the takeoff run, little or no damage occurs.

Thin-surface courses, not well-bonded to the underlying layers, are subject to erosion (e.g., weathering, raveling, jet blast) by a high-velocity blast, even though the binder is not melted. All jet aircraft currently in use are believed to produce blasts of sufficiently high velocity to flay such courses. Setback distances for running-up engines are established and included in UFC 3-260-01, *Airfield and Heliport Planning and Design*. Surface layers less than 1 inch (25.4 millimeters) thick and poorly bonded are considered unsatisfactory for parking areas and the 1,000-foot (304.8-meter) ends of runways and are so reported in the narrative portion of the evaluation report for all aircraft. DoD aircraft inventories now include aircraft with thrust vectors that potentially negatively impact airfield pavements, depending on operational usage. When these aircraft are present, the evaluation should consider the expected decrease in performance due to thrust vector forces.

6-4.4 Effects of Traffic Compaction on Paving Mixes.

Traffic tends to densify flexible pavements, depending on the gear loads applied and the characteristics of the mix. Densification is limited where traffic is widely distributed and is greatest where traffic is channelized. High tire pressures produce greater densification than low tire pressures. The probability of densification under a given loading decreases somewhat with pavement age because of hardening of the asphalt. A comparison of the in-place density and void relations of the pavement with the results of comparable tests on specimens recompacted in the laboratory gives an indication of future behavior. If the pavement is constructed so the voids fall near the lower limit of the specified allowable range, it is probable that aircraft with relatively high-pressure tires will produce sufficient densification to appreciably reduce the voids in the total mix. The pavement is considered unstable and may rut when the voids fall below the specified minimum (see UFC 3-260-02). These conditions cannot be translated into numerical evaluations, but they should be discussed in the evaluation report and summarized so engineers will have the information available.

6-4.5 Effects of Traffic Compaction on Base Course and Subgrade.

6-4.5.1 Degree of Compaction for CBR Values.

Definite degrees of compaction are specified for the subgrade and base course in airfield pavement construction to prevent excessive densification under traffic, the consequent development of surface roughness “birdbaths,” and loss of grade. The design CBR values are based on assumed degrees of compaction outlined in the specifications.

6-4.5.2 Density Requirements.

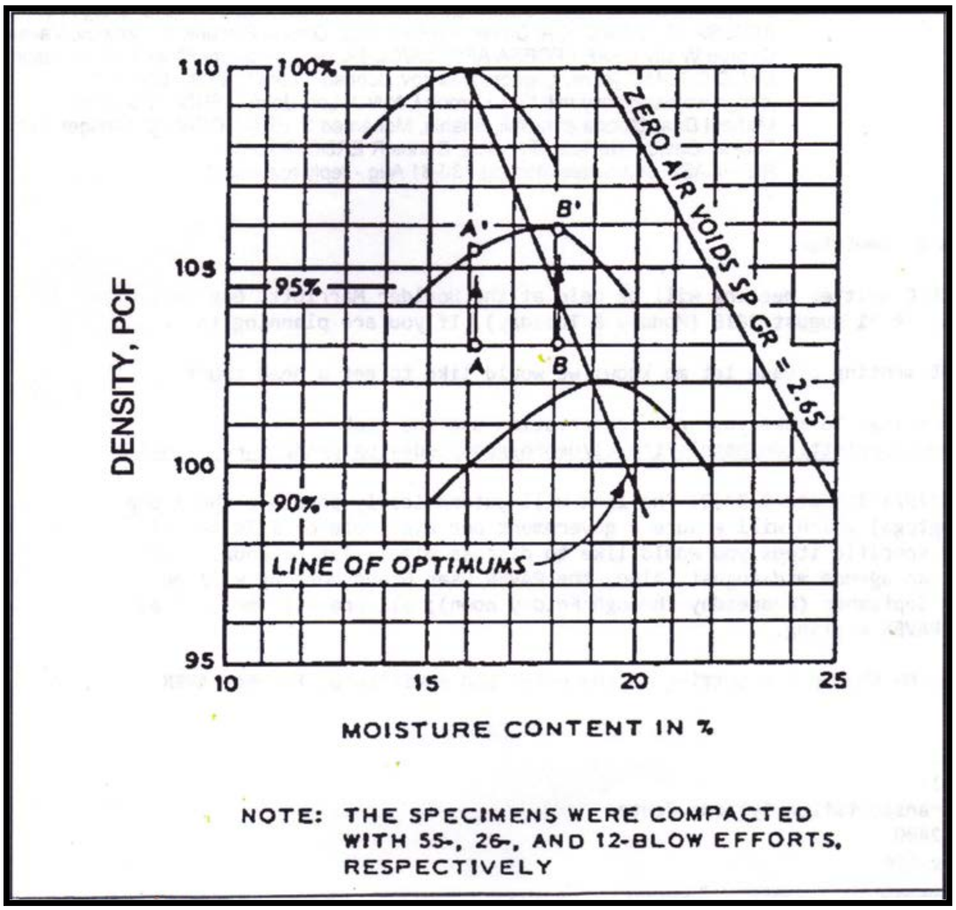
Compare the in-place densities, as a percentage of ASTM D1557, *Standard Test Methods for Laboratory Compaction Characteristics of Soil Using Modified Effort (56,000 ft-lbf/ft^3 [2,700 kN-m/m^3])*, maximum density, with the design requirements for the various loads and gear configurations that the pavement is expected to support to evaluate the base, subbase, and subgrade from the standpoint of future compaction. When the in-place density of a layer is appreciably lower than that required, assume that traffic will densify the layer in time. Density requirements at various depths are discussed in UFC 3-260-02.

6-4.5.3 Selection of Evaluation CBR Value.

Consider the effect of further compaction on strength of base and subgrade. Some cohesive soils, when highly saturated, potentially develop pore pressures under traffic of heavy wheel loads and show serious loss of strength. Compare the in-place density and moisture contents with those of the laboratory compaction tests made at three compaction efforts to determine if there is potential for strength loss. These data are used to determine the line of optimums illustrated in Figure 6-4 by a line drawn through the three optimum moisture contents. Pore pressure seldom develops unless the moisture and density results fall to the right of the line of optimums. When this occurs, it is likely that future compaction will produce pore pressures. For example, consider point

A plotted in Figure 6-4 at a moisture content of 16 percent and a density of 103 pounds per cubic foot (1,651 kilograms per cubic meter). Assume this represents a subgrade that has 95 percent of ASTM D1557 maximum density. If further compaction occurs, the density will increase to approximately 105 pounds per cubic foot (1,682 kilograms per cubic meter) (point A' on the curve for 26 blow effort). Since this is to the left of the line of optimums, no pore pressures will develop. If the subgrade had a moisture content of 18 percent (point B), the increased compaction would cause the density to be plotted to the right of the line of optimums (B') and pore pressures would result. The CBR that would develop under this condition could be estimated from laboratory CBR tests in which the material was compacted to the same density and moisture content.

Figure 6-4 Line of Optimums



It is not necessary to lower the load-carrying capacity of the facility below that derived based on thickness and CBR because compaction does not meet specifications. However, if the measured densities are considerably less than those specified, the deterioration of the pavement may be high, resulting in a decrease in service life. Note that materials of low density combined with low moisture content may not densify under traffic, but subsequent increases in moisture content will permit densification. There may be possible settlement due to densification in the evaluation of pavements being subjected to channelized and heavy wheel-load traffic. In the case of cohesive materials that may develop pore pressures and a loss in strength, consider a lower CBR when evaluating allowable aircraft loads.

6-5 EVALUATIONS IN ARID REGIONS.

The danger of saturation beneath flexible pavements is reduced when the annual rainfall is less than 15 inches (381 millimeters), the water table (including perched water table) is at least 15 feet (5 meters) below the surface, and the water content of the subgrade will not increase above the optimum as determined by the ASTM D1557 compaction test. Under such conditions, the total design thickness of the pavement, when based on a soaked CBR, can be reduced 20 percent. This reduction is subtracted from the thickness of the select material or the subbase course having the lowest design CBR value. Therefore, when flexible pavements are evaluated using a soaked CBR value, the total thickness above the subgrade is increased 25 percent before entering the evaluation curves. This increase in thickness is added to the select material, or the subbase course having the lowest CBR, or to the same layer in which the reduction was made in the design analysis. This increase in thickness does not apply for evaluations using in-place data.

6-6 EVALUATION FOR FROST CONDITIONS.

If the existing soil, water, and temperature conditions are conducive to detrimental frost effects in the base-course, subbase, or subgrade materials, then the pavement evaluation is based on criteria for frost areas as given in Chapter 8.

This Page Intentionally Left Blank

CHAPTER 7 RIGID PAVEMENT EVALUATION USING THE K PROCEDURE

7-1 PERFORMANCE CRITERIA.

This chapter presents criteria for evaluating rigid pavements using the Westergaard solution that uses medium-thick plate theory and treats the combined support of the base, subbase, and subgrade as a bed of independent springs (Winkler's Foundation) represented by the Modulus of Subgrade Reaction (k). Chapter 3 outlines how to use plate bearing tests or dynamic cone penetrometer (DCP) test data to determine the k value.

7-2 FACTORS LIMITING LOAD-CARRYING CAPACITY.

Jointed, plain PCC pavements are evaluated using stresses due to edge loading of a slab. Either first crack or shattered slab failure criteria are used for rigid pavements as described below. The Service dictates which criterion it uses in its evaluations.

7-2.1 Standard Evaluation Failure Criterion.

First crack failure (sometimes referred to as initial failure or standard failure) means that 50 percent of the slabs in a sample or section are cracked into two or three pieces.

7-2.2 Shattered Slab Failure Criterion.

Shattered slab failure (sometimes referred to as extended life failure) means that 50 percent of the slabs in a sample or section are cracked into approximately six pieces or when 50 percent of slabs are cracked into four pieces and cracks are medium or high severity.

7-2.3 Basis of Load-carrying Capability.

The load-carrying capability of rigid pavements depends on the thickness and flexural strength of the PCC surface layer and the support in terms of the modulus of subgrade reaction (k) value provided by the base, subbase, and subgrade. Long-term rigid pavement system performance depends on many elements, including PCC and stabilized base material durability, unbound material and subgrade gradations, moisture content and density, and regional climatic effects such as freezing and thawing.

7-2.4 Surface Condition

Assume a rigid pavement has lost some structural capability when the PCI is less than or equal to 40 (VERY POOR, SERIOUS, or FAILED). When this occurs, reduce the load on the section by 25 percent.

7-2.5 Load Transfer.

The rigid pavement analysis procedure assumes a 25 percent load transfer across joints from aggregate interlock in sawn joints or by dowels. When testing (by FWD) indicates inadequate joint load transfer, change the percent load transfer. This change recalculates the joint deflection ratio and increases the maximum edge stress to a maximum of 100 percent. The effect of this change is an allowable load reduction to 25 percent.

7-2.6 Combined Load Reduction.

Any allowable aircraft load reduction is based on engineering judgment, but there is typically no combined load reduction for both PCI and load transfer. The engineer must investigate all possible sources of pavement engineering data to ensure that site conditions, including field and laboratory test results, are consistent with proposed reductions in allowable loads.

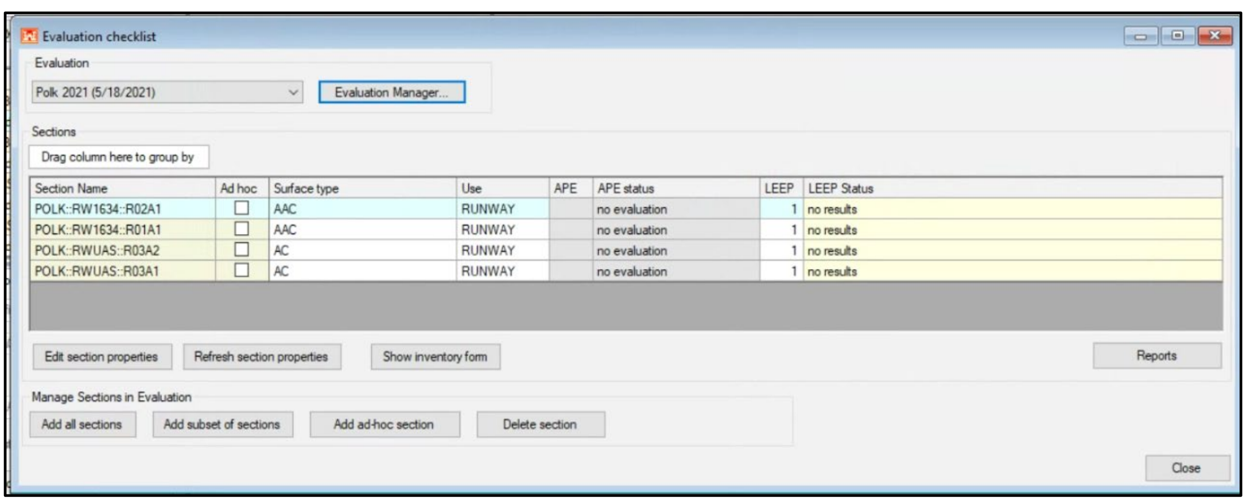
7-3 RIGID PAVEMENT (K) EVALUATION PROCEDURE.

The Westergaard (k) evaluation procedure applies to rigid pavements. It analyzes the critical tensile stresses produced within the slab by the vehicle loading. It uses layer properties determined from in situ measurements to compute allowable loads for a selected number of aircraft passes, allowable passes at a specified load, and the Pavement Classification Number (PCN). When the pavement structure cannot support the defined pass level and aircraft load, determine overlay requirements to strengthen the pavement when desired. The following paragraphs present a step-by-step procedure for evaluating a pavement section using the Pavement-Transportation Computer Assisted Structural Engineering (PCASE) Airfield Pavement Evaluation (APE) module that implements the CBR criteria. Repeat Steps 2 through 5 of this process for each section evaluated. More detailed information on PCASE is available in the PCASE *User Manual*.

7-3.1 Step 1 – Create a New Evaluation.

Open the PCASE Evaluation Checklist to create a new evaluation using the Evaluation Manager. Define the Service, climate data, evaluation traffic, and rigid failure criteria for the evaluation, then assign the inventory sections included in the evaluation.

Figure 7-1 Evaluation Checklist



7-3.2 Step 2 - Input Pavement Layers and Thickness.

Open the APE module, edit the default layer structure, and enter the pavement thickness. Determine the in-place thicknesses of PCC pavement to the nearest 0.25 inch and underlying unbound layers to the nearest inch by testing or from construction data when testing is not possible. Layer thickness testing can include measurements from coring, DCP, soil boring, GPR, or a combination of these tests. The number of tests required varies based on the area and use of the pavement as well as the uniformity of the structure. When the layer thicknesses vary for a given section, evaluate the section using different models that replicate field observations, but only report the controlling evaluation for the facility. Repeat this process for each section.

7-3.2.1 Stabilized Base Equivalent Thickness

When a pavement structure contains a stabilized base layer, determine the modulus of elasticity and thickness of the stabilized layer. The modulus of elasticity of the stabilized layer is more difficult to determine than the PCC layer. If the stabilized layer is a high-quality lean concrete or cement-stabilized layer, assign it a modulus value of 1,200,000 psi (8274 MPa). If the stabilized layer is lower quality, such as a lime or asphalt stabilized layer, assign it a modulus value of 500,000 psi (3447 MPa). Use the following equation to determine the equivalent thickness of the combined PCC and stabilized layers. Use this equivalent thickness value (h_e) with the PCC flexural strength and the modulus of subgrade reaction, k, of the material below the stabilized base layer in the analysis. PCASE automates this procedure.

Equation 7-1. Equivalent Thickness

$$h_e = 1.4\sqrt{(h_c)^{1.4} + \left(3\sqrt{\left(\frac{E_s}{E_c}\right)}\,h_s\right)^{1.4}}$$

Where:

h_e = *thickness of plain PCC equivalent to the combined PCC and stabilized base layer thicknesses, inches*

h_c = *thickness of PCC pavement, inches*

h_s = *thickness of stabilized base layer, inches*

E_c = *modulus of elasticity of PCC. The modulus values that are used in PCASE can be modified, based on engineering judgment. However, the UFC and PCASE should be consistent unless there is evidence to suggest otherwise.*

E_s = *modulus of elasticity of the stabilized base layer, psi. Estimate from Table 7-1 or calculate using deflections resulting from ASTM D1635.*

Table 7-1 E Values for Pavement Materials (Guide When E is not Available)

Material	Range (psi)	Typical Modulus (psi)
Portland cement concrete	3,000,000 – 6,000,000	4,000,000
Cement-treated bases	1,000,000 – 3,000,000	2,000,000
Soil cement materials	50,000 – 2,000,000	1,000,000
Lime-fly ash materials	500,000 – 2,500,000	1,000,000
Granular bases	40,000 – 100,000	60,000
Stiff clay	7,600 – 17,000	12,000
Medium clay	4,700 – 12,300	8,000
Soft clay	1,800 – 7,700	5,000
Very soft clay	1,000 – 5,700	3,000

7-3.2.2 Poisson's Ratios of Pavement Materials

Table 7-2 shows typical values for Poisson's ratios for different pavement materials.

Table 7-2 Poisson's Ratios for Pavement Materials

Material	Range	Typical Value
Hot mix asphalt	0.30 – 0.40	0.35
Portland cement concrete	0.15 – 0.20	0.15
Untreated granular base	0.30 – 0.40	0.35
Cement-treated granular base	0.10 – 0.20	0.15
Cement-treated fine soils	0.15 – 0.35	0.25
Lime-stabilized materials	0.10 – 0.25	0.20
Lime-fly ash mixtures	0.10 – 0.15	0.15
Loose sand or silty sand	0.20 – 0.40	0.30
Dense sand	0.30 – 0.45	0.35
Fine-grained soils	0.30 – 0.50	0.40
Saturated soft clays	0.40 – 0.50	0.45

7-3.3 Step 3 – Input the PCC Flexural Strength.

Enter the flexural strength for each PCC layer using the guidance below. Repeat the process for each section

7-3.3.1 PCC Flexural Strength, M_R Based on Testing.

Determine the representative M_R value using the results of split tensile tests or by conducting flexural strength beam tests. The M_R value used for each section in the evaluation is the arithmetical mean of all M_R values as described in Appendix A. Do not discard high or low results unless it is established that results were erroneous because the sample was defective or due to incorrect test procedures. In special instances the evaluating engineer may use a slightly lower or higher value that is more representative of existing conditions. Round the flexural strength to the nearest 5 psi (0.03 MPa), limit the maximum flexural strength for individual tests to 850 psi (5.9 MPa), and the average flexural strength to 800 psi (5.5 MPa) when reporting physical property data (PPD) and modeling.

7-3.3.2 PCC Flexural Strength, M_R Based on Construction Data.

For evaluations based on design or construction data, the representative M_R value is the arithmetical mean of the M_R values obtained in the construction-control beam tests. Disregard small changes in mix design necessary during construction to obtain the design strength when selecting representative M_R values. However, if there is a design strength change that necessitated a change in mix design, consider this change and a representative M_R value obtained for each facility for which the design strength was changed.

7-3.3.3 PCC Flexural Strength, M_R When No Data is Available.

When there is no test, design, or construction data available for an evaluation, assume a 650-psi (4.5-MPa) flexural strength when probability of construction quality control is high and 600 psi (4.1 MPa) when it is not.

7-3.4 Step 4 – Input Soil Layer Strength (k) Values.

Determine the subgrade and overlying subbase and base courses strengths by means of plate bearing tests described in CRD-C655, *Standard Test Method for Determining the Modulus of Soil Reaction*, and ASTM D1196, *Standard Test Method for Nonrepetitive Static Plate Tests of Soils and Flexible Pavement Components for Use in Evaluation and Design of Airport and Highway Pavements*, or DCP tests described in TM 3-34.48-2, Appendix G. Use construction data in conjunction with testing or when testing is not possible. The test results from an individual test pit or from multiple DCP test are seldom uniform; therefore, analyze the data carefully as described in Chapter 3 to determine reasonable k values to use for the evaluation.

7-3.4.1 Determining Representative k Values.

Compute an average k value for each pavement section, limiting the maximum k value to 500 psi/inch (13,840 grams per cubic centimeter) for evaluations. When the average k value exceeds 200 psi/inch (5,536 grams per cubic centimeter), round down to the nearest 25 psi/inch (692 grams per cubic centimeter). When it is less than 200 psi/inch (5,536 grams per cubic centimeter), round down to the nearest 10 psi/inch (277 grams per cubic centimeter). When test results are considerably higher or lower than the average of most values, conduct a thorough study of foundation conditions to determine whether the test was erroneous or whether the foundation is non-uniform. If the test is erroneous, discard the unusually high or low value. If the foundation is non-uniform, conduct more testing to select a representative k value. Do not make a saturation correction for k values since the material has likely reached an equilibrium moisture content.

7-3.4.2 Determining k Values with Plate Bearing Tests.

The plate bearing test procedures as described in CRD-C 655 and ASTM D1196 are the preferred methods to determine k values. However, existing pavement must be removed to create a test pit to conduct a plate bearing test. Operational considerations typically limit the ability to do a plate bearing test during an evaluation but will be used when the geotechnical work is for a specific project design.

7-3.4.3 Estimating k Values with DCP Tests.

When operational limitations prevent performing a plate bearing test for an evaluation, use the DCP test discussed in Chapter 3. The CBR is correlated to the k value for each layer using Figure 7-2 (based on Equations 7-2 through 7-4) and these values are used to determine the effective k at the bottom of the slab as described in the effective k procedure below. When performing DCP testing in conjunction with HWD testing, the volumetric k from HWD testing can be compared with the effective k derived from the DCP test as a checkpoint to determine the reasonableness of the k value. Note that k values derived from either of these procedures should be used with caution since CBR, volumetric k, and k values derived from plate bearing testing are fundamentally different soil engineering properties with poor correlations for many real-world cases.

Equation 7-2. CBR to k Coarse Grained Non-Plastic Subgrade Material

$$k = 129.58076 * CBR^{0.5} - 5.49306 * CBR - 242.93236$$

Equation 7-3. CBR to k Fine Grained Subgrade Material with LL < 50

$$k = 60.2282 * CBR^{0.5} + 2.1854046 * CBR - 11.245482$$

Equation 7-4. CBR to k Fine Grained Subgrade Material with LL > 50

$$k = 20 * CBR$$

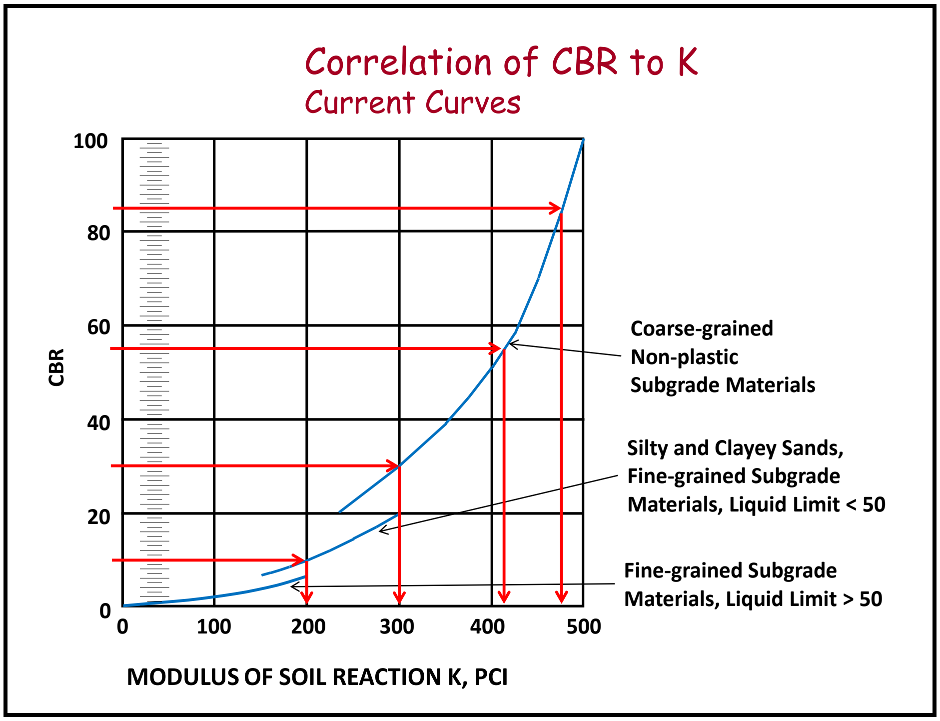
Where:
k = *Modulus of Subgrade Reaction*
CBR = *California Bearing Ratio*

Source: ERDC/GSL TR-12-20

7-3.4.4 Procedure to Determine Effective k Values.

Determine the k value for each layer in the pavement structure by inputting the CBR results from the DCP test into Equation 7-2, 7-3, or 7-4, depending on the material type. Figure 7-2 is derived from these equations. Determine the effective k for each layer using Figures 7-2 through 7-8. Compare the effective k for each layer to the k for each layer determined by Figure 7-2 and use the lower value for computing the effective k of the next layer. This process is automated in the PCASE APE module.

Figure 7-2 Estimation of K values from CBR



7-3.4.5 Determine Layer Structure and CBR Values from DCP Test.

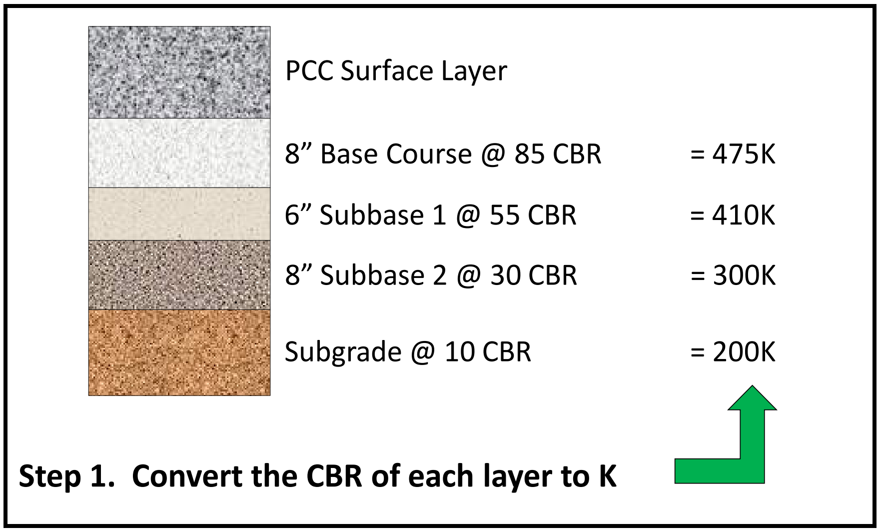
Using the following layer structure, determine k and effective k values.

- Base course is 8 inches (203 millimeters) thick with a CBR = 85
- Subbase 1 is 6 inches (152 millimeters) thick with a CBR = 55
- Subbase 2 is 8 inches (203 millimeters) thick with a CBR = 30
- Subgrade CBR = 10

7-3.4.5.1 Step 1 - Determine k Value for Each Layer Using Figure 7-2.

Use Figure 7-2 to determine the k values for the subgrade, subbase 1, subbase 2, and base course to compare with tentative k values at the top of each of these layers as shown in Figure 7-3.

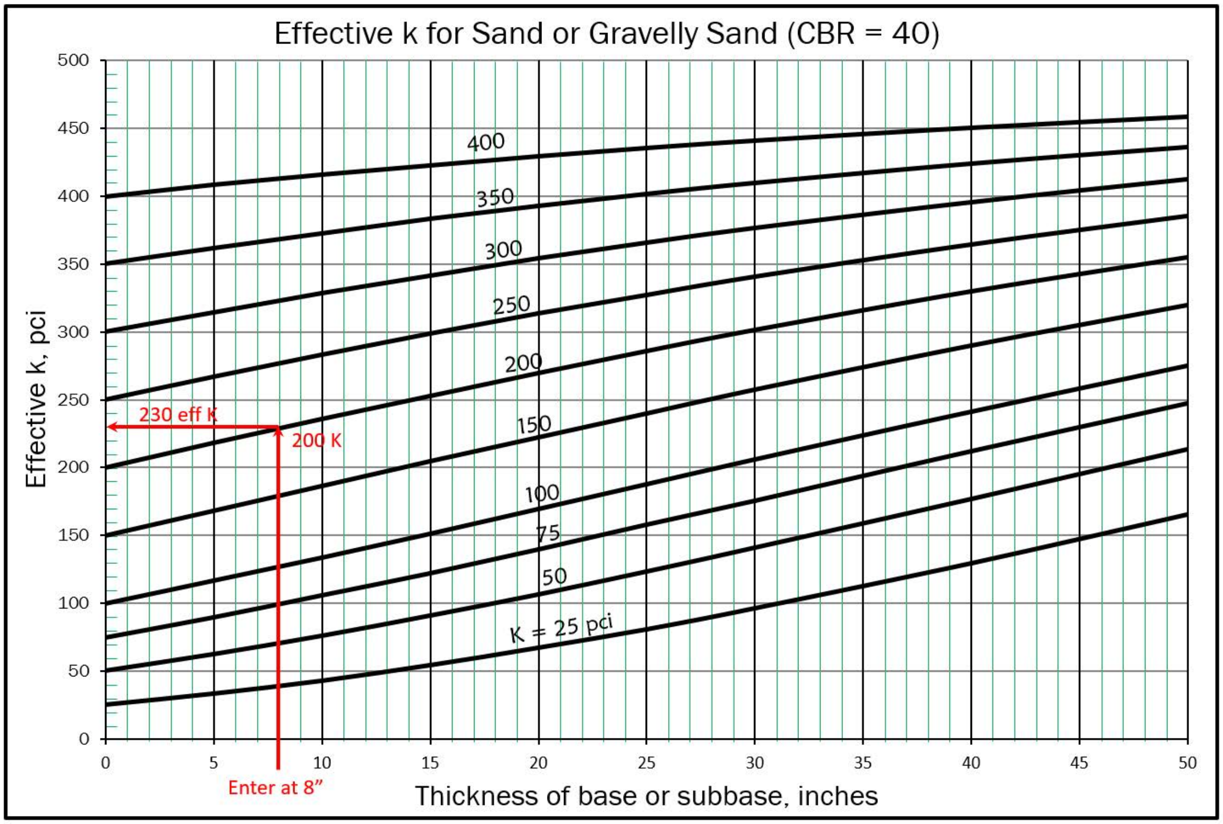
Figure 7-3 CBR to k Conversion Profile



7-3.4.5.2 Step 2 - Determine Effective k for Subbase 2.

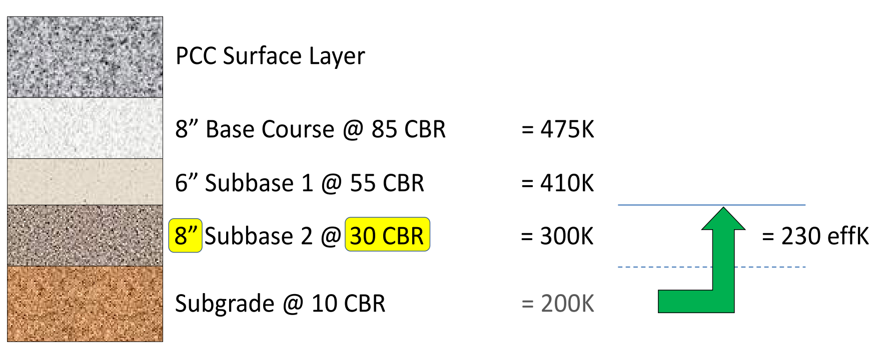
Use Figure 7-4 to determine effective k for layers with CBR values < 50. Results for this step are show in Figure 7-5.

Figure 7-4 Determine Effective k for Subbase 2



For base or subbase layers with CBR < 50 / (K < 399)

Figure 7-5 Effective k Subbase 2 Profile



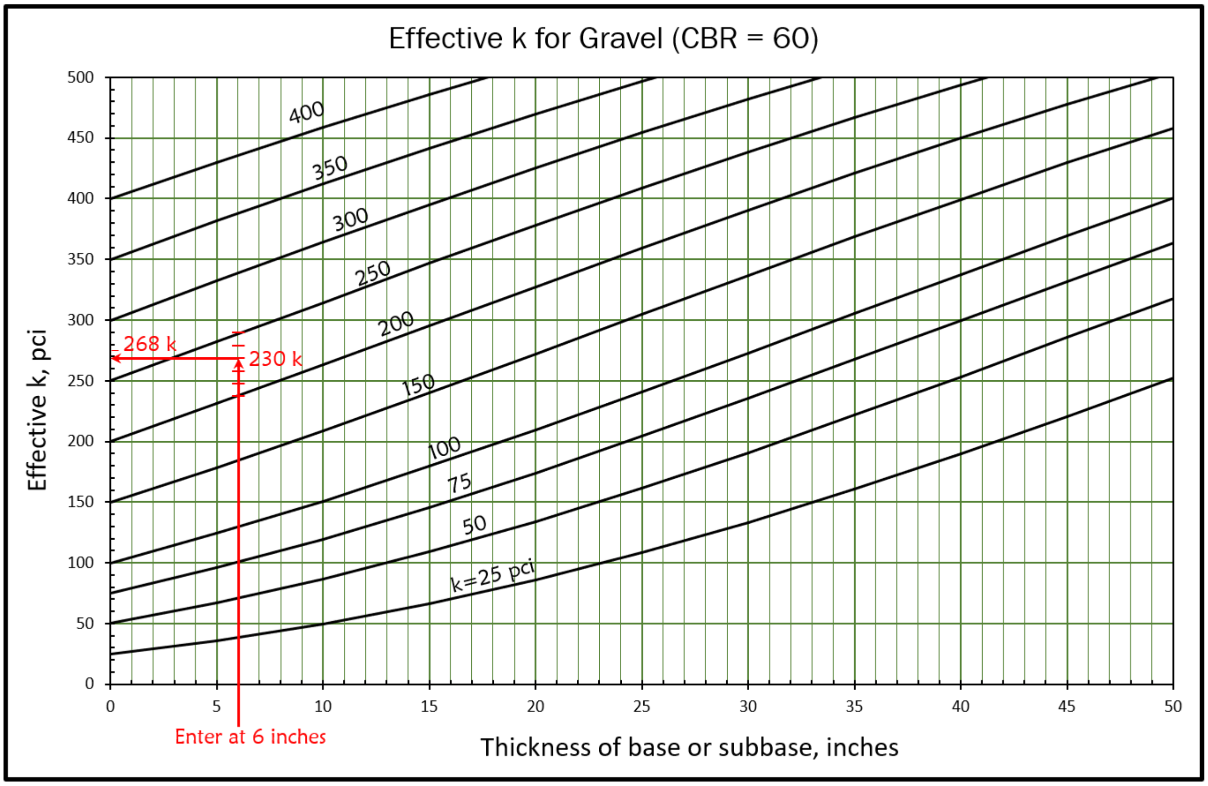
Step 2. Start with bottom layer:

Determine the effective K (230) of this layer (SG) based upon the strength and thickness (8") of the layer (SB 2) immediately above it

7-3.4.5.3 Steps 3 & 4 - Determine Effective k for Subbase 1.

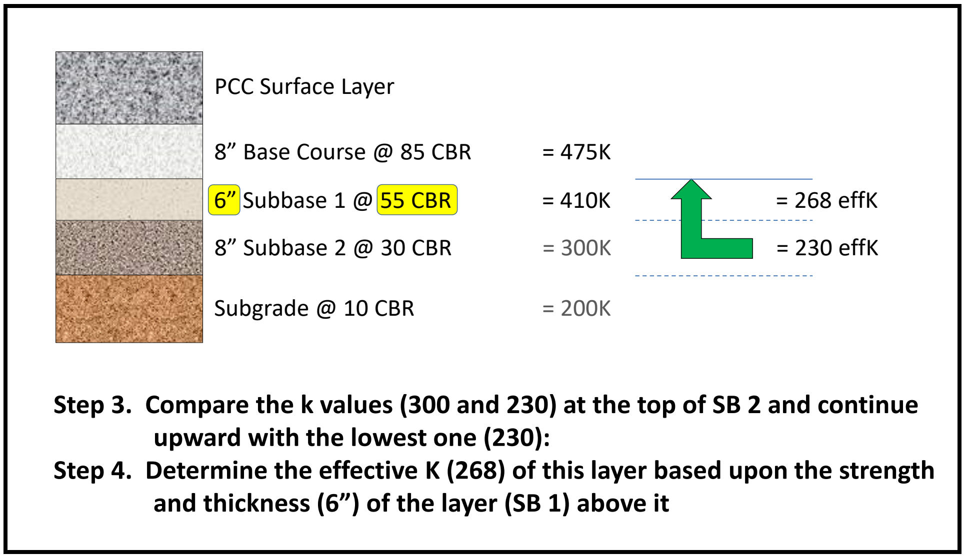
Use Figure 7-6 to determine effective k for layers with CBR values 50 ≤ CBR < 70. Results for this step are show in Figure 7-7.

Figure 7-6 Determine Effective k for Subbase 1



For base or subbase layers with 50 ≤ CBR < 70 / (399 ≤ k < 457 pci)

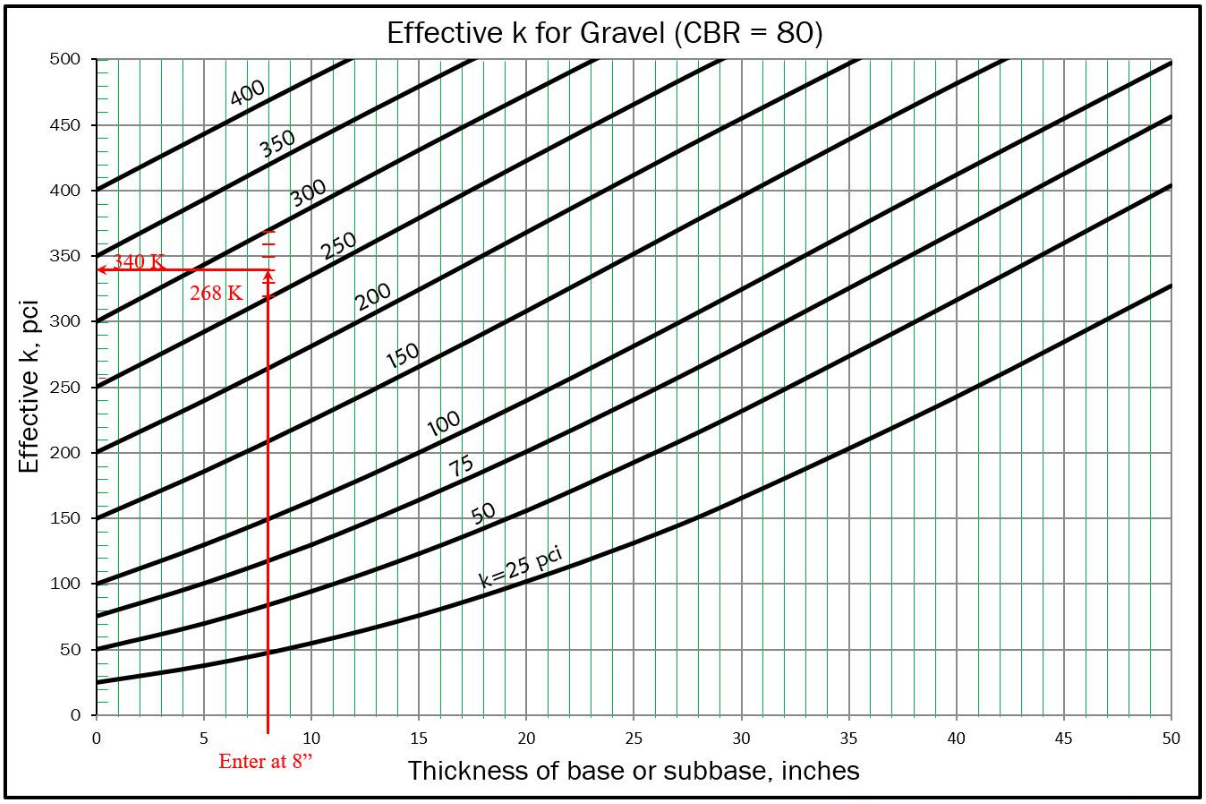
Figure 7-7 Effective k Subbase 1 Profile



7-3.4.5.4 Steps 5 & 7 - Determine Effective k for Base Course.

Use Figure 7-8 to determine effective k for layers with CBR values 70 ≤ CBR <90. Results for this step are shown in Figure 7-9. Use the lower of the measured k or computed effective k. In this case, use 435 pci to evaluate the structure.

Figure 7-8 Effective k Base Course Determination



For base or subbase layers with 70 ≤ CBR < 90 (457 ≤ K < 490)

Figure 7-9 Effective k Base Course Profile

Step 5. Compare the K values (410 and 268) at the top of SB 1 and continue upward with the lowest one (268):

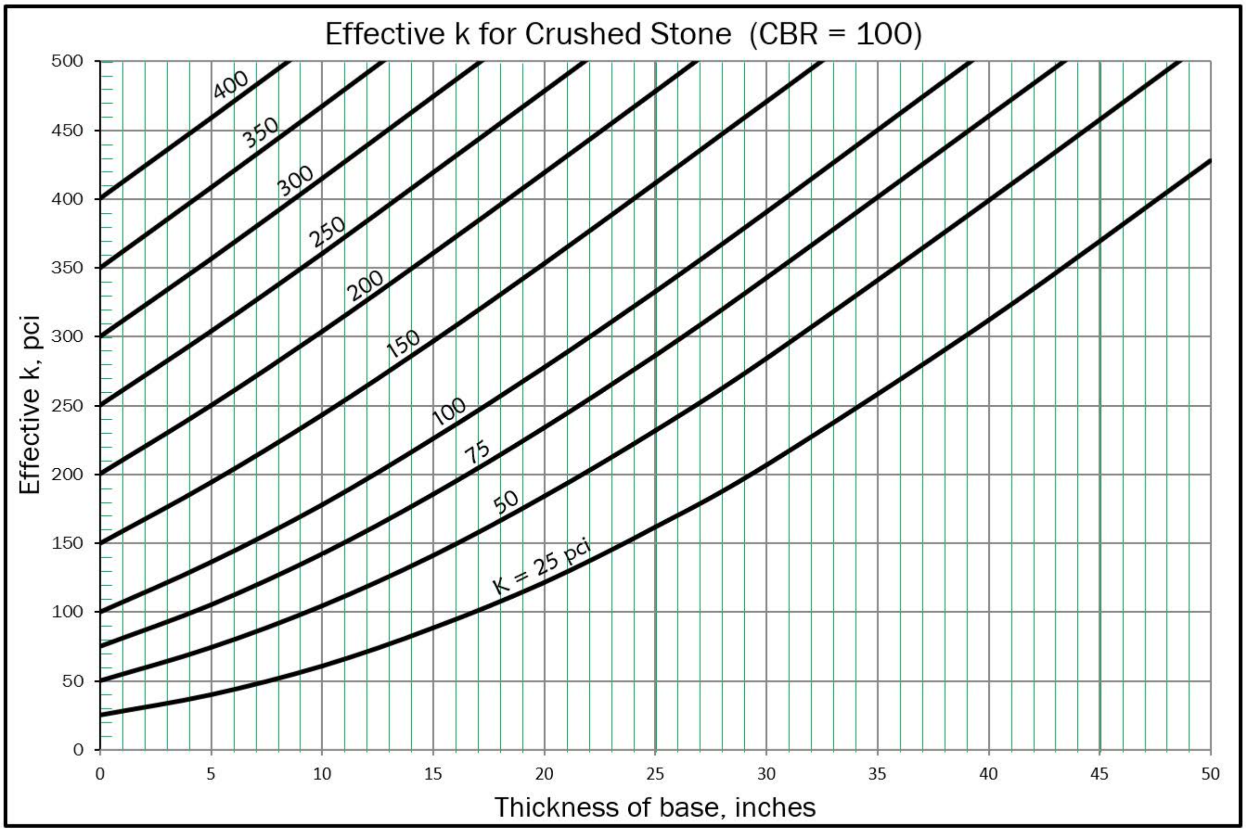
Step 6. Determine the effective K (340) of this layer based upon the strength and thickness (8”) of the layer (BC) above it

Step 7. Compare the eff K values of the layers immediately beneath the PCC (in this case 475 and 340) and use the lowest eff K (340) to evaluate the PCC

7-3.4.5.5 Effective k Crushed Stone Base Course.

While not used in the example problem, the set of curves in Figure 7-10 are used to determine the effective k when the material is crushed stone (CBR 100).

Figure 7-10 Effective k Crushed Stone Base Course Determination



For base layers with CBR $\geq$ 90 / (K $\geq$ 490)

7-3.5 Rigid Pavement Analysis.

7-3.5.1 Westergaard (k) Evaluation Procedure.

Once the thickness, flexural strength, and k values are selected for the respective layers, use these values to determine the critical tensile stresses produced within the slab by the vehicle loading based on the Westergaard procedure and assuming constant tire pressure. Note that results using the current criteria will differ from earlier criteria given that the procedure now assumes constant pressure rather than constant contact area used in past versions of this UFC. The objective of the analysis is to determine the allowable load and allowable passes for the structure. PCASE automates the analysis procedure outlined in this chapter and in Appendix D. The procedure for generating aircraft curves using the current criteria is in TSPWG M 3-260-03.02-19.

7-3.5.2 Procedure for Determining Allowable Gross Load (AGL).

The inputs for this analysis are the traffic mix with the load and number of passes for each vehicle in the mix defined, the pavement structure, and the traffic area. Determine the controlling/representative vehicle and equivalent passes based on one of the traffic analysis procedures outlined in Chapter 4. Compute the design factor based on the flexural strength and load transfer. Perform the allowable coverages calculation using the Westergaard (k) procedure to determine the free edge bending stress for the pavement structure. The bending stress is based on the controlling/representative vehicle load and the design factor. Then use the allowable coverages to compute the cumulative damage factor (CDF). If the CDF is less than 1, increase the Gross load and repeat the analysis procedure. If the CDF is greater than 1, decrease the load and repeat the analysis procedure. When CDF equals 1, use that value for the AGL. See Appendix D for details on this procedure.

7-3.5.3 Procedure for Determining Allowable Passes.

The inputs for this analysis are the traffic mix with the load and number of passes for each vehicle in the mix defined, the pavement structure, and the traffic area. Determine the controlling/representative vehicle and equivalent passes based on one of the traffic analysis procedures outlined in Chapter 4. Perform the allowable coverages calculation using the Westergaard (k) procedure with the free edge bending stress calculated for the pavement structure based on the controlling/representative vehicle load and the design factor that is computed based on the flexural strength and load transfer. See Appendix D for details on this procedure.

7-4 REINFORCED CONCRETE PAVEMENTS.

The process and data required to evaluate reinforced concrete pavements is essentially the same as those for plain concrete pavements, except the percent steel is also required.

7-4.1 Reinforcing Steel.

The reinforcing steel in a reinforced concrete pavement is normally located at or above the neutral axis of the pavement section. If the steel is below the neutral axis, it affects the determination of the flexural strength and the static modulus of elasticity in flexure. Therefore, when the reinforcing steel falls below the neutral axis in a test beam, turn the beam over and test it with the reinforcing steel above the neutral axis. The split tensile test cannot be performed on a core with reinforcing steel although it may be possible to obtain a core to test with no reinforcing steel. If the pavement is thick enough, saw the core just below the reinforcing steel and perform the split tensile test on the lower, non-reinforced portion.

7-4.2 Reinforced PCC Evaluation Procedure.

Determine the percentage of steel reinforcement S per foot of pavement cross-sectional area using Equation 7-5 then use Figure 7-11 to convert the existing reinforced pavement thickness (h_r) to an equivalent thickness (h_E) of plain concrete pavement and calculate the load-bearing capability using plain concrete equivalent thickness.

Equation 7-5. Steel Reinforcement Required

$$S = \frac{A_s}{A_p} * 100$$

Where:

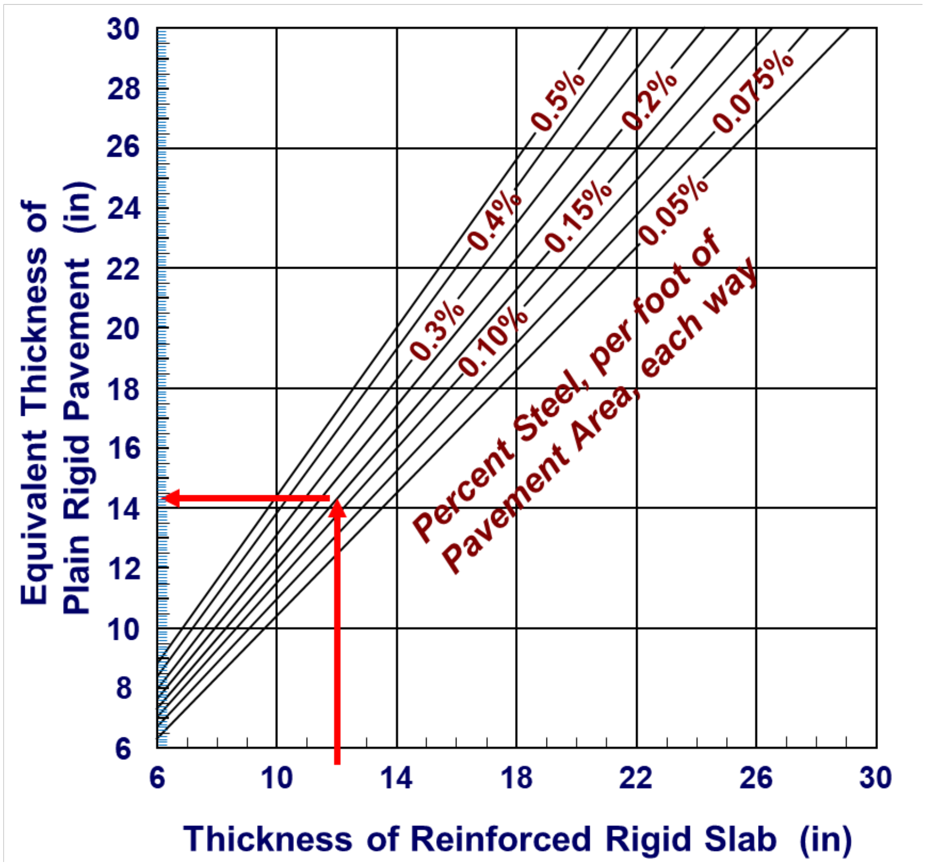
A_s = *cross-sectional area of the reinforcing steel per foot of pavement width or length, square inches*

A_p = *cross-sectional area of pavement per foot of pavement width or length, square inches*

7-4.2.1 Determine Equivalent Plain PCC Thickness of Reinforced PCC.

Compute the percent steel in both the longitudinal and transverse directions. Typically, it will be the same in both directions, but if there is a difference, use the smaller value. Next, enter Figure 7-11 with the known value of h_r, thickness of reinforced PCC pavement. Make a vertical projection and extend it until it intersects the diagonal line representing the computed value of S. Then make a horizontal projection to the left until it intersects the scale line representing the value for h_E, thickness of plain PCC equivalent that would have the same load-carrying capacity as the reinforced concrete pavement. When S is less than 0.05, h_E will equal h_r. When S is greater than 0.5, use the diagonal line representing S = 0.5 percent to determine h_E.

Figure 7-11 Reinforced to Plain PCC, Equivalent Thickness



7-4.2.2 Evaluating Reinforced PCC Overlay or with Stabilized Base.

Determining the equivalent thickness of a reinforced PCC overlay is a two-step process. First, determine the equivalent plain PCC thickness, then determine the equivalent thickness using the fully, partially, or unbonded overlay equivalent thickness calculation described in paragraph 7-4. When a reinforced concrete pavement is placed over a stabilized layer, determine the equivalent thickness of plain concrete pavement as described above using Figure 7-11, then determine the equivalent thickness h_E of the PCC and stabilized layer using Equation 7-1. See reinforced PCC equivalent thickness calculation examples in the PCASE Getting Started module and *User Guide*.

7-5 RIGID OVERLAY ON RIGID PAVEMENT.

The first step in rigid pavement structure with rigid overlay(s) is determining the equivalent thickness of the combined pavement structure. The equivalent thickness is defined as a single thickness of plain concrete pavement with the same load-carrying capacity as the combined thickness of the rigid overlay(s) and the rigid base pavement. Overlay equivalent thickness calculation examples are provided in the PCASE Getting Started module and *User Guide*.

7-5.1 Determining Equivalent PCC Thickness of a Rigid Overlay.

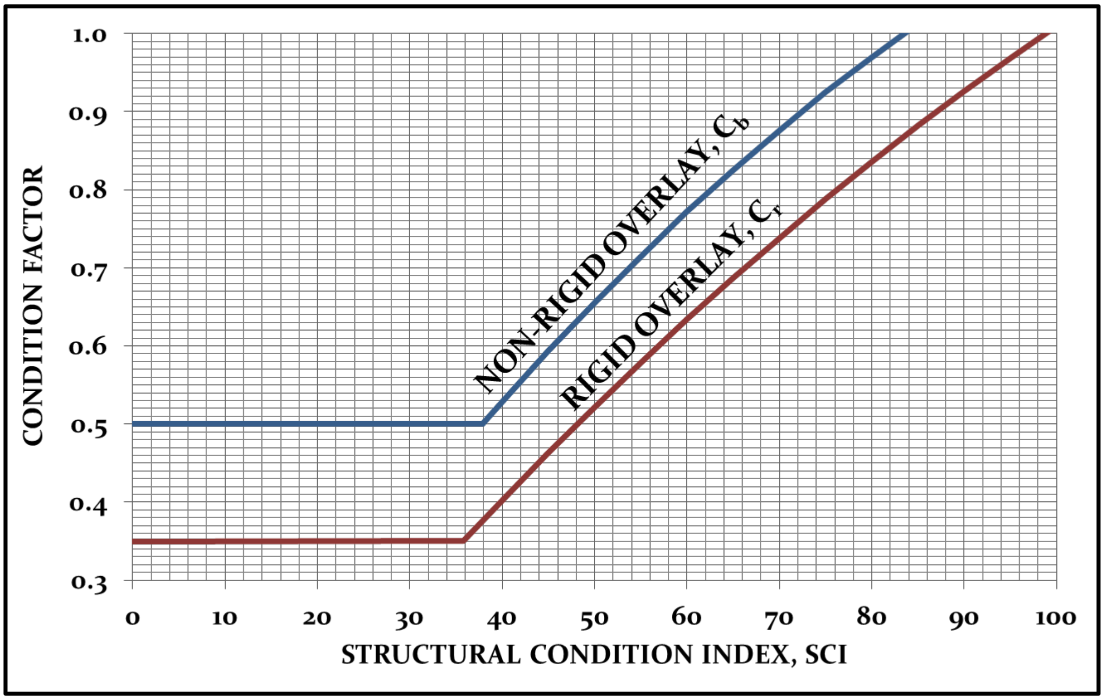
The condition of the base pavement is a key input in determining the equivalent thickness. Structural distresses in the base slab will migrate through the overlay so if the overlay pavement only has minimal structural defects (e.g., reflected longitudinal and transverse cracking as opposed to joint reflective cracking), it is an indication the base pavement is still in good condition. FWD testing or evaluation data from prior to the overlay can also help discern the condition of the base slab and strength of underlying surface layers. Start at the bottom of the structure and determine the equivalent thickness of the base pavement and overlay using the appropriate equation for the overlay type. If there is more than one overlay, use that equivalent thickness and the next overlay to determine the combined equivalent thickness. Continue this procedure with any remaining overlays. When there is variability in the base slab and overlay thicknesses across a section, use the average thickness of each layer in the section to determine the equivalent thickness.

7-5.1.1 PCC Overlay Condition Factors.

Estimate the rigid overlay condition factor (Cr) based on the current surface condition (PCI) and percent of load-related distresses that are used to compute the structural condition index (SCI). PCASE computes the Cr value, but if PCI data is not available, use the recommended Cr values below. In addition, use the values below when it is not possible to visually determine the condition of the existing base PCC slab. The relationship between the SCI and Cr is shown in Figure 7-12. An SCI of 100 indicates good condition and an SCI of 0 indicates poor condition.

- Cr = 1.00 for base PCC in very good condition. There are no structural or reflective cracks in the rigid overlay. If the condition of the base pavement cannot be determined or is unknown, do not use this value.
- Cr = 0.75 for base PCC in good condition. There are a few initial cracks in the surface PCC due to loading or reflective cracks from the base PC slabs, but no progressive cracks.
- Cr = 0.35 for badly cracked base PCC layer. Approximately 60 percent of the slabs in the overlay contain medium- or high-severity cracking or 50 percent of the slabs contain high-severity cracks.

Figure 7-12 SCI – Condition Factor Relationship



7-5.1.2 Partially Bonded PCC Overlays.

If the overlay slab was cast directly on the base slab and no effort was made to break the bond between the overlay and the base pavement by means of a tack coat, sand, paper, bituminous concrete, or other materials placed between the overlay and the base pavement, treat it as a partially bonded overlay. Compute the equivalent thickness h_E of the combined partially bonded overlay and base pavement using Equation 7-6.

Equation 7-6. Equivalent Thickness for Partially Bonded PCC Overlays

$$h_E = \sqrt[1.4]{(h_o)^{1.4} + Cr\,(h_b)^{1.4}}$$

Where:

h_o = thickness of rigid overlay pavement, inches
C_r = coefficient representing condition of rigid base PCC layer
h_b = thickness of rigid base pavement, inches

7-5.1.3 Unbonded PCC Overlays.

If a bond-breaker layer was used between the rigid overlay and the rigid base pavement, treat it as an unbonded overlay. Compute the equivalent thickness h_E of the combined unbonded overlay and base pavement using Equation 7-7. Do not give any thickness credit to the bond breaker layer if it is less than 4 inches (102 millimeters). If the thickness of the bond breaker is greater than 4 inches (102 millimeters), evaluate it as a composite pavement.

Equation 7-7. Equivalent Thickness for Unbonded PCC Overlays

$$h_E = \sqrt{(h_o)^2 + Cr(h_b)^2}$$

7-5.2 Structural Analysis Using the h_E Value.

After determining the h_E value using Equation 7-6 or 7-7, determine the weighted average flexural strength (R) of the overlay and base pavement using Equation 7-8 and use these values to determine the load capability the same as a plain PCC pavement.

Equation 7-8. Weighted Average Flexural Strength

$$R = \frac{h_o(R_o) + h_b(R_b)}{h_o + h_b}$$

Where:
h_o = *thickness of overlay*
R_o = *flexural strength of overlay*
h_b = *thickness of base slab*
R_b = *flexural strength of base slab*

7-6 FLEXIBLE OVERLAY ON RIGID PAVEMENT.

First determine if the flexible (e.g., asphalt) overlay meets the structural design (minimum thickness) requirements in UFC 3-260-02. Thin overlays used to correct surface defects are not given structural credit. When the overlay meets minimum thickness requirements, the procedures outlined below recommend evaluating the pavement as both a rigid and flexible structure and using the method that yields the higher AGL. Use the procedures in Chapter 6 and treat the base slab as a base course for the flexible analysis. For the rigid pavement analysis, determine the equivalent thickness h_E of the combined pavement structure. The equivalent thickness is defined as a single thickness of plain concrete pavement with the same load-carrying capacity as the combined thickness of the flexible overlay(s) and the rigid base pavement. Overlay equivalent thickness calculation examples are provided in the PCASE Getting Started module and *User Guide*.

7-6.1 Determining Equivalent PCC Thickness of a Flexible Overlay.

Just as with a rigid overlay, the condition of the base pavement is a key input in determining the equivalent thickness. In addition, the degree of cracking allowed in the base slab is also required for the equivalent thickness computation. Start at the bottom of the structure and determine the equivalent thickness of the base pavement and overlay using the appropriate equation for the overlay type. If there is more than one overlay, use that equivalent thickness and the next overlay to determine the combined equivalent thickness. Continue this procedure with any remaining overlays. When there is variability in the base slab and overlay thicknesses across a section, use the average thickness of each layer in the section to determine the equivalent thickness.

7-6.1.1 Flexible Overlay Condition Factor.

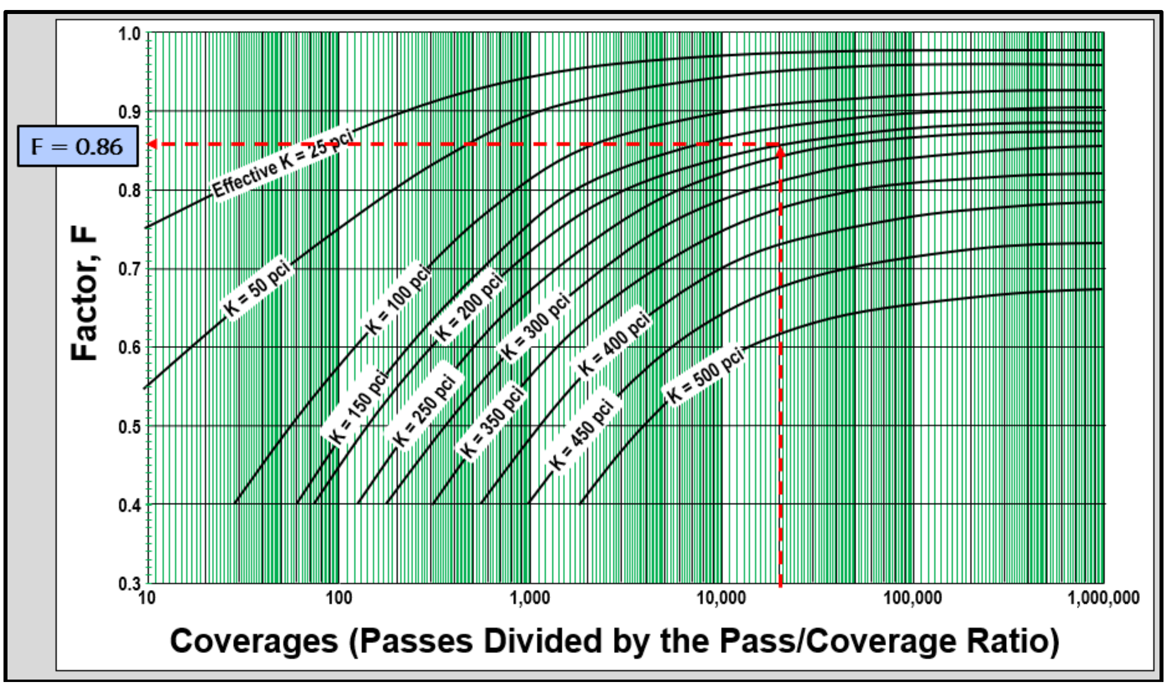
Estimate the flexible overlay condition factor (C_b) based on the current surface condition (PCI) and percent of load-related distresses, which are used to compute the SCI. PCASE will compute the Cb value, but if PCI data is not available or if it is not possible to visually determine the condition of the existing base PCC slab, use the recommended Cb values below. The relationship between the SCI and Cb is shown in Figure 7-11. An SCI of 100 indicates good condition and an SCI of 0 indicates poor condition:

- C_b = 1.0 Use if there are no reflective distresses on the asphalt surface and it is positive that the base pavement is in good condition.
- C_b = 0.8 Use if there are only joint reflective distresses on the asphalt surface.
- C_b = 0.5 Use if there are reflective cracks in addition to reflective joints.

7-6.1.2 Controlled Cracking with F Factor.

The F factor in the equivalent thickness Equation 7-9 defines the degree of cracking allowed in the rigid base pavement during the life of the pavement. It is dependent on the modulus of subgrade reaction k (measured or computed directly under the pavement) and traffic intensity in terms of coverages (passes/pass to coverage ratio of the critical aircraft). PCASE computes the F factor based on the relationship shown in Figure 7-13. The maximum k value used to compute the h_E value is 500 pci. The equivalent thickness equation can yield h_E values greater than the combined thickness of h_b + t for some F factors. If this occurs, use the h_b + t value for h_E.

Figure 7-13 SCI – Condition Factor Relationship



7-6.1.3 Flexible Overlay on Rigid Pavement – Rigid Analysis.

Use the measured pavement thicknesses for the base slab and overlay and the Cb and F values described above to calculate the equivalent thickness h_E in Equation 7-9. The equivalent thickness, h_E, is defined as the thickness of a plain concrete pavement having the same load-carrying capacity as the combined overlay section. Use h_E and the flexural strength of the base slab to determine the load capability using the same procedure as a plain PCC pavement.

Equation 7-9. Equivalent Thickness for Flexible Overlay

$$h_E = \frac{1}{F}(0.33\,t + C_b\,h_b)$$

Where:

t = *thickness of non-rigid overlay pavement, inches*
h_b = *thickness of rigid base pavement, inches*
C_b = *coefficient representing the condition of the rigid base*
F = *a factor which controls the degree of cracking in the rigid base pavement (Several F Factor curves are included in TSPWG M 3-260-03.02-19.)*

7-6.2 Flexible Overlay on Rigid Pavement – Flexible Analysis.

The flexible pavement evaluation method uses the procedures in Chapter 6 and considers the flexible overlay on rigid pavement as a flexible pavement, with the rigid base pavement assumed to be a high-quality base course with a CBR of 100 and the subbase and subgrade characterized by their respective CBR values.

7-6.3 Other Considerations.

7-6.3.1 PCC Material Property Limitations.

When conditions indicate PCC or soil properties are not typical, modify the evaluation accordingly. Consider the possible factors that are influencing the material properties such as those outlined below. Discuss the effect that any of the following factors may have on the evaluation of the pavement in the narrative portion of an evaluation report.

- High moisture absorption and shrinkage of the PCC
- High variations in daily ambient air temperature
- Wide variation in the flexural strength within a given pavement section
- Heterogeneous subgrade, base, or moisture conditions resulting in wide variations in modulus of subgrade reaction values
- Non-rigid overlays (bituminous concrete and flexible overlay) that do not meet design requirements for flexible pavements
- Poor PCC joint load transfer (e.g., NDT deflection ratios)

7-6.3.2 Joint Load Transfer.

As stated previously (see paragraph 5-3.9.2), rigid pavement criteria assume 25 percent joint load transfer. If test data indicate this assumption is not valid, adjust the percent load transfer to reflect what was measured.

7-6.3.3 Asphalt Overlay Quality.

The evaluation procedure outlined above assumes the asphalt concrete meets UFC 3-260-02 design requirements. Determine whether surface cracking is the result of inadequate strength in the overlay or reflective cracking from joints and structural defects in the rigid base pavement. When the surface condition indicates the quality assumption is not valid, it may be necessary to conduct additional tests on the asphalt overlay as outlined in Chapter 3 to determine whether it meets design requirements. Construction records may also be used to determine the quality of the overlay materials. When the asphalt concrete does not meet design requirements, discuss the consequences, such as rutting and raveling, in the narrative portion of the evaluation report. Raveling can be a sign of a poor mix design or construction issues. Rutting or surface cracking can be signs of inadequate strength or asphalt compaction.

7-6.3.4 Comparing the Rigid and Flexible Analysis Procedure.

Typically, the rigid overlay evaluation method yields higher allowable gross weights than the flexible procedure and will be used for reporting purposes. However, when the flexural strength of the rigid base pavement is less than 400 psi (2.8 MPa) or the k value of the foundation is greater than 200 pci, the flexible pavement evaluation method can yield the higher allowable gross weight at a selected pass level. Therefore, especially when the test results indicate that the flexural strength of the rigid base pavement is less than 400 psi (2.8 MPa) or the k value is greater than 200 pci, evaluate the flexible overlay on rigid pavement by both methods to determine which yields the higher allowable gross weight for a selected pass level.

7-6.4 Asphalt Additional Overlay Thickness.

Use Equation 7-10 to determine the additional asphalt overlay thickness required to support aircraft operations.

Equation 7-10. Additional Overlay Thickness Calculation

$$t_{ao} = 3 \cdot [F \cdot h_d - h_E]$$

Where:

t_{ao} = *additional overlay required, inches*
h_d = *new pavement PCC layer design thickness, inches*
h_E = *equivalent thickness of existing PCC base and overlay, inches*
F = *a factor which controls the degree of cracking in the rigid base pavement, see paragraphs 7-6.1.2 and 7-6.1.3.*

7-7 RIGID OVERLAY ON FLEXIBLE PAVEMENT.

The flexible pavement layer (e.g., asphalt concrete) in a rigid overlay on flexible pavement structure is treated as a base course for the rigid overlay. Determine the k value on the surface of the flexible pavement with the plate-bearing test subject to the limitations described in paragraph A-5.9 or using the effective k procedure described in paragraph 7-3, but in no case use a k value greater than 500 pci.

7-7.1 Rigid Overlay on Flexible Pavement Analysis.

Select representative thickness values for the rigid overlay and other layers in the structure, determine the flexural strength of the rigid overlay, and modulus of subgrade reaction (k) on the surface of the existing flexible pavement as described in paragraph A-5.9.2. Evaluate the rigid overlay on flexible pavement using the same procedures used for plain PCC pavement on a base course.

7-8 COMPOSITE PAVEMENT.

A composite pavement consists of three or more pavement layers. This section specifically addresses the situation in which there is a rigid layer over asphalt over a rigid base slab. The analysis procedure depends on whether the asphalt layer is less than or greater than 4 inches (102 millimeters).

7-8.1 Asphalt Layer Less than 4 Inches (102 Millimeters).

When the thickness of the asphalt layer is less than 4 inches (102 millimeters), treat the rigid surface as an unbonded overlay, with the thickness of the asphalt layer assumed to be a bond-breaking layer. Determine the layer thicknesses of each layer in the structure, the equivalent thickness of the asphalt and base pavement, the flexural strength of the rigid overlay and base pavement, and the k value of the foundation materials beneath the rigid base pavement. Estimate the condition of the base slab as described in paragraph 7-5.1.1 and use Equation 7-7 for an unbonded overlay to determine h_E.

7-8.2 Asphalt Layer Greater than or Equal to 4 Inches (102 Millimeters).

When the thickness of the asphalt between the rigid pavements is greater than or equal to 4 inches (102 millimeters), treat the surface layer as rigid pavement on a base. Determine thickness of each layer in the structure, the flexural strength of the rigid overlay, and the k value on the surface of the asphalt layer beneath the rigid surface layer. Use the procedure described in paragraph 7-7.1 for a rigid overlay on a flexible pavement to determine the effective k.

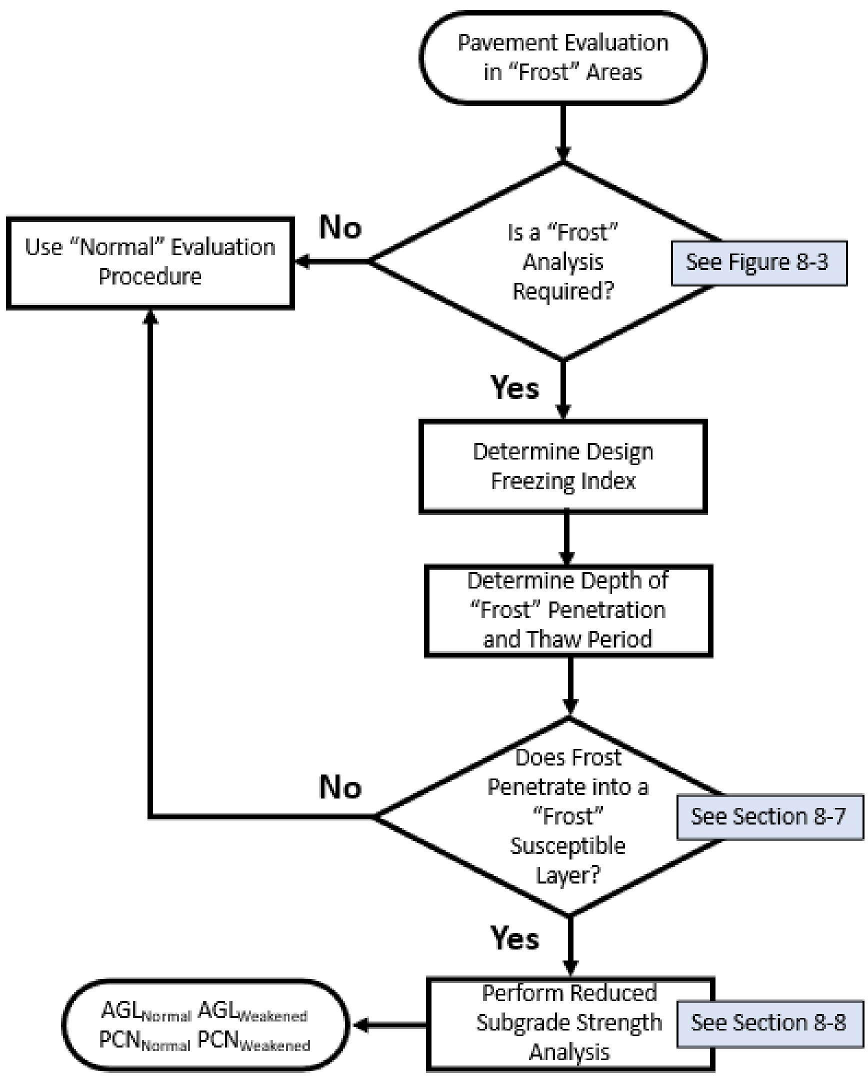
CHAPTER 8 PAVEMENT FROST EVALUATION

8-1 PAVEMENT FROST EVALUATION PROCESS.

The term frost evaluation is used to describe the process of determining if a pavement is susceptible to the detrimental effects of frost action and, if so, analyzing the pavement structure to determine the impact of these effects on the load-carrying capacity of the pavement during the thaw period. Figure 8-1 describes the overall process. The first step is to determine if a frost analysis is warranted. If it is, compute the design freezing index (DFI) using climate data from the WorldIndex database, then determine the depth of frost penetration and start and duration of the freezing season. If the depth of frost penetration does not penetrate into a layer of frost-susceptible material, use the normal evaluation procedure. If it does, then use the reduced subgrade strength procedure. Terms used in this chapter that are not explained in the text are defined in the glossary in Appendix F.

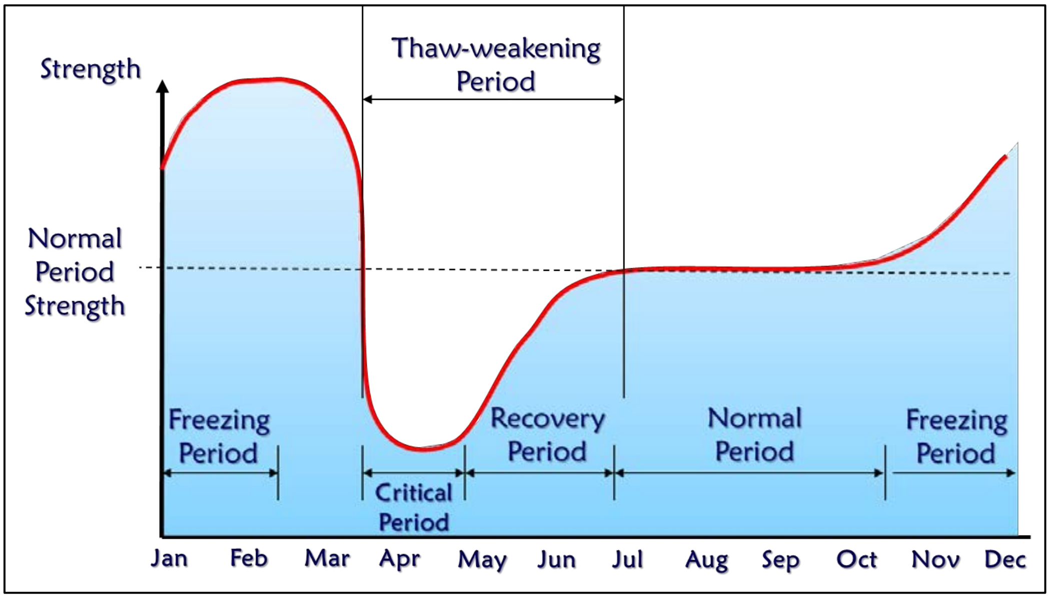
Figure 8-1 Pavement Frost Evaluation Process



8-2 FROST ACTION.

Frost action is a general term for freezing and thawing of moisture in materials and the resultant effects on these materials, the overall structure, and adjacent structures. Detrimental effects can occur when a pavement structure is exposed to freezing temperatures, has frost-susceptible soils, and has a source of water near the freezing front. When these conditions exist, water is drawn upward to the freezing front, creating ice lenses, which can result in pavement frost heave that increases the roughness of the pavement surface. As the ice melts, water does not readily drain or redistribute itself, saturating and thus weakening the soil and reducing the pavement structure's load-bearing capacity during the thaw period. The weakened pavement transitions back to a normal state as the soil drains, pore water pressure dissipates, and soil reconsolidates. Figure 8-2 provides a conceptual graphic of the freeze-thaw cycle.

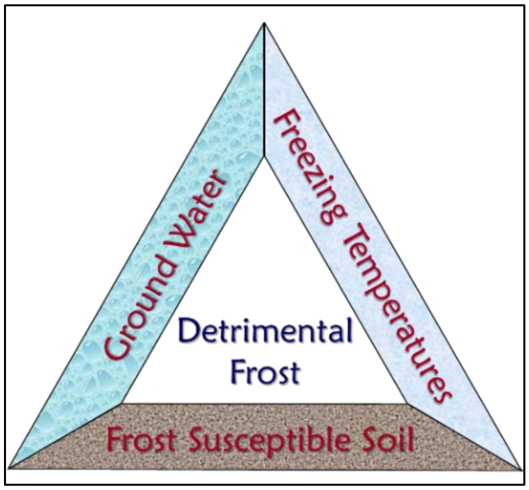
Figure 8-2 Freeze-thaw Cycle



8-3 WHEN TO PERFORM A FROST EVALUATION.

A frost evaluation is not warranted unless all the elements that increase the risk of detrimental frost action exist as shown in Figure 8-3. Additional soil sampling and laboratory testing is required to determine the moisture content, dry density, and frost susceptibility of the soil. This information is used to determine the depth of frost penetration and potential loss of load-carrying capability.

Figure 8-3 Detrimental Frost Action



8-3.2 Temperature.

The average daily air temperature at the location must remain below freezing for sufficient time for the freezing front to extend into frost-susceptible soil layers. If it does not, frost analysis is not warranted.

8-3.3 Frost-Susceptible Soil.

The frost susceptibility of soil is defined by the percent of soil finer than a #200 (.075 mm) sieve by weight and the percent finer than 0.02 mm by weight. This determines the frost group of the soil, which is described in more detail in paragraph 8-6.1.2. Non-frost-susceptible soils have a minimal risk of detrimental frost action.

8-3.4 Ground Water.

Generally, if the water table is below 10 feet (3 meters), detrimental frost action is not a problem.

8-3.5 Evidence of Detrimental Frost Effects.

Even when it appears all the elements shown in Figure 8-3 and described above exist, check for evidence of damage due to detrimental frost action. If the conditions described below do not exist, frost analysis may not be required.

- Pavement heave and cracking
  - Differential heave caused by swelling of materials in subgrade and base due to frost action
  - Differential settlement caused by soil reconsolidation after heave
- Excessive cracking of rigid pavement
  - Pumping along cracks and joints
  - Durability (D) cracking

   - Excessive joint and crack spalling
   - Longitudinal cracking or other load-related distresses in non-traffic areas
- Accelerated cracking of flexible pavement
   - Alligator cracking or other load-related distresses
   - Distresses located in non-traffic areas
   - Accelerated deterioration along cracks

8-3.5.1 Detrimental Frost Effects.

Detrimental frost effects include frost heave and thaw weakening. Frost heave occurs when the pavement surface is raised. It is directly associated with ice segregation and is visible evidence on the surface that ice lenses have formed in the subgrade, subbase, or base layer materials. When ice segregation occurs in a frost-susceptible soil, the soil is subsequently weakened during prolonged thaw periods that can occur during winter partial thaws and early in the spring. When the segregated ice melts, it leads to excess water in the base, subbase, or subgrade that cannot drain through the still-frozen underlying soil. Drainage could also be restricted laterally at this time of the year; thus, the period of severe weakening may last several weeks. When the pavement structure has a drainage layer, this period of severe thaw-weakening can decrease.

8-3.5.2 Frost Heave.

Pavements constructed over F4 subgrade soils, and in some instances over F3 soils, as described in Table 8-1, may experience heave. Heave can be uniform or non-uniform, depending on variations in exposure to solar radiation, the character of the soil, and groundwater conditions underlying the pavement. Non-uniform heave results in unevenness or abrupt changes in grade at the pavement surface. This surface roughness may be objectionable for aircraft with high landing and takeoff speeds. If experience indicates this is the case, the report should include the locations and descriptions of the objectionable roughness. Obtain surface elevations at least once a month during the following winter to determine the magnitude of the detrimental heave.

8-3.5.3 Thaw Weakening.

The load-bearing capacity of both flexible and rigid pavements can be severely reduced during critical weakening periods; however, the reduction is less critical for rigid than for flexible pavements. Rigid pavements experience a smaller reduction because the subgrade has less influence on the supporting capacity of rigid pavements than on that of flexible pavements. Subgrade soils under rigid pavements are subjected to less shearing deformation and remolding during critical weakening periods.

Soils, such as clays, which often show no frost heave, may significantly lose supporting capacity during thawing periods. Frost-susceptible granular unbound base materials may also weaken significantly during frost-melting periods because of increased saturation and associated decrease of moisture tension, combined with reduced density that is derived from expansion in the previously frozen state. As the percent of fines in granular material increases, so does its potential for thaw weakening during frost-melting periods due to reduction of its permeability.

Traffic loads may cause excess hydrostatic pressures within the pores of the frost-affected soil during thaw-weakening periods, resulting in further reduction in strength or even failure. The degree to which a soil loses strength during a frost-melting period and the duration of the period of thaw weakening depend on the soil type, temperature conditions during freezing and thawing, the amount and type of traffic during frost melting, the availability of water during freezing and thawing, and drainage conditions.

8-3.5.4 Visible Surface Effects.

Visible surface effects associated with frost action include random cracking and roughness due to differential frost heave as described above. Noticeable cracking and weakening or deflection can also occur in flexible pavements during the thaw period but may not become visible in rigid pavements during thaw until subsurface damage accumulates and leads to visible surface cracking. As a result, thaw weakening may not always be recognized as the dominant factor causing accelerated deterioration. In either case damage due to thaw weakening may be more severe than cracks caused by frost heave or low-temperature contraction because it leads to destruction of the pavement, requiring reconstruction.

Cracks in flexible pavements may be the result of contraction of the pavement during periods of extremely low temperatures. Flexible pavements that experience accelerated deterioration because of thaw weakening can show alligator cracking or other load-associated cracking at an early age. Rigid pavements can exhibit slab cracking or pumping at cracks and joints. Studies of rigid pavements have shown that cracks may develop more rapidly during and immediately following the spring frost-melting period due to differential thaw than during the period of active heave. D cracking is also a common indication of freeze-thaw damage to PCC pavements but is primarily associated with aggregates of poor quality in the concrete mixture. These are closely spaced crescent-shaped cracks that occur adjacent to longitudinal and transverse joints or free edges.

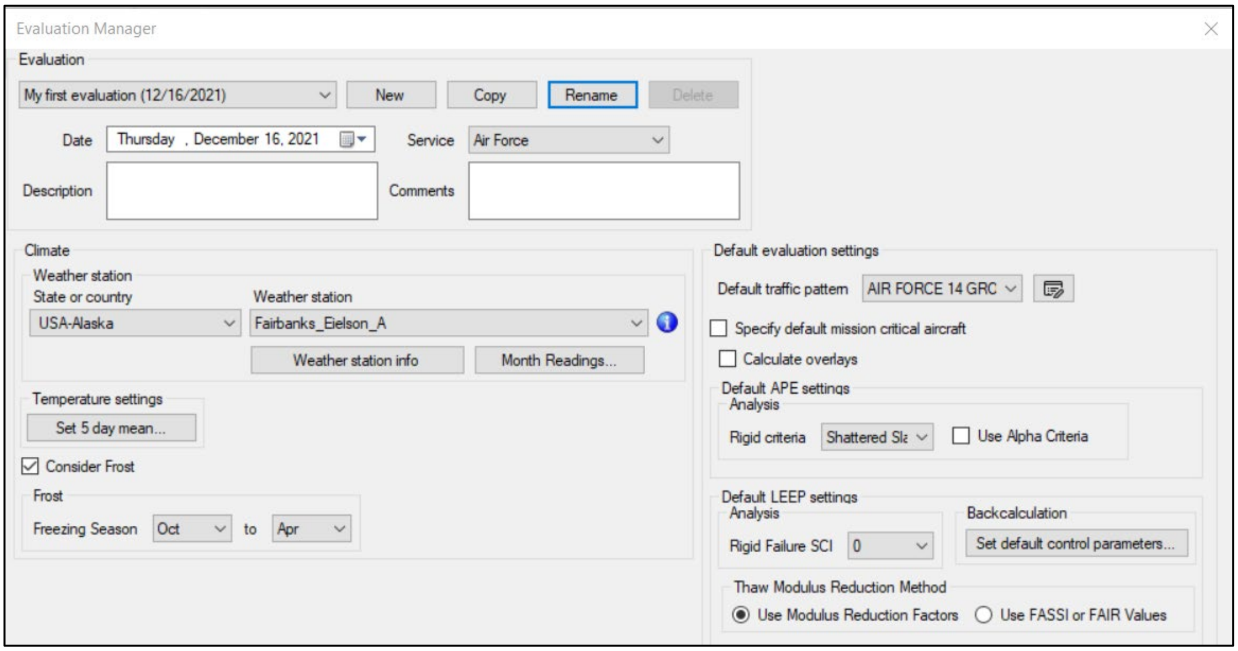
8-3.5.5 Field Inspection and Previous Records.

During pavement inspections, note any cracking, faulting, or pumping. Give particular attention to locations of transitions between cuts and fills and at any boundaries of subgrade soils of varying frost susceptibility. HWD testing can help determine where these transitions take place. Note all spalling at the edges of open cracks which can be an indication of “working cracks” caused by frost action. Construction maintenance and previous evaluation records may help in confirming whether frost-susceptible conditions exist. Records of highway performance in the vicinity of the airfield that have similar subgrade conditions may provide a clue as to whether weakening occurs because of frost melting. In the analysis of highway performance records, the evaluator should carefully note and assess the many local influences that may affect frost action, such as variations in ground-water level, soil conditions, type of pavement surface, degree of shading, north versus south slope, frequency of snow plowing, position of underlying bedrock, etc.

8-4 SETTING UP PCASE FOR FROST ANALYSIS.

When a frost analysis is required, in the Pavement-Transportation Computer Assisted Structural Engineering (PCASE) application the user must check the “Consider Frost” box on the Evaluation Manager form as shown in Figure 8-4, then select the state/country and station for the evaluation location. If there is no station for the specific location, select the station closest to the location at a similar elevation and with similar climatic conditions. This process identifies the climate data from the WorldIndex database to be used for the evaluation. Selecting the “Consider Frost” checkbox also activates additional fields on the airfield pavement evaluation (APE) and Layered Elastic Evaluation Program (LEEP) forms for use in frost analysis.

Figure 8-4 “Consider Frost” Checkbox and Select Station



8-5 DESIGN FREEZING INDEX (DFI).

The DFI is based on climate data from the WorldIndex database for the selected station. The DFI is a description of the length and severity of the winter for a given location. It is used to determine the surface freezing index which, in turn, is used to determine the depth of frost penetration. While the term “design” is used, the DFI is equally applicable to evaluation.

Historically, the DFI was defined as the average air freezing index (AFI) of the three coldest winters in the latest 30 years of record. If 30 years of record were not available, the AFI for the coldest winter in the latest ten-year period was used. This climate data was presented in maps showing the distribution of design AFI values or mean air freezing index values as described in paragraphs 8-5.5 and 8-5.6. The WorldIndex database provides a numerical solution for determining the DFI. The USACE Cold Regions Research and Engineering Laboratory (CRREL) created the WorldIndex database to aggregate climate data from the National Oceanic and Atmospheric Administration (NOAA).

8-5.1 WorldIndex Database.

The WorldIndex database is available through the PCASE program. The current version of the database was published in 2018 and uses historical surface air-temperature observations from 1980 to 2017 (37 years) at over 16,000 locations around the globe. Each station has a minimum of five years of continuous data available. The WorldIndex database is updated every five years. It aggregates data from the Global Surface Summary of Day (GSOD) database (version 7) and the Global Historical Climatology Network (GHCN) Cooperative Observer Program database, which are published by NOAA's National Centers for Environmental Information (NCEI) and the National Weather Service, respectively.

The database contains 80 air-temperature-based parameters determined for each station, including the parameters PCASE uses to determine the depth of frost penetration, the start and duration of the thaw season, and temperature data used to determine asphalt design/evaluation modulus values. All data is stored in Celsius units. Note that the WorldIndex database uses the term freezing degree-days (FDD) rather than the terms AFI or DFI. More details on the structure and content of the WorldIndex database are available in the ERDC/CRREL Technical Report TR-19-13, *WorldIndex Database Update 2018*.

8-5.2 Degree Days.

The number of degree-days for any given day is the difference between the average daily air temperature and 32 °F. The degree-days are negative when the average daily temperature is below 32 °F (freezing degree-days) and positive when above (thawing degree-days) although in both cases, the sign is typically omitted when presenting the data. Air temperatures are measured approximately 4.5 feet (1 meter) above the ground. Degree days may be computed in either Fahrenheit or Celsius units.

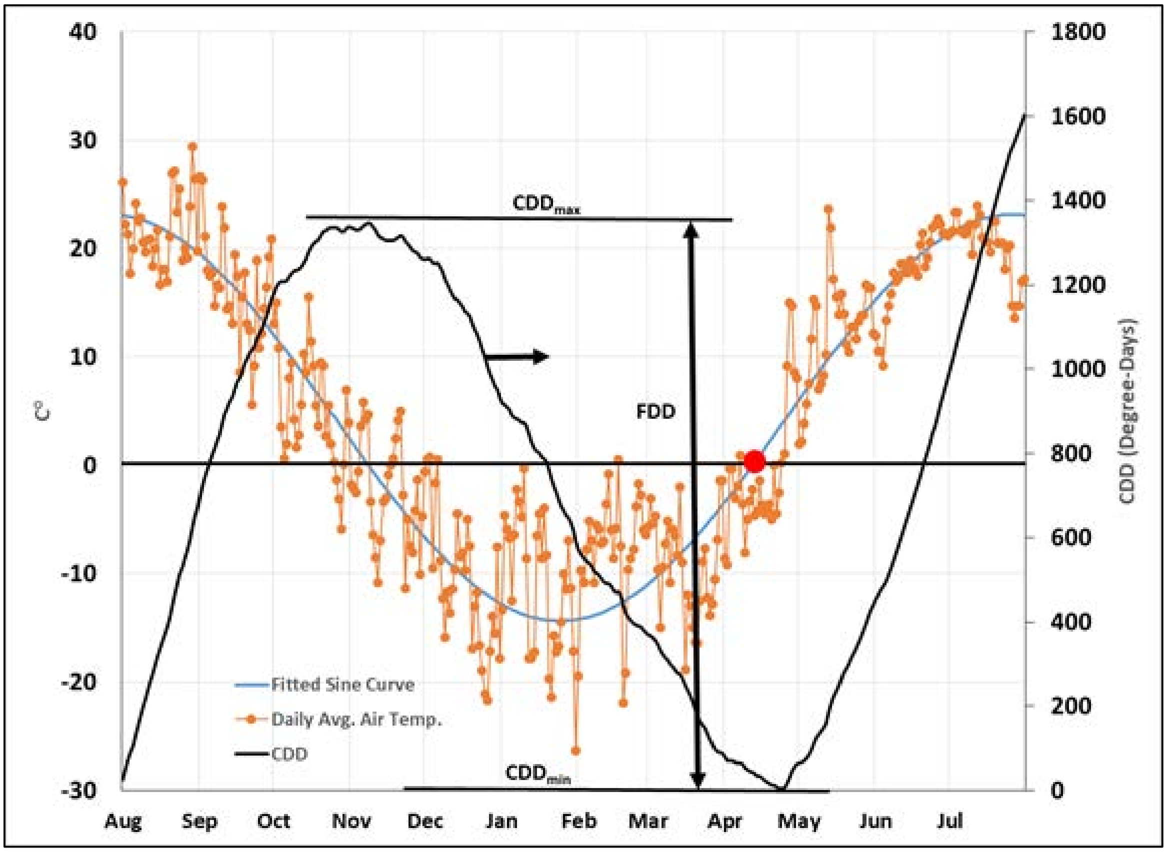
8-5.3 Cumulative Degree Days (CDD).

CDD are the arithmetic sum of FDD over time (typically a year). When CDD are plotted versus time, it generates a curve used to determine the AFI, as shown in Figure 8-5.

8-5.4 Air Freezing Index (AFI).

The AFI is the number of FDD between the highest (CDD_{max}) and lowest points (CDD_{min}) on a CDD curve versus time for a single freezing season. It is also called the annual AFI and is used as a measure of the combined duration and magnitude of below-freezing temperatures occurring during any given freezing season. Note that the AFI is shown as FDD in Figure 8-5 to reflect the terminology used in the WorldIndex database.

Figure 8-5 Air Freezing Index



8-5.5 Average Annual Air Freezing Index (AFI).

The average AFI is the average of all the annual AFIs over the period of record. As noted above, the period of record for the data in the WorldIndex database is 37 years rather than 30 years as described in past criteria documents. The WorldIndex database uses the term “average annual maximum cumulative freezing degree days (YRLY_AVG_FDD).” This value and the standard deviation of the average annual maximum cumulative FDD (YRLY_STDEV_FDD) are passed to PCASE to compute the DFI.

8-5.6 Computing the Design Freezing Index (DFI).

Past criteria defined the DFI as the average AFI of the three coldest winters in the latest 30 years of record. The current procedure uses the average annual AFI and its standard deviation to define the DFI as shown in Equation 8-1. This approach represents the 91st percentile of the freezing indices for the period of record for a given location assuming a normal distribution (Reference: Cortez, E.R., M.A. Kestler, and R.L. Berg. 2000, *Computer-Assisted Calculations of the Depth of Frost Penetration in Pavement-Soil Structures*).

Equation 8-1. DFI Computation

$$\text{DFI (°F days)} = 1.8 * \left(\overline{AFI_{Ann}} + (1.5 * \sigma_{AFI})\right)$$

Where:

$1.8 = constant\ to\ convert\ \text{°C}\ days\ to\ \text{°F}\ days$

$\overline{AFI_{Ann}} = Average\ AFI = YRLY\_AVG\_FDD\ (\text{°C}\ days)$

$\sigma_{AFI} = standard\ deviation\ of\ the\ average\ AFI = YRLY\_STDEV\_FDD\ (\text{°C}\ days)$

For example, if the average annual AFI is 990 ℃ days and the standard deviation is 310 ℃ days, the DFI is 2619 °F days.

$$1.8 * \left(990\ \text{°C}\ Days + (1.5 * 310\ \text{°C}\ days)\right) = 2619\ \text{°F}\ days$$

Figure 8-6 is taken from the previous version of this UFC based on data prior to 1987. It graphically depicts DFI distribution in North America and is presented here as a general guide. Note that the current release of the WorldIndex database identified overall decreases in global annual AFI values from previous data.

8-5.7 Alternate DFI Procedure.

In cases where climate data for a location is not available in the WorldIndex database but the mean freezing index is available from other data sources, the DFI can be roughly estimated using the equations below and used to manually compute the depth of frost penetration for use in PCASE. It is important to note the period of record for the available data. At a minimum, it should cover the latest 10 years and preferably at least 30 years. Special considerations will be necessary to compensate for local topographic conditions that will cause deviations from general freezing index values. Note that the mean freezing value must be multiplied by 13.33 to convert from degrees F days to degrees C hours in the second equation.

<u>*English Units*</u>

$$(DFI) = 429 + 1.143 \times mean\ freezing\ (^{o}\ F\ days)$$

<u>*SI Units*</u>

$$(DFI) = 5{,}718 + 1.143 \times mean\ freezing\ index\ (^{o}\ C\ hours)$$

8-6 DETERMNE DEPTH OF FROST PENETRATION AND THAW PERIOD.

The general process to determine the depth of frost penetration and the start and duration of the thaw period for a given pavement structure is outlined below. It focuses on the numerical procedure used in PCASE, but both the depth of frost penetration and length of the thaw period can be entered in PCASE based on manual calculations or experience at the location.

- Define the pavement layer structure
  - o Pavement type and thickness
  - o Soil layer type classifications and thicknesses
    - ▪ Soil frost group
    - ▪ Moisture content
    - ▪ Dry unit weight
- Compute the surface freezing index

- Determine the start and length of the thaw season

8-6.1 Define the Pavement Layer Structure.

Chapter 3 outlines field procedures for testing to determine the pavement layer structure. Chapters 5, 6, and 7 outline the procedure for entering the layer structure data for layered elastic and conventional (CBR and k) structural analysis. Frost analysis requires a frost code (soil frost group), gravimetric moisture content, and dry unit weight for each layer in addition to entering the pavement and soil layer types and thicknesses.

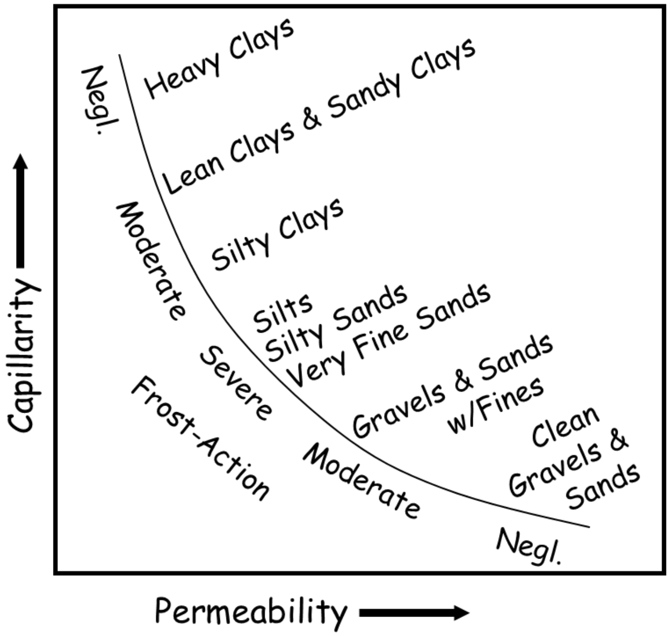
8-6.1.1 Supplementary Soil Testing for Frost Analysis.

When a frost analysis is warranted based on the criteria in paragraph 8-3, conduct testing on the base, subbase, and subgrade material to determine its frost susceptibility. Even if the materials were not frost-susceptible at construction, base and subbase materials can degrade due to freeze-thaw cycles and traffic loads over time. This degradation may introduce additional fines, increasing its thaw-weakening potential.

8-6.1.2 Frost Susceptibility of Base, Subbase, and Subgrade.

Use sieve and Atterberg limits testing to classify base, subbase, and subgrade soils according to the Unified Soil Classification System (USCS) (ASTM D2487, *Standard Practice for Classification of Soils for Engineering Purposes (Unified Soil Classification System)*). The frost susceptibility of soil is defined by the percent of soil finer than a #200 (.075 mm) sieve by weight and the percent finer than 0.02 mm by weight. Additional testing is required to characterize the percent finer than 0.02 mm by weight using methods described in ASTM D1140, *Standard Test Methods for Determining the Amount of Material Finer than 75-µm (No. 200) Sieve in Soils by Washing*, and ASTM D7928, *Standard Test Method for Particle-Size Distribution (Gradation) of Fine-Grained Soils Using the Sedimentation (Hydrometer) Analysis*. Table 8-1 identifies the frost susceptibility by soil type and percent fines. They are listed in approximate order of increasing frost susceptibility and decreasing bearing capacity during periods of thaw. The percent of fines defines the potential for capillary action and the permeability of soil, which both effect the potential for detrimental frost action as shown in Figure 8-7. Note that while clay materials may not show frost heave, they can still have significant loss of bearing capacity during thawing periods.

Figure 8-7 Frost Action Severity Based on Soil Type



Most cohesive soils have high capillarity but low permeability, water moves too slowly for growth of thick ice lenses.

Low-plasticity soils with high percentage of silt-sized particles, have pore sizes small enough to develop capillary potential, but large enough to permit travel of water to the frozen zone.

Coarser soils have higher rates of flow, but do not have the capillary potential to lift enough moisture for heaving.

Table 8-1 Frost Susceptibility Soil Classification

Frost Group	Soil Type	% Finer than 0.02 mm by Weight	% Finer than #200 Sieve by Weight[1]	Typical Soil Types (Unified Soil Classification System)
NFS[2]	(a) Gravel, crushed stone, crushed rock	0 - 1.5	0 - 3	GW, GP
	(b) Sands	0 – 3	0 - 7	SW, SP
PFS[3]	(a) Gravel, crushed stone, crushed rock	1.5 - 3	3 - 7	GW, GP
	(b) Sands	3 – 10		SW, SP
S1	Gravelly soils	3 - 6	7 - 15	GW, GP, GW-GM. GP-GM
S2	Sandy soils	3 - 6	7 - 15	SW, SP. SW-SM, SP-SM
F1	Gravelly soils	6-10		GM, GW-GM, GP-GM
F2	(a) Gravelly soils	10-20		GM, GW-GM, GP-GM
	(b) Sands	6-15		SM, SW-SM, SP-SM
F3	(a) Gravelly soils	Over 20		GM, GC
	(b) Sands, except very fine silty sands	Over 15		SM, SC
	(c) Clays, PI > 12	--		CL, CH
F4	(a) Silts	--		ML, MH
	(b) Very fine silty sands	Over 15		SM
	(c) Clays, PI < 12	--		CL, CL-ML
	(d) Varved clays and other fine-grained, banded sediments	--		CL, ML, and SM, CL, CH, and ML, CL, CH, ML, and SM

Notes: 1. These are rough estimates. If there are surface indications of frost action, then frost-susceptibility tests should be conducted.
2. Nonfrost susceptible.
3. Possibly frost susceptible; requires lab test to determine frost soil classification.

8-6.1.3 Moisture Content.

The moisture content and dry unit weight of the soil in each layer are required inputs that PCASE uses to compute the frozen and unfrozen soil thermal properties of each layer. Optimally, these values are determined based on field and laboratory testing such as ASTM D6938, *Standard Test Methods for In-Place Density and Water Content of*

Soil and Soil-Aggregate by Nuclear Methods (Shallow Depth), or ASTM D2216, *Standard Test Methods for Laboratory Determination of Water (Moisture) Content of Soil and Rock by Mass*. These values are used to estimate average moisture contents in the base subbase and subgrade at the start of the freezing period. When testing is not possible, average estimated values can be used based on pit data from previous pavement evaluations or data from construction projects.

PCASE assigns default moisture contents as shown in Table 8-2 based on the layer types. Use these conservative defaults when no other data is available. Note that the depth of frost penetration is sensitive to the moisture content. In general, for a given dry density, frost penetration increases with decreasing moisture content. For example, as shown in Figure 8-8, for a soil with a dry density of 115 pcf and an AFI of 2,000 ˚F Days, frost is able to penetrate 70 inches at 15 percent moisture content but penetrates to 80 inches at 5 percent moisture content.

Figure 8-8 Effect of Moisture on Frost Penetration

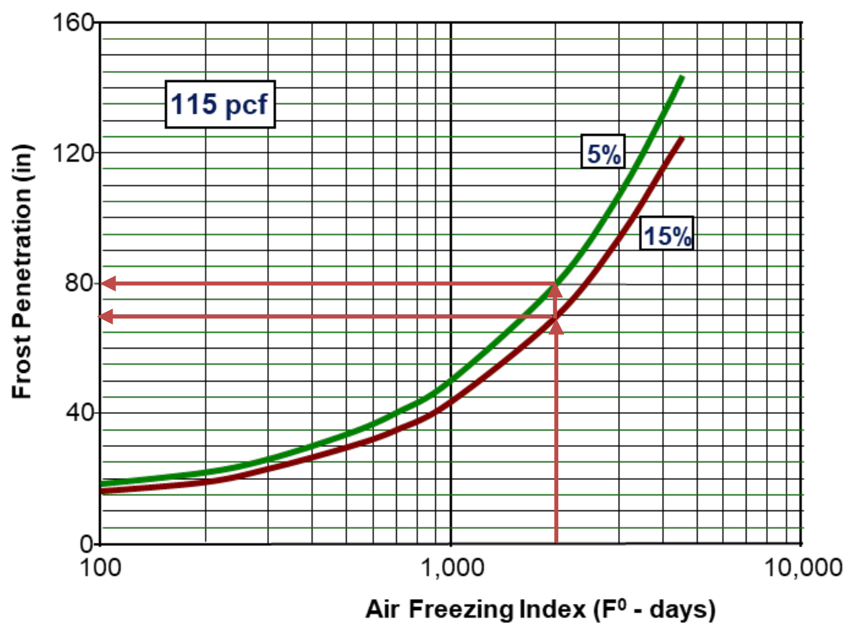


Table 8-2 Default Moisture Contents and Dry Densities

Layer Type	Moisture Content (%)	Dry Unit Weight (pcf)
Asphalt	0	140
Concrete	0	145
Stabilized base AC / PCC	5 / 0	140
Base	5	135
Drainage layer	5	135
Separation layer	5	135
Subbase	5	135
Stabilized subbase AC / PCC	5 / 0	130 / 140
Select fill	5	135
Stabilized subgrade PCC / Lime	0 / 10	130 / 110
Modified subgrade cohesive / cohesionless	18 / 10	100 / 120
Compacted subgrade	18 / 10	100 / 120
Natural subgrade cohesive / cohesionless	18 / 10	100 / 120

8-6.1.4 Dry Unit Weight.

The dry unit weight of a soil is determined based on field and laboratory testing using a nuclear gauge, sand cone, or compaction testing. Table 8-2 has the default dry unit weight values assigned in PCASE and Figure 8-9 provides estimated ranges of dry unit weight for various soil types. Note that in general, the depth of frost penetration will be greater for a soil with a higher dry unit weight at a given moisture content. For example, given a 12-inch rigid pavement overlying a homogeneous material at an infinite depth, at an AFI of 2,000 ˚F Days with 5 percent moisture content, the depth of frost penetration would be 100 inches for a soil with a density of 150 pcf, 80 inches at 115 pcf, and 70 inches at 100 pcf.

Figure 8-9 Soil Density Chart

Soil Types		Symbol		Drainage Characteristics	Unit Dry Weight Lb. per Cu Ft	Field CBR	Subgrade Modulus K Lb per Cu In
Coarse-grained Soils	Gravels and Gravelly Sands	GW		Excellent	125 - 140	60 - 80	300 or more
		GP		Excellent	110 - 130	25 - 60	300 or more
		GM	d	Fair to poor	130 - 145	40 - 80	300 or more
			u	Poor to impervious	120 - 140	20 - 40	200 to 300
		GC		Poor to impervious	120 - 140	20 - 40	200 to 300
	Sands and Sandy Gravels	SW		Excellent	110 - 130	20 - 40	200 to 300
		SP		Excellent	100 - 120	10 - 25	200 to 300
		SM	d	Fair to poor	120 - 135	20 - 40	200 to 300
			u	Poor to impervious	105 - 130	10 - 20	200 to 300
		SC		Poor to impervious	105 - 130	10 - 20	200 to 300
Fine-grained Soils	Silts and Clays LL <50	ML		Fair to poor	100 - 125	5 - 15	100 to 200
		CL		Impervious	100 - 125	5 - 15	100 to 200
		OL		Poor	90 - 105	4 - 8	100 to 200
	Silts and Clays LL >50	MH		Fair to poor	80 - 100	4 - 8	100 to 200
		CH		Impervious	90 - 110	3 - 5	50 to 100
		OH		Impervious	80 - 105	3 - 5	50 to 100
Highly Organic Soils		Pt		Fair to poor	-----	-----	-----

GM and SM groups are divided into subdivisions d and u for roads and airfields
Suffix d is used when LL $\leq$ 28 and PI $\leq$ 6 Suffix u is used when LL > 28

8-6.2 Surface Freezing Index.

As noted earlier, the DFI is based on the average annual AFI and standard deviation but this index is determined for air temperatures at 4.5 feet (1 meter) above the ground. We use the AFI because the data is more readily available than surface temperatures. The DFI and the n-Factor (Figure 8-10) are used in Equation 8-2 to estimate the surface freezing index, which is the temperature immediately below the pavement surface. PCASE determines the n-Factor based on the surface type of the layer model being analyzed (see Figure 8-10).

Equation 8-2. Surface Freezing Index

$$\text{Surface Freezing Index} = \text{n Factor} * \text{DFI}$$

Figure 8-10 n-Factors

Surface Type[1]	n-Factor for Freezing Conditions	n-Factor for Thawing Conditions
Snow Surface	1.00	-
Portland Cement Concrete	0.75	1.50
Bituminous Pavement	0.70	1.60 - 2.00[2]
Bare Soil	0.70	1.40 - 2.00[2]
Shaded Surface	0.90	1.00
Turf	0.50	0.80
Tree-Covered	0.30[3]	0.40

1. Surface exposed directly to sun or air without any overlying dust, soil, snow or ice, except as noted otherwise and with no building heat involved.
2. Use lowest value except in extremely high latitudes or at high elevations where a major portion of summer heating is from solar radiation.
3. Data from Fairbanks, Alaska, for single season with snow cover permitted to accumulate naturally.

8-6.3 Determine Start and Length of Thaw Season.

8-6.3.1 Thaw-weakened Period.

As shown in Figure 8-11, thaw-weakened periods are intervals of the year when the base, subbase, or subgrade strength are below normal summer values. These intervals correspond to frost melting periods. The period ends when the material is either refrozen or when the subgrade strength has returned to the normal summer value at the end of the spring thaw-weakening period.

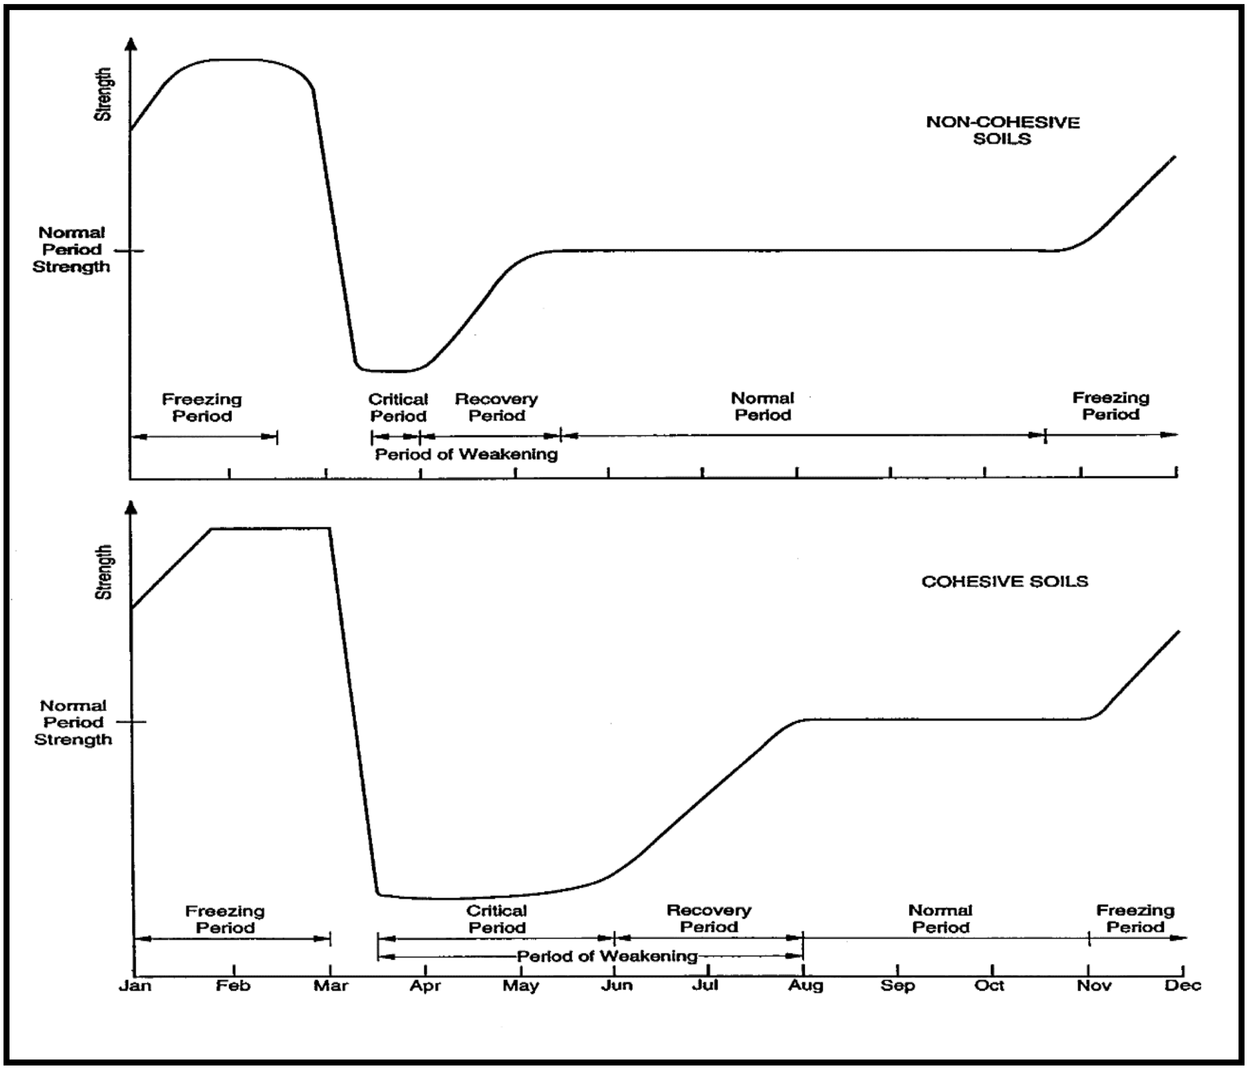
8-6.3.2 Critical Weakening Period.

The critical weakening period is the time interval during the thaw-weakened period when the base, subbase, or subgrade are at their lowest strength. As shown in Figure 8-11, the critical weakening period comes during the early stages of frost-melting and may occur intermittently during the winter when the segregated ice in the base, subbase, or subgrade is melting. This critical period can last from a week to several months, depending on the soil type and environmental conditions. The likely duration of the critical period can be estimated based on the performance of highways with a comparable subgrade in the vicinity of the airfield. However, since airfield pavements are wider and drainage paths longer, the thaw-weakened period is likely to be longer.

8-6.3.3 Recovery Period.

As the soil drains and reconsolidates, the pavement gradually regains full normal-period bearing capacity. The length of the recovery period varies from a few weeks to several months, depending on the intensity of ice segregation, depth of frost penetration, rate of thawing, permeability of the soil, drainage conditions, precipitation, and atmospheric humidity.

Figure 8-11 Illustration of Thaw-Weakening Period



8-6.3.4 Estimating Thaw Weakened Period Start and Duration.

Several frost-melting periods may occur during a typical winter period. The procedure outlined below is used to estimate the start and total period of weakening, including frost-melting periods during the winter. The length of the thaw-weakened period can be changed based on local experience. Principal factors affecting the recovery time are depth of frost penetration, type of frost-susceptible material, and subsurface drainage. Normally, the time for recovery will be from several weeks to several months.

The end of the freezing period defines the start of the thaw period. The thaw-weakened periods for different frost-susceptible soils are presented in Table 8-3. These values are adjusted based on whether the DFI ≤ 1,000-degree F-days or DFI > 1000 degree F-days as shown in Table 8-4. Note that the general soil type (cohesive or cohesionless) is used to determine the period adjustment for soils in the F3 and F4 frost groups.

Table 8-3 Length of End-of-Winter Thaw-Weakened Period

Frost Group	Thaw-Weakened Period (Months)
F1	1
F2	1
F3 and F4 (Cohesionless)	2
F3 and F4 (Cohesive)	3

Table 8-4 Thaw-Weakened Period Adjustment

Frost Group	Soil Type	DFI	Adjusted Thaw-weakened Period (Months)
F1, F2	N/A	< = 1,000 deg F days	1
F1, F2	N/A	> 1,000 deg F days	2
F3, F4	Cohesionless	< = 1,000 deg F days	2
F3, F4	Cohesionless	> 1,000 deg F days	3
F3, F4	Cohesive	< = 1,000 deg F days	3
F3, F4	Cohesive	> 1,000 deg F days	4

8-7 DETERMINE DEPTH OF FROST PENETRATION.

The objective of this step is to determine whether the freezing front penetrates a frost-susceptible layer. If not, use the normal evaluation procedure. Once the layer type and thickness, frost code, dry unit weight, and moisture content are entered for each layer and the analysis is run, PCASE will display the allowable passes, AGL, and Pavement Classification Number (PCN) for the thaw weakened period if the freezing front penetrates a frost-susceptible layer or will report only the normal values if it does not. Instructions for computing the depth of frost using PCASE are included in the PCASE *User Manual*.

This step can be performed manually by determining the surface thickness of the pavement (p), the total pavement (surface, base, and subbase) thickness (x) and estimate the depth of frost penetration (d) and following the criteria below:

- If ($x \geq d$) use the normal evaluation procedure.

- If ($x < d$), the pavement structure is inadequate for complete frost protection. If there are indications of frost action, evaluate the pavement structure with the reduced subgrade strength approach.
- If ($x - p \geq 60$ inches) or the base, subbase, and/or subgrade is classified as NFS, S1, or S2 and there are no surface indications of frost action, use the normal evaluation procedure.
- If ($x - p \geq 60$ inches) or the base, subbase, and/or subgrade is classified as NFS, S1, or S2 and there are indications of frost action, evaluate pavement structure with the reduced subgrade strength approach.

8-8 EVALUATE PAVEMENT FOR REDUCED SUBGRADE STRENGTH.

Both conventional and layered elastic reduced subgrade strength (RSS) evaluation procedures are based on the application of the fatigue damage concept (Miner's Hypothesis). The conventional evaluation procedure substitutes frost area soil support indices (FASSI) values for California Bearing Ratio (CBR) values in flexible pavement analysis and Frost Area Index of Reaction (FAIR) values for modulus of subgrade reaction values (k) in rigid analysis. In layered elastic evaluation, either the FASSI/FAIR procedure or the reduced modulus procedure can be used.

8-8.1 Frost Area Soil Support Indices (FASSI).

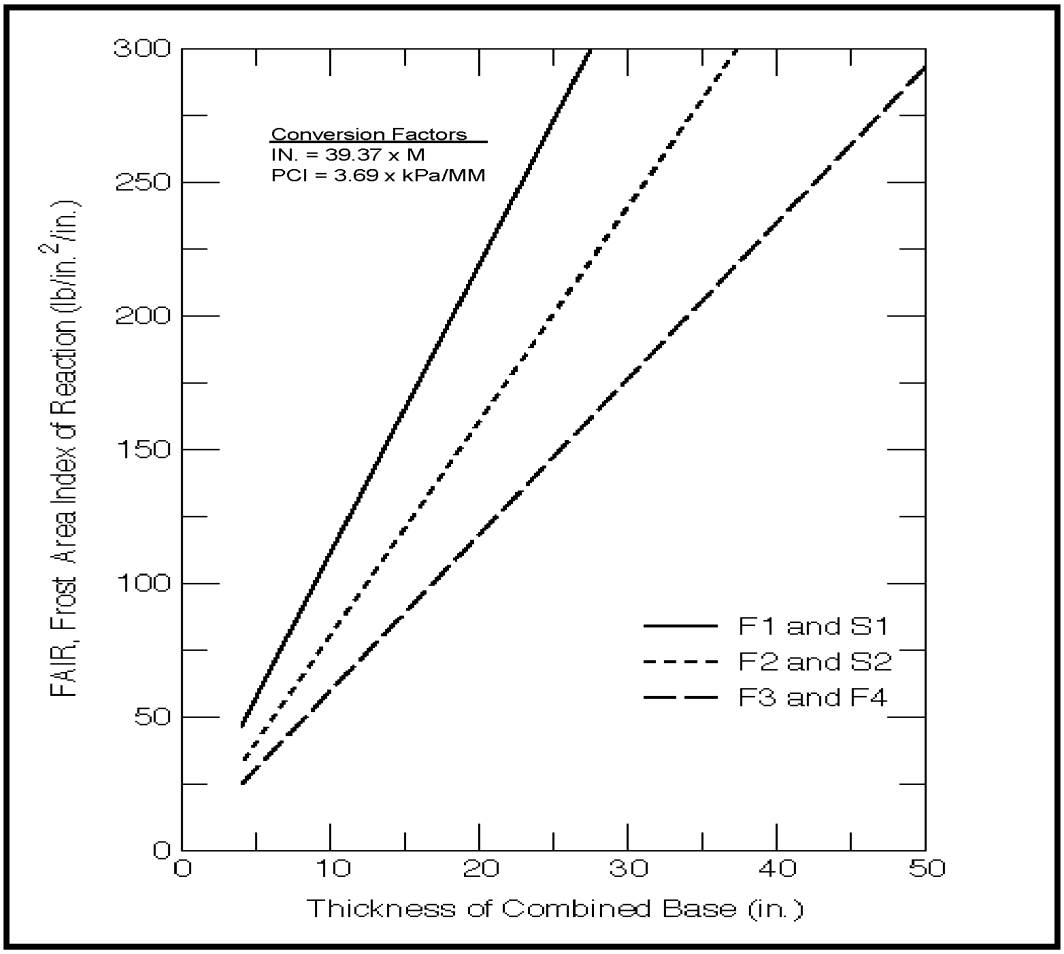
The FASSI values are used as if they were CBR values. The term CBR is not applied to them, however, because they are weighted average values for the annual cycle and their values cannot be determined by CBR tests. FASSI values are assigned based on the soil layer's frost group. Ideally, base and subbase layers are not frost susceptible but this is not always the case, so, for any layer with a frost code assigned (other than NFS), PCASE will replace the CBR with a FASSI value when the depth of frost penetrates that layer. If the depth of frost does not penetrate the layer, PCASE uses the assigned CBR. FASSI values for the respective frost codes are listed below.

- F1 and S1 soils = 9.0 FASSI
- F2 and S2 soils = 6.5 FASSI
- F3 and F4 soils = 3.5 FASSI

8-8.2 Frost Area Index of Reaction (FAIR).

FAIR values are used as if they were modulus of subgrade reaction values, k, and have the same units. However, the term modulus of subgrade reaction is not applied to them because the FAIR values are weighted average values for an annual cycle and cannot be determined by a plate-bearing test. Figure 8-12 shows the equivalent weighted average FAIR values for an annual cycle that includes a thaw-weakening period in relation to the combined thickness of the base and subbase. This figure is based on the FAIR value Equations 8-3, 8-4, and 8-5. If the depth of frost does not penetrate the layer, PCASE uses the assigned k value, or when the modulus of subgrade reaction k, determined from tests on the equivalent base course and subgrade for the normal period, is less than the FAIR value obtained from the equations, use the test value for the analysis.

Figure 8-12 Determination of FAIR Value



Equation 8-3. FAIR Value for F1 or S1 Material

$$FAIR\ ((psi/in.) = 4.2 + 10.8 \times \text{Combined } Base\ Course\ Thickness\ (inches)$$

Equation 8-4. FAIR Value for F2 or S2 Material

$$FAIR\ ((psi/in.) = 1.3 + 8.0 \times \text{Combined } Base\ Course\ Thickness\ (inches)$$

Equation 8-5. FAIR Value for F3 or F4 Material

$$FAIR\ ((psi/in.) = 1.6 + 5.9 \times \text{Combined } Base\ Course\ Thickness\ (inches)$$

8-9 MODULUS REDUCTION FACTORS.

There are two alternatives for reduced subgrade strength analysis using layered elastic procedures. In the first, the FASSI or FAIR values determined using the procedures above are correlated to modulus values and used for the RSS analysis. In the second approach, the modulus values of the respective layers during the normal period are reduced using the reduction factors shown in Table 8-5. The modulus for the normal period is multiplied by the reduction factor for the given frost group and this reduced modulus is used for the analysis. If the depth of frost does not penetrate the layer, PCASE uses the normal period modulus value. If modulus values were determined during the thaw period, then use those values in the thaw period analysis. In this case, the modulus for the normal period can be estimated by dividing the thaw period modulus value by the modulus reduction factor.

Table 8-5 Modulus Reduction Factors for Seasonal Frost Areas

Frost Group	Modulus Reduction Factors
NFS	1.00
PFS	0.90
S1	0.75
S2	0.70
F1	0.60
F2	0.50
F3/F4	0.30

8-10 EVALUATION USING DAMAGE CONCEPTS.

The fatigue damage concept (Miner's Hypothesis) is used to evaluate pavement structures when frost is a consideration. Damage is defined as the ratio of applied load repetitions to the allowable load repetitions to a failure and is expressed as:

Equation 8-6. Damage Definition

$$d = \frac{n}{N}$$

Where:
n = applied load repetitions
N = allowable load repetitions

When the applied load repetitions equal the allowable number of load repetitions, the damage ratio is equal to 1.0. This means that 100 percent of the pavement life has been consumed. The goal is to determine the allowable load or the allowable passes such that the damage ratio is equal to one (d = 1.0) for an analysis period.

8-10.1 Cumulative Damage Factor (CDF).

The damage concept can be extended to multiple aircraft and multiple seasons. A CDF can be expressed as the sum of individual damage contributions from different aircraft and different seasons or evaluation periods. The general equation for CDF, where the aircraft load and passes result in the maximum utilization of pavement life, is defined as:

Equation 8-7. General Cumulative Damage Factor

$$CDF = \sum_{i=1}^{nac} \sum_{j=1}^{ns} d_{ij} = 1.0$$

Where:

$d_{i,j}$ = damage for aircraft i and season *j*
nac = number of aircraft in mix
ns = number of seasons or analysis period

In pavement evaluation, the analysis is performed for only a single aircraft (*nac* = 1) and two seasons (*ns* = 2). The two evaluation seasons considered are the normal and thaw-weakened periods. The cumulative damage factor represented by Equation 8-7 can now be reduced to Equations 8-8 and 8-9.

Equation 8-8. Reduced Cumulative Damage Equation

$$CDF = d_{normal} + d_{thaw} = 1.0$$

Equation 8-9. Expanded Cumulative Damage Equation

$$CDF = \frac{n_{normal}}{N_{normal}} + \frac{n_{thaw}}{N_{thaw}} = 1.0$$

Where:
n_{normal}, N_{normal} are the applied and allowable number of coverages (or passes) during the normal period
n_{thaw}, N_{thaw} are the applied and allowable number of coverages (or passes) during the thaw-weakened period

8-10.2 Prorating Passes for Normal and Thaw Periods.

When evaluating pavement structures, the aircraft AGL is analyzed for a life expectancy expressed as the evaluation passes, *n*. Since *n* is the total number of passes applied throughout the whole year, a fraction of *n* is applied during the normal period and a fraction of *n* is applied during the thaw-weakened period. Each of these fractions will contribute to the total accumulated damage during a year. These fractions of *n* are determined as the prorated number of passes during the normal months and thaw-weakened months. For example, if evaluating the subgrade of a pavement structure for *n* = 50,000 passes and one month of the year is in a thaw-weakened condition, then Equations 8-10 and 8-11 represent the contribution of the total number of passes *n* in each season.

Equation 8-10. Prorated Evaluation Passes during the Normal Period

$$n_{normal} = n\left(\frac{11}{12}\right) = 50{,}000\left(\frac{11}{12}\right) = 45{,}833\ Passes$$

Equation 8-11. Prorated Evaluation Passes during the Thaw-weakened Period

$$n_{thaw} = n\left(\frac{1}{12}\right) = 50{,}000\left(\frac{1}{12}\right) = 4{,}167\ Passes$$

8-10.3 Damage in Conventional Flexible and Rigid Pavement Evaluation (APE)

The airfield pavement evaluation (APE) CBR / k models were not developed with the cumulative damage concept in mind. Therefore, the damage concept cannot be applied directly because the analysis is based on a single evaluation period and the APE analysis will only return the allowable number of coverages (or passes) for the entire pavement life, *N*. Equation 8-9 is solved in APE by allowing a predetermined amount of damage to occur during the thaw-weakened period as shown in Figure 8-11. The predetermined damage is assumed to be 25 percent during the thaw period (d_{thaw} = 0.25) and 75 percent during the normal period (d_{normal} = 0.75), as shown in Equations 8-12 and 8-13:

Equation 8-12. Damage Allowed during the Thaw Period

$$d_{thaw} = 0.25 = \frac{n_{thaw}}{N_{thaw}}$$

Equation 8-13. Damage Allowed during the Normal Period

$$d_{normal} = 0.75 = \frac{n_{normal}}{N_{normal}}$$

Both N_{thaw} and N_{normal} are the allowable number of coverages for the respective analysis periods or seasons. If we define N'_{thaw} as the allowable number of coverages (or passes) at failure when d'_{thaw} = 1.0, then 100 percent of the life will be consumed. Therefore, we must adjust N'_{thaw} by a factor of 0.25 as shown in Equation 8-14, because only one-quarter of its life is allowed be consumed during this analysis period.

Equation 8-14. Pavement Life Adjustment during the Thaw-weakened Period

$$N_{thaw} = 0.25\ N'_{thaw}$$

This leads to the equation of damage during the thaw-weakened period (Equation 8-15), that is interpreted as an adjustment to the allowable coverages (or passes), N'_{thaw} or as an adjustment to the evaluation coverages (or passes) n_{thaw}.

Equation 8-15. Adjustment to Evaluation Passes during the Thaw-weakened Period

$$d_{thaw} = \frac{n_{thaw}}{N_{thaw}} = \frac{n_{thaw}}{0.25\, N'_{thaw}} = \frac{4\, n_{thaw}}{N'_{thaw}}$$

Similarly, make an adjustment during the normal period using Equation 8-16, because only three-quarters of its life is consumed during the normal period.

Equation 8-16. Pavement Life Adjustment during Normal Period

$$N_{normal} = 0.75\, N'_{normal}$$

The damage during the normal period can then be estimated using Equation 8-17.

Equation 8-17. Damage Allowed during the Normal Period

$$d_{normal} = \frac{n_{normal}}{N_{normal}} = \frac{n_{normal}}{0.75\, N'_{normal}} = \frac{\frac{4}{3}\, n_{normal}}{N'_{normal}} = \frac{1.33\, n_{normal}}{N'_{normal}}$$

Aircraft AGL for the normal and thaw-weakened periods satisfying Equations 8-15 and 8-17 are individually calculated by an iteration process. In APE, the AGL is determined by evaluating for the following adjusted number of passes:

$$Thaw\ period = 4\ times\ prorated\ passes = 4\, n_{thaw}$$
$$Normal\ period = \frac{4}{3}\ times\ prorated\ passes = \frac{4}{3} n_{normal}$$

For our example in Equations 8-10 and 8-11, the cumulative damage factor becomes:

Equation 8-18. Example Cumulative Damage Factor for Two Analysis Periods

$$CDF = \frac{\frac{4}{3}(45{,}833)}{N'_{normal}} + \frac{4(4{,}167)}{N'_{thaw}} = 1.0$$

Equation 8-18 is solved iteratively by assuming an AGL for each season (AGL_{normal}, AGL_{frost}) and calculating the allowable number of passes (N'_{normal}, N'_{thaw}) until the *CDF* = 1.0 within an acceptable tolerance value. Here, N'_{normal} is a function of the subgrade strength during the normal period and N'_{thaw} is a function of the subgrade strength during the thaw-weakened period. In summary, in APE the AGL is determined by evaluating for the following equivalent number of passes:

$$Thaw\ period = 4\ times\ prorated\ passes = 4\, n_{thaw}$$
$$Normal\ period = \frac{4}{3}\ times\ prorated\ passes = \frac{4}{3} n_{normal}$$

8-11 DEFINING DAMAGE IN LAYERED ELASTIC EVALUATION PROGRAM (LEEP).

When designing flexible pavements using the layered elastic method, load repetitions are equated to coverages and both the limiting asphalt horizontal strain and the subgrade vertical strain criteria are checked in terms of coverages. However, when evaluating flexible pavements, the subgrade strain criterion is only checked in terms of passes. This simplification was adopted during the early stages of development of the evaluation criteria because passes at the subgrade level are approximately equal to coverages. Equation 8-19 defines damage in terms of the subgrade criterion for layered elastic evaluation of flexible pavements and Equation 8-20 defines the damage in terms of the asphalt criterion.

Equation 8-19. Subgrade Damage in Terms of Passes

$$d = \frac{applied\ passes}{allowable\ passes}$$

Equation 8-20. Asphalt Damage in Terms of Coverages

$$d = \frac{applied\ coverages}{allowable\ coverages}$$

When evaluating rigid pavements, the bending stress criterion at the bottom of the concrete layer is checked against the bending stress criterion in terms of coverages as shown by Equation 8-21.

Equation 8-21. Concrete Damage in Terms of Coverages

$$d = \frac{applied\ coverages}{allowable\ coverages}$$

Even though the layered elastic method permits the calculations of the damage for normal and thaw-weakened periods directly without having to assume d_{thaw} = 0.25 and d_{normal} = 0.75, the same procedure outlined here for APE is also applied with layered elastic analysis. In theory, the damage distribution between analysis periods could be changed to any another value if the field conditions warrant a different damage distribution between the two analysis periods.

8-11.2 LEEP (WESPAVE) Frost Analysis.

Earlier PCASE versions used the WESPAVE layered elastic model for LEEP analysis. The current PCASE version allows the user to set the WESPAVE option to replicate previous pavement evaluation results. When the WESPAVE option is on, the AGLs for the normal and thaw-weakened periods are determined by evaluating for the following adjusted number of passes:

$$Thaw\ period = \ 4\ times\ prorated\ passes = 4\ n_{thaw}$$
$$Normal\ period = \frac{4}{3}\ times\ prorated\ passes = \frac{4}{3}n_{normal}$$

8-11.3 LEEP (YULEA) Frost Analysis.

The current PCASE version (7.x and later) uses the YULEA layered elastic model in LEEP. When using YULEA, the AGLs for the normal and thaw-weakened periods are determined by setting the target damages during the two analysis periods directly as follows:

$$Thaw\ period - Set\ d_{thaw} = 0.25$$
$$Normal\ period - Set\ d_{normal} = 0.75$$

8-12 EVALUATING PAVEMENTS ON PERMAFROST.

Typically, pavements on permafrost are in their weakest condition during the summer. The permafrost thaws from the top down and provides excess water that cannot drain because of the underlying frozen permafrost. Pavement evaluations are performed during the weakened state, which may only last a few months. This is essentially the opposite of the evaluation procedures previously discussed in this chapter.

In this case, the pavement evaluation is conducted during the summer with a heavy weight deflectometer (HWD) when the pavement is in a weakened condition. Modulus values are established for each layer, including the saturated thawed layers and the frozen permafrost. This establishes the basis for the AGLs and PCNs published for the summer period. For the winter period, assume that the previously thawed layers (base, subbase, and subgrade) would have the same modulus values when frozen as those established for the frozen permafrost during the summer evaluation. Alternatively, apply the factors in Table 8-5 using the procedure in paragraph 8-9 to determine a conservative estimate of the modulus during the winter period. Assume that modulus values for the asphalt surface would be the same as established during the summer. These modulus values are used to determine the AGLs and PCNs during the winter period.

CHAPTER 9 STANDARDIZED METHOD FOR REPORTING AIRFIELD PAVEMENT STRENGTH

9-1 BACKGROUND.

The Aircraft Classification Number (ACN) - Pavement Classification Number (PCN) method was adopted by the International Civil Aviation Organization (ICAO) as an effective, simple, and readily comprehensible means for reporting the aircraft weight-bearing capability of runways. As a cooperating member of the ICAO, the United States report airfield weight-bearing limits by this method as outlined in Doc 9157-AN/901, *Aerodrome Design Manual*, and Amendment 35 to *International Standards and Recommended Practices, Aerodromes (*Annex 14, Volume I to the Convention on International Civil Aviation). These weight-bearing limits are included in evaluation reports and reported in flight information pamphlets (FLIP).

9-2 ACN DEFINITION.

The ACN is a number that expresses the relative structural effect of an aircraft at a given weight on different pavement types (flexible or rigid) for four specified standard subgrade strengths in terms of a standard single-wheel load. ACN values are determined by the aircraft manufacturers. These same numbers can be calculated using computer programs such as Pavement-Transportation Computer Assisted Structural Engineering (PCASE) as outlined below.

9-2.1 Computing the ACN.

Computing the ACN requires detailed information on the operational characteristics of the airplane, such as maximum aft center of gravity, maximum weight, wheel spacing, tire pressure, and other factors. ACN values are available from aircraft manufacturers, Technical Report TSC 13-2, *Aircraft Characteristics for Airfield Pavement Design and Evaluation - Air Force and Army Aircraft*, and Technical Report TSC 13-3, *Aircraft Characteristics for Airfield Pavement Design and Evaluation - Commercial Aircraft*, or are computed by PCASE.

9-2.2 Subgrade Category.

The ACN-PCN method adopts four standard levels of subgrade strength for rigid pavements and four standard levels of subgrade strength for flexible pavements. These standard support conditions are used to represent a range of subgrade conditions as shown in Tables 9-1 and 9-2. Modulus values (E) for use in layered elastic analysis are shown in Tables 9-3 and 9-4. E values in Table 9-3 were obtained using k=.07906(E^0.7788). E values in Table 9-4 were obtained using E = 1500*CBR.

Table 9-1 Rigid Pavement k Subgrade Categories

Subgrade Strength Category	k-Value (pci)	Represents (pci)	Code Designation
High	552.6	K ≥ 442	A
Medium	294.7	221 < k <442	B
Low	147.4	92 < k ≤221	C
Ultra-low	73.7	k ≤ 92	D

Table 9-2 Flexible Pavement CBR Subgrade Categories

Subgrade Strength Category	CBR Value	Represents	Code Designation
High	15	CBR ≥ 13	A
Medium	10	8 < CBR <13	B
Low	6	4 < CBR ≤ 8	C
Ultra-low	3	CBR ≤4	D

Table 9-3 Rigid Pavement Modulus Subgrade Categories

Subgrade Strength Category	E Value (psi)	Represents (psi)	Code Designation
High	86,374	E≥ 64,840	A
Medium	38,530	22,627 <E< 64,840	B
Low	15,829	8,642 <E≤ 22,627	C
Ultra-low	6,500	E ≤ 8,642	D

Table 9-4 Flexible Pavement Modulus Subgrade Categories

Subgrade Strength Category	E Value	Represents	Code Designation
High	22,500	E≥ 19,500	A
Medium	15000	12,000 <E< 19,500	B
Low	9000	6,000 <E≤ 12,000	C
Ultra-low	4,500	E ≤ 6,000	D

9-2.3 Rigid Pavement ACN.

The aircraft landing gear flotation requirements for rigid pavements are determined by the Westergaard solution for a loaded elastic plate on a Winkler foundation (interior load case) for each subgrade category, assuming a concrete working stress of 399 psi (2.8 MPa).

9-2.4 Flexible Pavement ACN.

The airplane landing gear flotation requirements for flexible pavements are determined by the California Bearing Ratio (CBR) method for each subgrade support category. The CBR method uses a Boussinesq solution for stresses and displacements in a homogeneous, isotropic elastic half-space. To standardize the ACN calculation and to remove operational frequency from the relative rating scale, ACN values are determined for 10,000 coverages.

9-2.5 ACN Calculation.

A mathematically derived single-wheel load is calculated to define the landing gear/pavement interaction using the parameters defined for each type of pavement. The derived single-wheel load implies equal stress to the pavement structure and eliminates the need to specify pavement thickness for comparative purposes. This is achieved by equating the thickness derived for a given airplane landing gear to the thickness derived for a single wheel load at a standard tire pressure of 181 psi (1.2 MPa). The ACN is defined as two times the derived single wheel load (expressed in thousands of kilograms). The procedure for determining ACN is outlined in ICAO Doc 9157-AN/901, *Aerodrome Design Manual, Part 3 - Pavements*.

9-2.6 Variables Involved in Determining ACN Values.

Because airplanes can be operated at various weight and center of gravity combinations, ICAO adopted standard operating conditions for determining ACN values. The ACN is determined at the weight and center of gravity combination that creates the maximum ACN value. Tire pressures are assumed to be those recommended by the manufacturer for the noted conditions. Airplane manufacturers publish maximum weight and center of gravity information in their Airplane Characteristics for Airport Planning (ACAP) manuals.

9-2.7 PCASE ACN Example.

Figure 9-1 is from the PCASE ACN calculator. It shows the ACN information for the P-8 Poseidon aircraft operating at a weight of 188.2 kips on a flexible pavement. The ACN values for each subgrade category are displays as well as an ACN curve plot. Table 9-5 shows a summary of the ACNs for this aircraft on each subgrade category, assuming unlimited tire pressure as indicated by the “W” tire-pressure category.

Figure 9-1 Rigid and Flexible ACN Values for P-8 Poseidon Aircraft

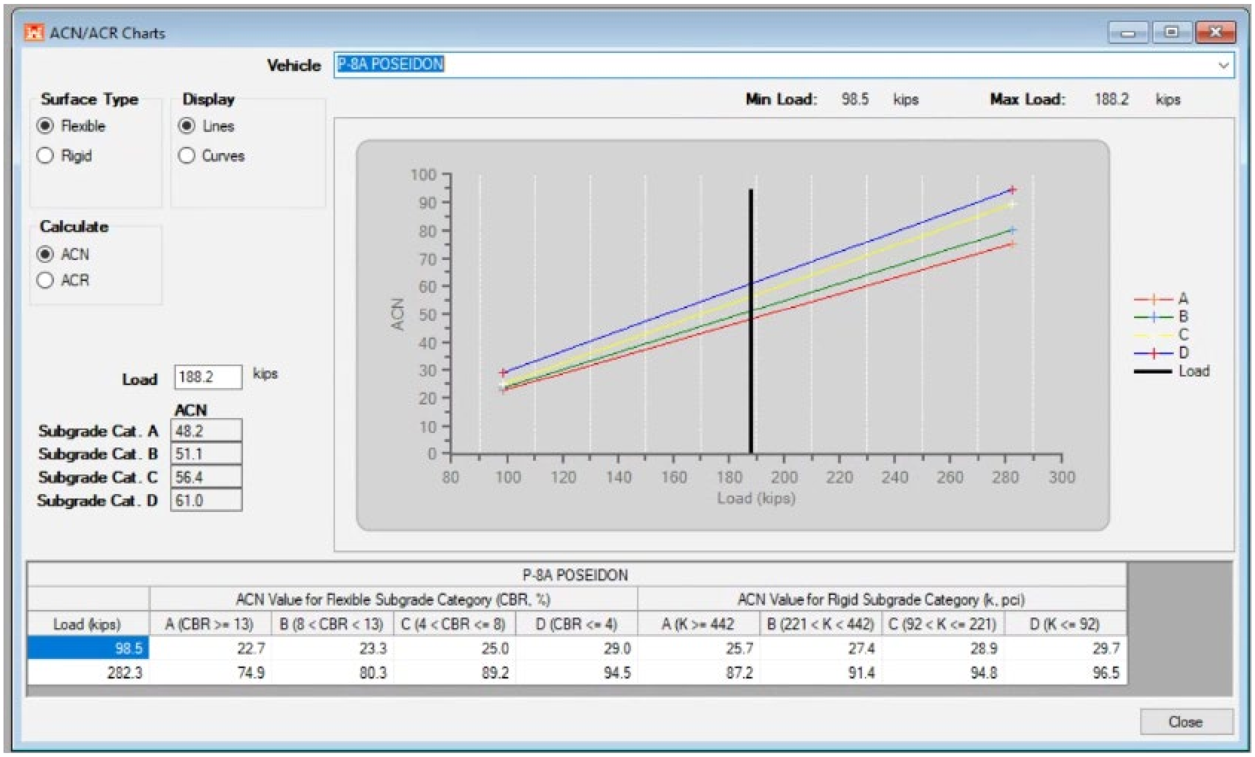

Table 9-5 ACN Ratings for P-8 Operating at 188.2 Kips

Rigid	Flexible
56/R/A	48/F/A
59/R/B	51/F/B
61/R/C	56/F/C
62/R/D	61/F/D

9-2.8 Adjusted ACN Due to Increase/Decrease in Tire Pressure.

Tire pressure is a secondary factor in determining an ACN; however, ICAO procedures can determine the increase or decrease in ACN if the aircraft is operating at a tire pressure different from the one used to determine the ACN. The adjusted ACN can be used if conditions, such as a thin asphalt surface or a weak upper pavement layer, exist. Figures 9-2 and 9-3 are used to adjust the ACN for flexible pavements and Figure 9-4 is used for rigid pavements. On flexible pavements, it is assumed that adjustments will only be one category. Figures 9-2 and 9-3 were developed by ERDC based on the equation in FAA Advisory Circular 150/5335-5D, *Standardized Method of Reporting Airport Pavement Strength – PCR*.

Figure 9-2 Adjusting Flexible Pavement ACN Due to an Increase or Decrease in Tire Pressure (Z to Y or Y to Z)

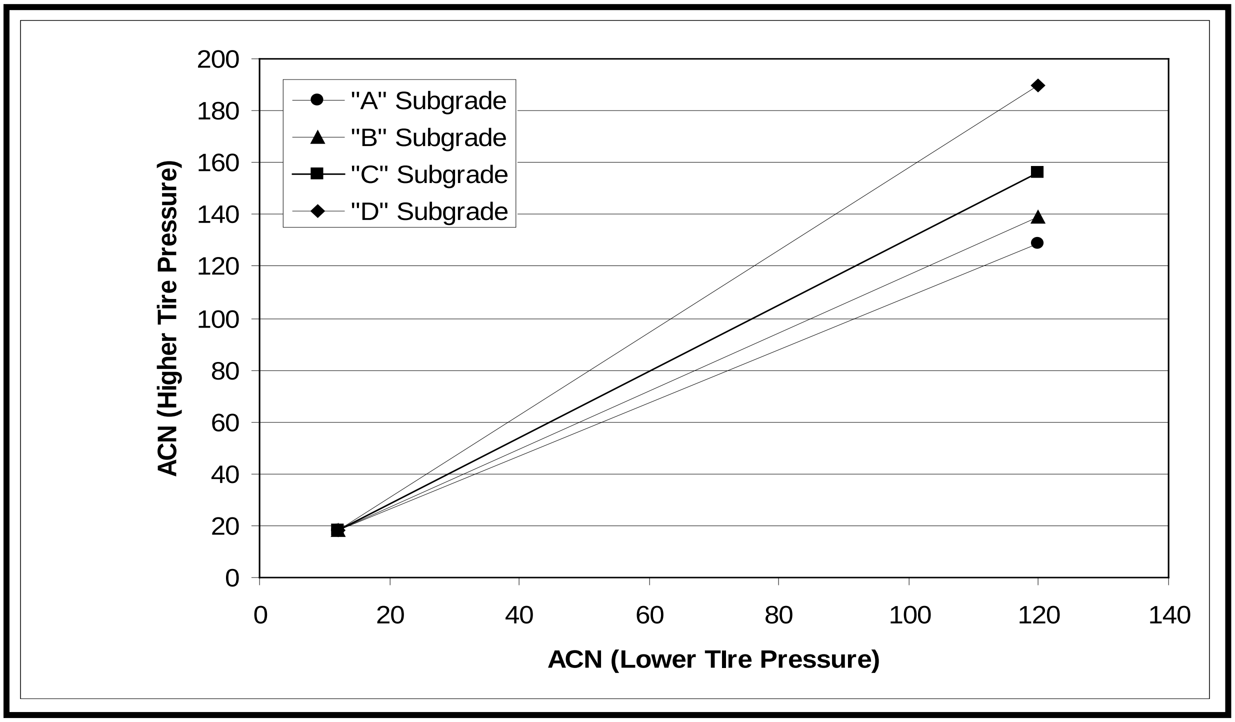

Figure 9-3 Adjusting Flexible Pavement ACN Due to an Increase or Decrease in Tire Pressure (Y to X, X to Y, X to W, W to X)

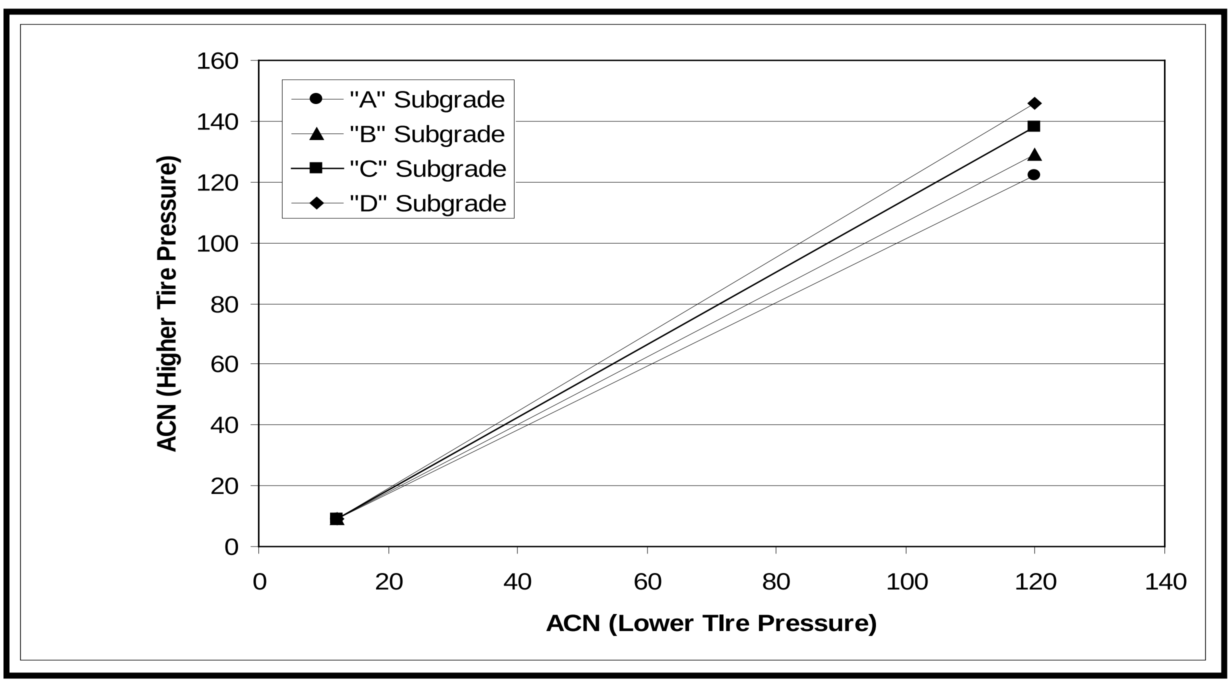

Figure 9-4 Adjusting Rigid Pavement ACN for Changes in Tire Pressure

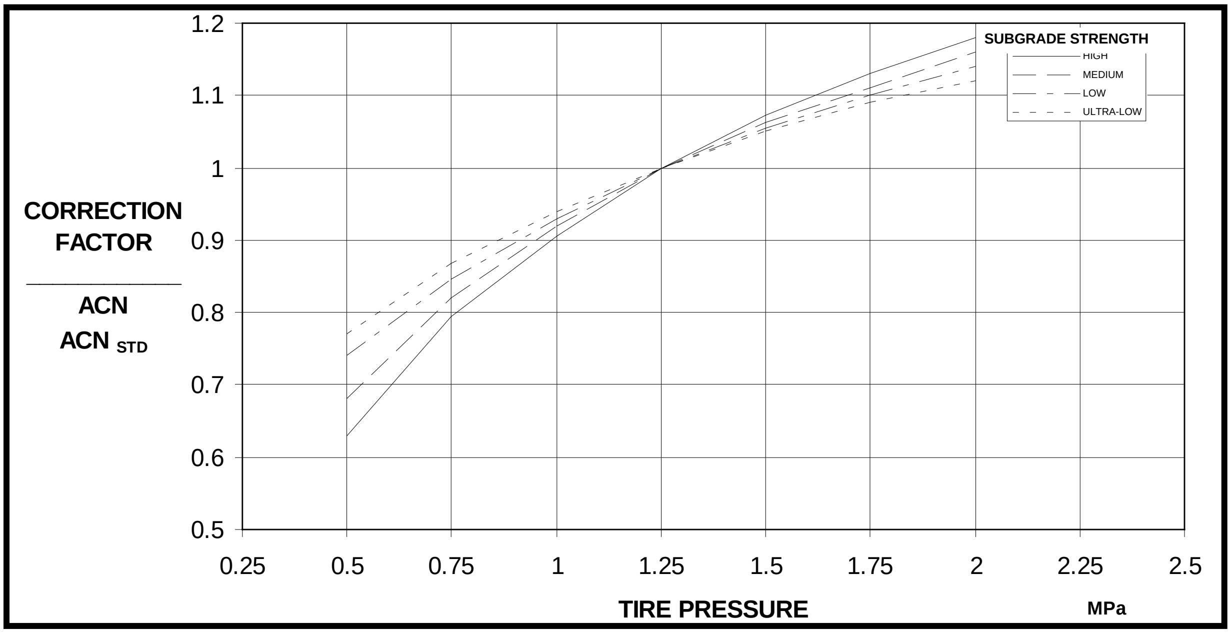


9-2.8.2 Flexible Pavement ACN Adjustment Due to Tire Pressure.

The ACN for an aircraft was determined to be 60/F/D using a tire pressure of 160 psi (1.1 MPa). Using Figure 9-3, the ACN will be 55/F/D if the tire pressure is reduced to 140 psi (1.0 MPa).

9-2.8.3 Rigid Pavement ACN Adjustment Due to Tire Pressure.

An aircraft operating at a tire pressure of 180 psi (1.2 MPa) on a medium-strength subgrade has an ACN of 50/R/B. The ACN will be 53/R/B if the tire pressure is increased to 215 psi (1.5 MPa). (Enter Figure 9-4 with a tire pressure of 1.5 MPa and proceed vertically until the medium subgrade is intercepted. Proceed horizontally and read the correction factor of 1.06. (50 x 1.06 = 53).

9-3 PCN DEFINITION.

The PCN is a number that expresses the bearing strength (load-carrying capability) of a pavement based on a specified aircraft in terms of a standard single-wheel load at a specified number of passes. The aircraft and number of passes are determined based on the traffic approach as defined in Chapter 4 that is used in the evaluation. This can be a set number of passes of a specific aircraft (e.g., 50,000 passes of the C-17), the equivalent passes of the controlling aircraft over the next 20 years as defined in the mission aircraft group approach, or equivalent passes for representative groups as defined in the mission/representative aircraft group approach. The PCN value is for reporting pavement strength only. The PCN value expresses the results of pavement evaluation in relative terms and cannot be used for pavement design or as a substitute for a structural evaluation.

9-3.1 Computing the PCN.

The numerical PCN value is simply the ACN value of the specified aircraft at the specified number of passes as defined in paragraph 9-3. The entire PCN is a five-part code made up of the numerical portion of the PCN as well as a four-letter code that defines the pavement type, the subgrade category, and the tire pressure described below, as well as the procedure used to determine the numerical PCN value, the using aircraft method, or the technical evaluation method. ICAO procedures permit member states to determine how PCN values will be determined based upon internally developed pavement evaluation procedures. DoD PCN values are based on the technical evaluation method whenever possible.

9-3.1.1 Using Aircraft Method.

The using aircraft method is a simple procedure where ACN values for all aircraft currently permitted to use the pavement facility are determined and the largest ACN value is reported as the PCN. An underlying assumption is that the pavement structure has the structural capacity to accommodate all aircraft in the traffic mix and that each aircraft can operate on the pavement structure without restriction. Using an excessively damaging aircraft that uses the pavement on a very infrequent basis to determine the PCN can result in significant over-estimation of the pavement capacity. This procedure can also result in significant under-estimation of the pavement capacity, preventing acceptable traffic from operating. Use of the using aircraft method is discouraged due to these concerns.

9-3.1.2 Technical Evaluation Method.

The accuracy of a technical evaluation is better than the using aircraft method but requires more time and resources. Pavement evaluation may require a combination of on-site testing and engineering judgment. Numerical PCN values for DoD are determined from an allowable load determined by a technical pavement evaluation conducted in accordance with this UFC.

9-3.1.3 Numerical PCN Value.

Report the numerical PCN value in whole numbers, rounding off any fractional parts to the nearest whole number. For pavements of diverse strengths, the weakest section PCN value normally controls the reported numerical PCN value. Engineering judgment is required if the weakest section is not in the most heavily used part of the runway. In this case, consider another representative section as the basis for the reported PCN.

9-3.1.4 Pavement Type.

Pavement types are either flexible or rigid structures. Table 9-6 lists the pavement codes for purposes of reporting PCN.

Table 9-6 Pavement Codes for Reporting PCN

Pavement Type	Pavement Code
Flexible	F
Rigid	R

9-3.1.4.1 Flexible Pavement.

Flexible pavements support loads through bearing rather than flexural action. They are normally composed of several layers of selected materials designed to gradually distribute loads from the surface to the layers beneath. For a CBR evaluation, each layer in the pavement structure is evaluated to determine structural capacity. The layer that produces the lowest allowable gross load (AGL) is the controlling layer. For a Layered Elastic Evaluation Program (LEEP) evaluation, the tensile strain in the AC surface layer and the vertical strain in the subgrade are used to determine the structural capacity. For the two location points in a LEEP evaluation, the location that produces the lowest allowable load controls the AGL. For LEEP evaluations, the default locations are the bottom of the AC surface layer and the top of the subgrade.

9-3.1.4.2 Rigid Pavement.

Rigid pavements employ a single structural layer, which is very stiff or rigid, to support the pavement loads. The rigidity of the structural layer and resulting beam action enable a rigid pavement to distribute loads over a large area of the subgrade. The load-carrying capacity of a rigid structure is highly dependent upon the strength of the structural layer, which relies on uniform support from the layers beneath.

9-3.1.4.3 Composite Pavement.

Various combinations of pavement types and stabilized layers can result in complex pavements that could be classified as either rigid or flexible. A pavement section may comprise multiple structural elements representative of both rigid and flexible pavements. Composite pavements are most often the result of pavement surface overlays applied at various stages in the life of the pavement structure. If a pavement is of composite construction, the pavement type should be reported as the type which provides the highest allowable load.

9-3.1.5 Subgrade Strength Category.

As discussed in paragraph 9-2.2, there are four standard subgrade strengths identified for calculating and reporting ACN or PCN values. The standard values for rigid and flexible pavements are shown in the section on ACNs in Tables 9-1 through 9-4.

9-3.1.6 Allowable Tire Pressure.

Table 9-7 lists the allowable tire pressure categories used in the ACN-PCN system. The tire pressure codes apply equally to rigid or flexible pavement sections; however, the application of the allowable tire pressure differs substantially for rigid and flexible pavements.

Table 9-7 Tire Pressure Codes for Reporting PCN

Category	Code	Tire Pressure Range
Unlimited	W	No pressure limit
High	X	Pressure ≤ 254 psi
Medium	Y	Pressure ≤ 181 psi
Low	Z	Pressure ≤ 73 psi

9-3.1.6.2 Tire Pressures on Rigid Pavements.

Tire pressure has little effect on pavements with PCC surfaces. Rigid pavements are inherently strong enough to resist high tire pressures and can usually be rated as code W. However, when the rigid layer is very thin (less than 4 inches [102 millimeters]) or is thoroughly shattered (PCI ≤ 25, with pieces less than about 3 feet [1 meter] wide), the tire pressure code is reduced to X.

9-3.1.6.3 Tire Pressures on Flexible Pavements.

Tire pressures may be restricted on asphaltic concrete, depending upon the quality of the asphalt mixture, climatic conditions, or thickness and condition of the surface. Tire pressure effects on an asphalt layer relate to the stability of the mix to resist shearing or densification. A poorly constructed asphalt pavement can be subject to rutting due to consolidation under load. A properly prepared and placed mixture that conforms to DoD specifications can withstand tire pressures more than 254 psi (1.8 MPa) and be rated as tire pressure code W. A flexible pavement that has a PCI > 25 and is ≥ 4 inches (102 millimeters) thick but less than the minimum required thickness per UFC 3-260-02 is assigned code X. Pavement that has a PCI > 25 but is < 4 inches (102 millimeters) thick is assigned code Y. Pavement with a PCI ≤ 25 (aged or severely cracked pavements) is assigned code Y.

9-3.1.6.4 Method Used to Determine PCN.

As discussed in paragraph 9-3.1, two pavement evaluation methods are recognized in the PCN system. If the evaluation represents the results of a technical study, the evaluation method should be coded T. If the evaluation is based on “using airplane” experience, the evaluation method should be coded U. Technical evaluation implies that some form of technical study and computation were involved in the determination of the PCN. Using airplane evaluation means the PCN was determined by selecting the highest ACN among the airplanes currently using the facility.

9-3.2 Critical PCN for a Runway.

When selecting the critical PCN rating for a runway with multiple sections, it is important to examine the entire rating, not just the numerical value. A PCN rating that includes the lowest numerical value may not be the critical PCN rating. It depends on the subgrade category. Examine the AGL when PCN values with different subgrade categories are similar and then use the PCN rating with the lower AGL. Typically, this critical PCN selection for multiple-section runways will occur either within the 75-foot keel or the full-width ends in the first 1,000 feet of the runway.

9-3.3 Example PCN Reporting.

An example of a PCN code is 80/R/B/W/T, with 80 expressing the PCN numerical value, R for rigid pavement, B for medium-strength subgrade, W for high allowable tire pressure, and T for a PCN value obtained by a technical evaluation.

9-3.4 Reporting the PCN Value.

The Service determines the traffic analysis approach used to determine the allowable load for critical/representative aircraft and passes used in the PCN numerical computation for each section. The standard aircraft approach (e.g., the C-17 at a pavement life of 50,000 passes) facilitates PCN comparison between installations. The mission group approach looks at the critical mission aircraft and equivalent passes for a specific installation for a 20-year period. This provides more value to the installation but does not allow for a comparison of load-carrying capacity between multiple installations. The mission/representative approach bases the PCN on the mission aircraft group in terms of a representative aircraft for each gear type group. This last approach provides fidelity for managing pavements at the installation level while facilitating comparison between installations. Note that the PCN and the ACN/PCN procedure described in the following paragraphs provides the first look for managing aircraft traffic at an installation. Ultimately, the allowable loads and allowable passes should be used to manage operations when questions arise. Once a PCN value and the coded entries are determined, the PCN code should be reported to:

National Geospatial-Intelligence Agency (NGA)
Attn: Air Information Library, L27
3838 Vogel Rd.
Arnold MO, 63010

9-4 AIRCRAFT/PAVEMENT (ACN/PCN) CLASSIFICATION NUMBERS.

The ACN/PCN method is a weight-bearing capability reporting tool and is not an evaluation procedure. The NGA publishes PCNs from the Services in their FLIPs for civil and international use. The FLIPs are used to determine weight-bearing limits in terms of the ACN/PCN ratio. The intent is to avoid either overloading pavement facilities or refused landing permission by providing planning information for individual flights or multi-flight missions.

9-4.1 ACN/PCN Concept.

The pavement PCN for a pavement structure is simply the ACN for the selected or most critical aircraft. Under these conditions, any aircraft with an ACN equal to or less than the reported PCN value can safely operate on the pavement, subject to limitations on tire pressure.

9-4.2 Limitations of the ACN/PCN System.

The ACN/PCN system is only intended as a method of reporting relative pavement strength so airport operators can evaluate acceptable operations of airplanes. It is not intended as a pavement design or pavement evaluation procedure, nor does it restrict the methodology used to design or evaluate a pavement structure. Operators should use the allowable loads or allowable passes contained in each Service's pavement evaluation reports to manage day-to-day operations. The use of the standardized method of reporting pavement strength applies only to pavements with bearing strengths of 12,500 pounds (5,700 kg) or greater.

9-5 PAVEMENT OVERLOAD.

Pavement overloading can result from aircraft loads that are too high, a substantial increase in operations rate, or both. Loads larger than the defined design or evaluation load shorten the design life, while smaller loads extend it. Except for massive overloading, pavements are not subject to a particular limiting load above which they suddenly or catastrophically fail. The structural behavior of pavements is such that a pavement can sustain a definable load for an expected number of repetitions during its design life. As a result, occasional overloading is acceptable, when expedient, with only a limited loss in pavement life expectancy and a relatively small acceleration of the pavement deterioration rate. Examples of situations where operators may decide that it is acceptable to overload a pavement are emergency landings, short-term contingencies, exercises, and air shows.

9-5.1 Structural Index (ACN/PCN Ratio) Standards.

9-5.1.1 Structural Index (ACN/PCN) ≤ 1.1.

Structural index (SI) values less than or equal to 1.1 have minimal impact on pavement life.

9-5.1.2 1.1 ≤ Structural Index (ACN/PCN) ≤ 1.4.

When the SI value is greater than 1.1 and less than or equal to 1.4, limit aircraft operations to ten passes and inspect the pavement after each operation, or consult the AGL and Pass-Level tables, or request a pavement engineer evaluate the structural capacity of the pavement to support the required mission. Ensure the airfield surface meets aircraft and mission requirements such as FOD and smoothness.

9-5.1.3 Structural Index (ACN/PCN) ≥ 1.4.

When the SI value is greater than 1.4, do not allow aircraft operations except for emergencies, or request a pavement engineer evaluate the structural capacity of the pavement to support the required mission.

9-5.2 Aircraft Movements.

The annual number of movements by aircraft exceeding an ACN/PCN ratio of 1.0 should not exceed 5 percent of the total annual aircraft movements.

9-5.2.1 Aircraft Movements During a Thaw Period.

Movements by aircraft exceeding an ACN/PCN ratio of 1.0 are normally not permitted on pavements exhibiting substantial signs of distress or failure. If the pavement must be used for operations, perform an analysis using the PCN criteria in Chapter 8 during any periods of thaw-weakening following frost penetration or when the strength of the pavement or its subgrade could be weakened by the presence of water.

9-5.2.2 AGL/Pass Level Methodology.

The AGL/pass level methodology must be used to determine airfield structural capability when the ACN/PCN ratios exceeds a value of 1.1.

CHAPTER 10 REPORTING EVALUATION RESULTS

10-1 OVERVIEW.

Evaluation results are reported using maps, tables, and figures compiled in an evaluation report. The content of the report varies based on the scope and intended use of the evaluation by each Service, such as a contingency evaluation versus an evaluation at a main operating installation where the report is used to generate pavement management plans. In either case, the report always describes and discusses the type and number of tests performed, the analytical process used to determine thickness and strength values, and any limitations or assumptions.

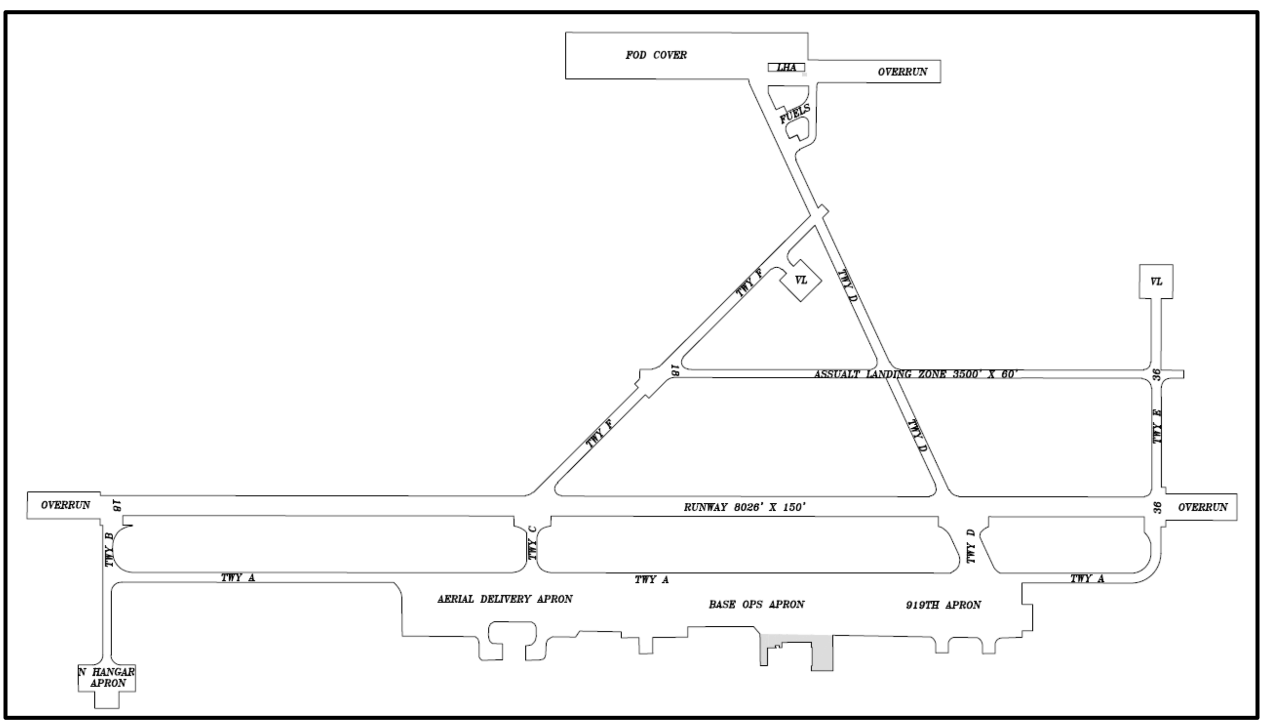
10-2 INVENTORY.

The pavement network, branch, and section inventory structure defines each pavement area for testing, analysis, and reporting. Tabular reports are sorted by branch and section or just by section, depending on the information presented and Service preferences. Maps also use branch and section IDs to organize and present inventory and analysis results. The following paragraphs present examples of inventory maps and tables.

10-2.1 Branch Maps.

Branch maps show the location of each branch on the airfield as shown in Figure 10-1. Variations of this basic map show both branches and sections or are color-coded to show condition data as shown in other examples in this chapter.

Figure 10-1 Branch Map Example



10-2.2 Section Maps.

Section maps show the location of each section on the airfield. They can include the pavement type and thickness as shown in Figure 10-2 or show only the section ID or branch and section ID as shown in Figure 10-3. Variations of these basic maps are color-coded to indicate condition data as shown in other examples in this chapter.

Figure 10-2 Section Map Example 1

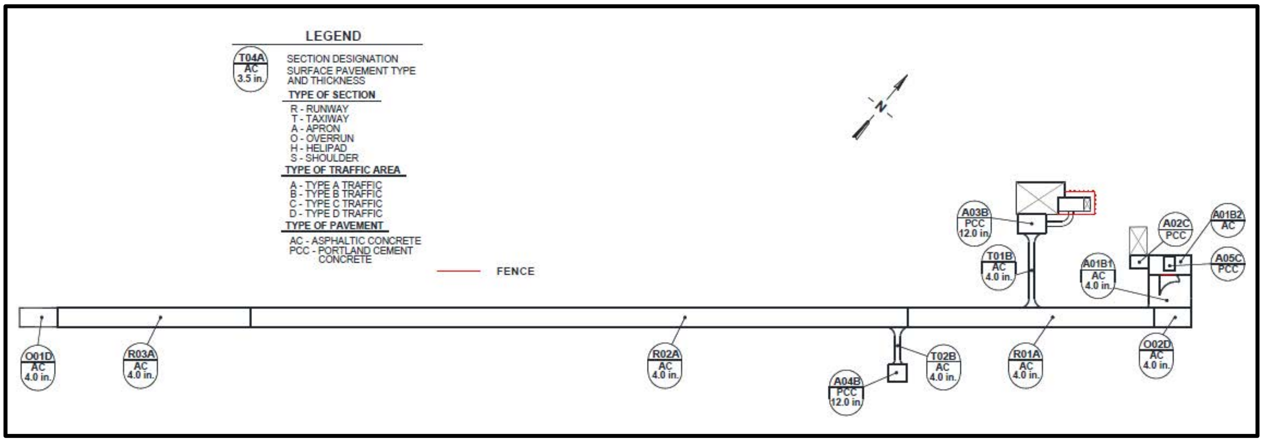


Figure 10-3 Section Map Example 2

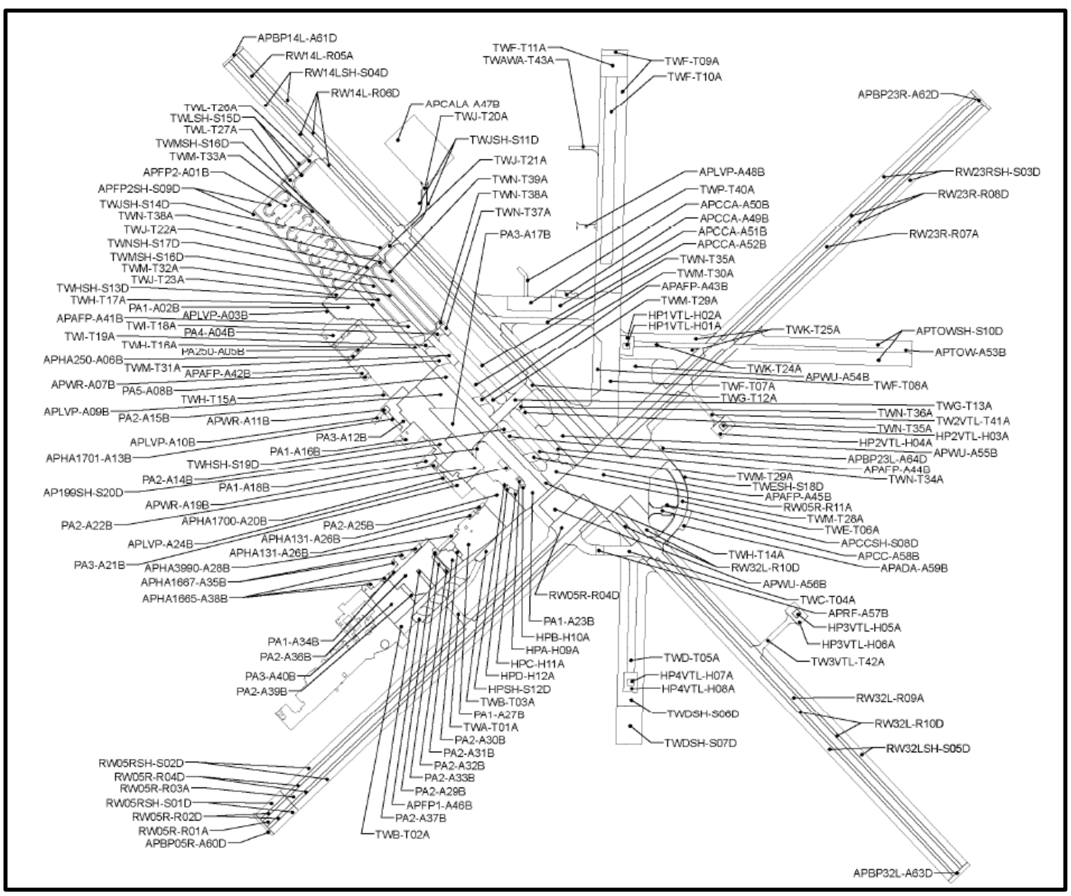

10-2.3 Construction History.

Construction history, also known as work history, is integral to developing deterioration models and maintenance and repair (M&R) strategies. Typically, construction history is presented in tables and, while there are variations, construction history tables always have the section ID, the pavement type and thickness, and the construction date. Figure 10-4 is an example of a report generated by the PAVER application and Figure 10-5 is an example of a report generated in a spreadsheet. Variations of the report include information on subsurface layers or surface treatments.

Figure 10-4 Construction History Report Example 1

10-3 TRAFFIC.

An evaluation report typically includes a table that outlines the traffic used in the analysis. This may be one of the standard traffic patterns shown in Chapter 4 or the mission traffic as shown in Figure 10-6. In all cases, traffic tables include the aircraft used in the analysis, the load, the number of passes and, for a mixed traffic analysis, the controlling vehicle(s) and equivalent passes.

Figure 10-6 Mission Traffic Example

10-4 ACN CHARTS AND TABLES.

The report uses charts, tables, or both to present ACN data. In all cases, the information includes the aircraft, pavement type, load, subgrade category, and the ACN.

10-4.1 ACN Table Example.

Figure 10-7 contains ACN values for the representative aircraft in Table 4-5 at various evaluation loads and Figure 10-8 shows an example at a single load. Figure 10-9 shows the ACN values for a single aircraft at varying operational loads.

10-5 REPORTING TEST RESULTS.

As discussed in Chapter 3, testing typically includes a mix of one or more of the following: coring or drilling, GPR, or MIRA testing to determine pavement thickness; GPR testing to determine subsurface layer structure; DCP testing to determine subsurface layer structure and strength; and FWD/HWD testing to determine the modulus of the layers in the pavement structure. Although not used as frequently as in the past, test pits are an option. The scope and intended use of the evaluation typically defines testing requirements. A comprehensive report includes test results to ensure readers have the necessary information to make decisions and provides a foundation for future evaluations.

10-5.1 Surface Condition.

The PCI provides an objective measure of the surface condition that is used in most instances. Use a cursory inspection with a direct rating of GOOD, FAIR, or POOR for contingency evaluations when a full PCI inspection is not performed. In either case, report the surface condition in either a table or a map.

10-5.1.1 Surface Condition Maps.

Surface condition maps vary depending on the scope and intended use of the evaluation. Maps show either the standard seven-tier PCI rating scale for a full PCI as shown in Figure 10-10 or a three-color condition map as shown in Figure 10-11. If a full PCI is not performed or when Service standards dictate, use three-color maps. Figure 10-10 includes the section information with the pavement types. At a minimum, the map includes either a branch or section ID.

Figure 10-10 Seven-Color PCI Map Example

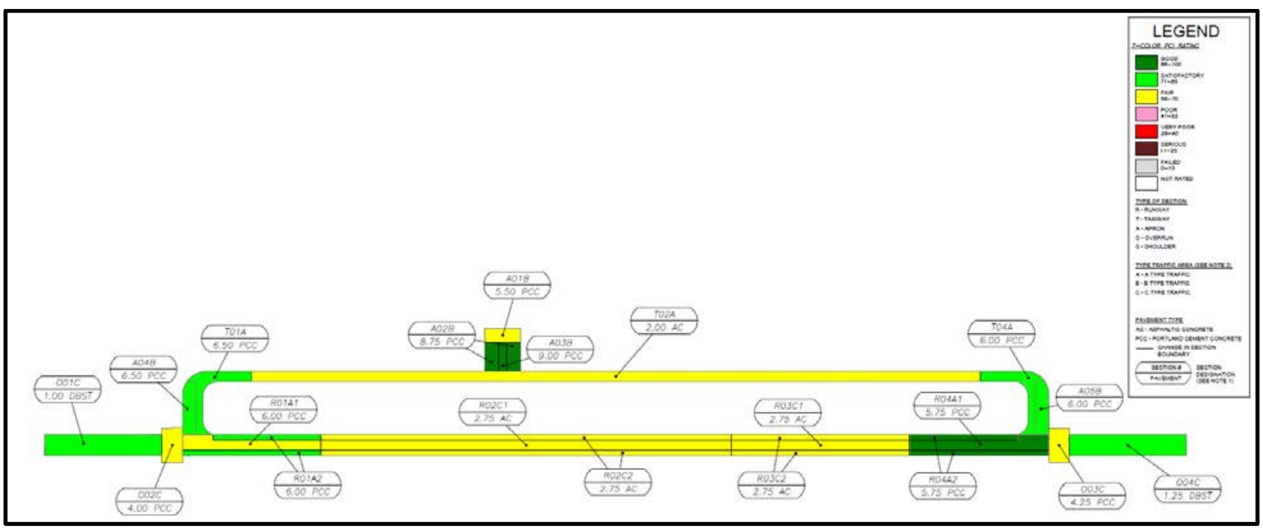

Figure 10-11 Three-Color PCI Map Example

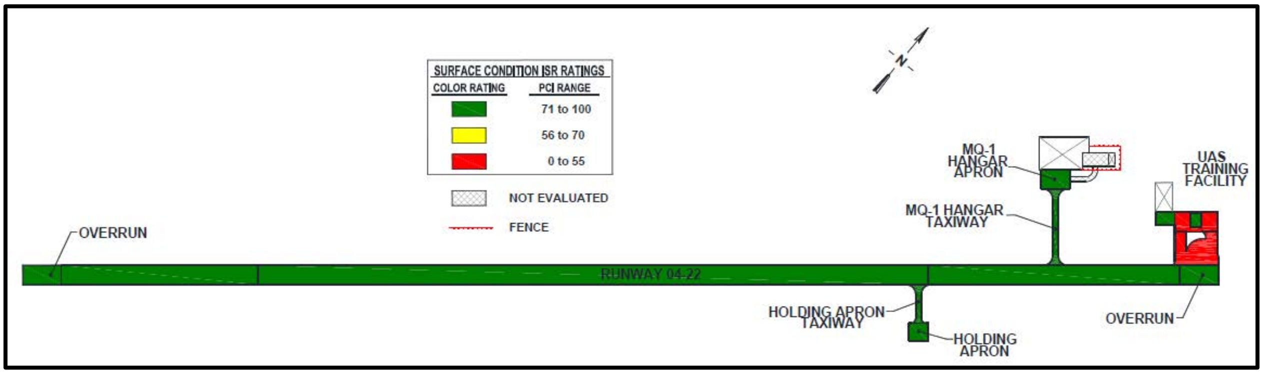
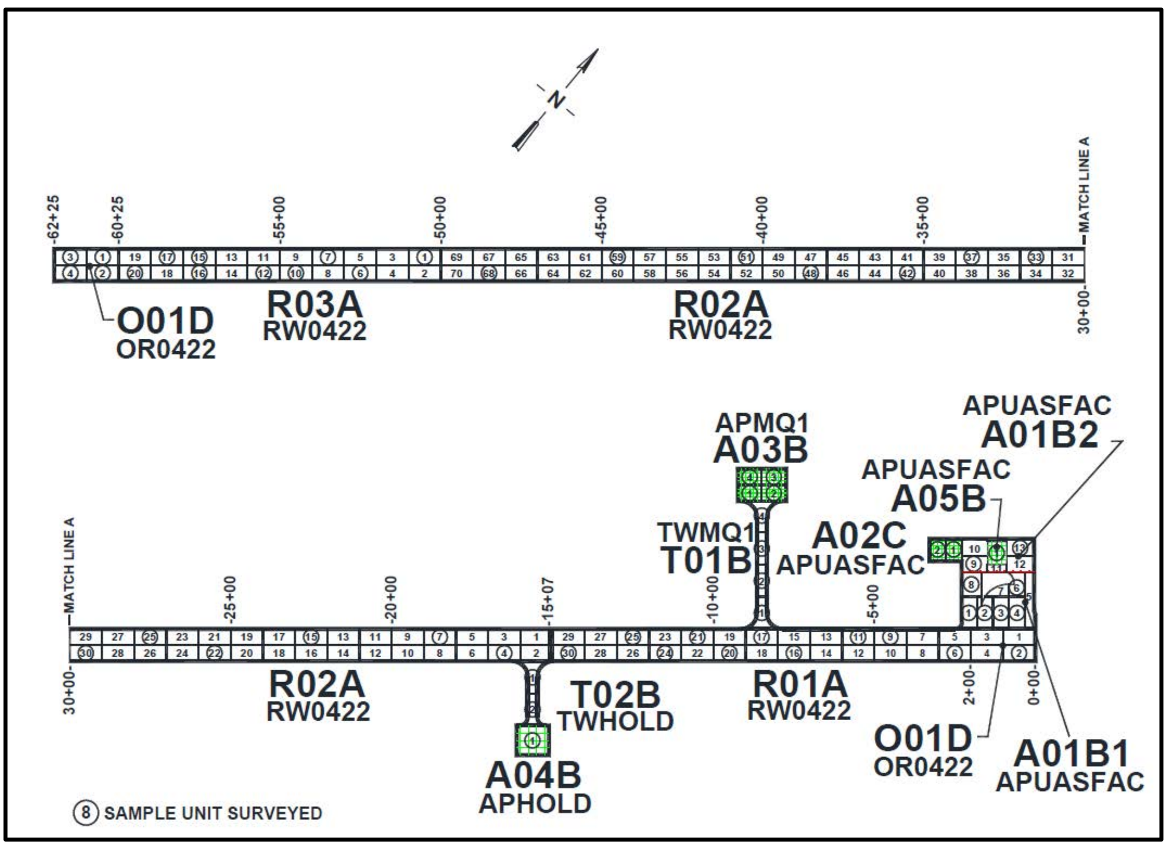


10-5.1.2 Sample Unit Maps.

Sample unit maps define the location of each sample unit in an inspection. Sample unit maps show the section delineation and identification and include each sample unit with its number. In addition, sample unit maps for rigid pavements include the slab layout. All sample units are numbered and inspected samples have a circle around the number.

Figure 10-12 Sample Unit Map Example



10-5.1.3 Surface Condition Table.

The PCI is often included in other tables such as the physical property data (PPD) or M&R summary tables to provide context. When the PCI is the primary focus, summarize the data at the branch level as shown in Figure 10-13 or at the section level as shown in Figure 10-14, depending on the intended use. In either case, at a minimum, a surface condition table shows the branch and/or section ID, the condition, and last inspection date. Tables typically include other inventory information as well as the deterioration rate and predicted PCI.

10-5.2 Dynamic Cone Penetrometer (DCP) Report.

DCP reports include the location of the evaluation as well as the date and location or number of the test. Include the blow and penetration data as well as a data plot. This is typically a CBR plot, but a plot of k or other values may be presented as well. Identify the hammer correlation and soil correlation used to determine the CBR values. The layer structure used to populate the PPD table may also be included on the graph, in tabular form, or both. See Figure 10-15.

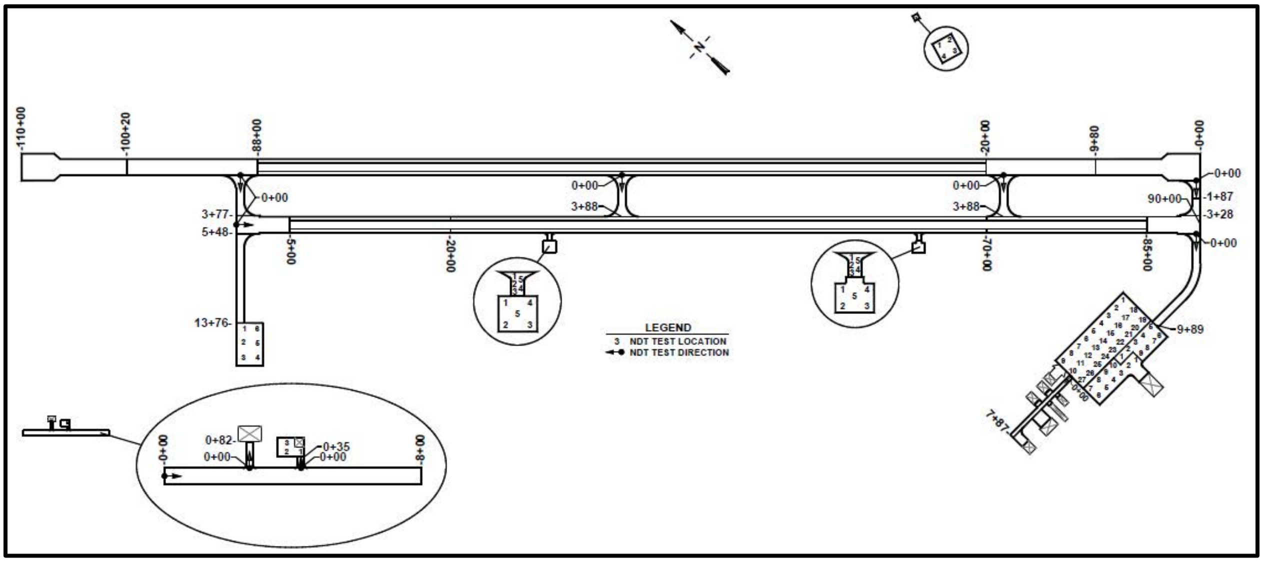
10-5.3 Falling/Heavy Weight Deflectometer (FWD/HWD) Data.

As described in paragraph 3-4.1, FWD is the generic term for the device, with the HWD capable of applying a heavier load than other FWDs, but the terms are used synonymously. FWD data is reported using one or more report types, including maps, charts, and tables.

10-5.3.1 FWD Data Maps.

FWD data maps report the test locations. They can vary from a map that shows the general location of tests to one based on the GPS coordinates of each test location. The latter are typically included at a larger scale. Figure 10-16 shows a map of the general location and direction of testing. Both the general map and the more detailed GPS-based map show distance measurements on long, linear structures such as a runway. The distance measurement can be used to identify the test location or, more typically, the test is just given a number. The term station is used for either the test number or the test location.

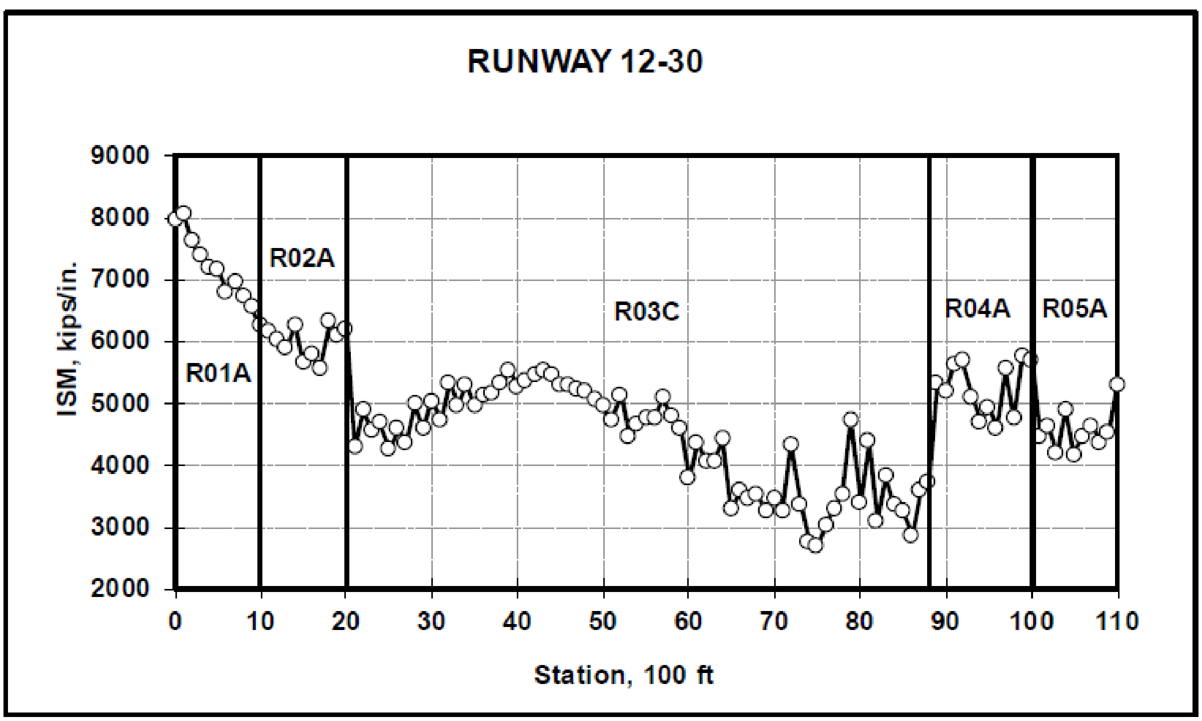
Figure 10-16 FWD Test Location Map



10-5.3.2 FWD Data Charts.

FWD data charts typically display the impulse stiffness modulus (ISM) as described in paragraph 5-3.5.1. These ISMs provide a quantitative stiffness comparison between test stations and between pavement sections. The ISM values are plotted on the Y axis for each station (test point) in the section. These data are used to visually determine if a change in strength exists and define where sections change when the FWD file has basin data from multiple sections, as shown in Figure 10-17.

Figure 10-17 ISM Plot



10-5.3.3 FWD Data Tables.

When included in a report, FWD data are typically limited to the representative basin that is used for analysis for each section (see paragraph 5-3.8) rather than reporting all basin data. The representative basin data is presented in a table that includes the section identification, the ISM, and load, as well as the deflection data (in mils) for each FWD sensor. Figure 10-18 shows a typical representative basin table.

Figure 10-18 Representative Basin Table

Section	ISM, kips/in.	Load, lb	Deflection, mils						
			D1	D2	D3	D4	D5	D6	D7
Runway 12-30									
R01A	7,182	49,985	6.96	6.41	5.85	5.42	5.00	4.52	4.03
R02A	6,075	50,303	8.28	7.95	7.38	6.93	6.38	5.70	5.15
R03C	4,411	50,062	11.35	10.74	9.78	8.82	7.83	6.68	5.62
R04A	5,323	50,040	9.40	8.88	8.16	7.71	6.93	6.05	5.30
R05A	4,602	49,930	10.85	10.26	9.48	8.73	7.84	6.96	5.94

10-5.4 Ground Penetrating Radar (GPR).

As described in paragraph 3-4.2, GPR is used to determine pavement and soil layer thicknesses and determine the presence of voids. When used to determine thickness, the average thickness values for a section are populated in the physical property data table. When used to identify the location of anomalies such as voids, images from the GPR application may be included in the report.

10-6 PHYSICAL PROPERTY DATA (PPD).

PPD is the term used to describe the pavement layer structure. When included in a report, these data are presented in tabular format. At a minimum, this table will include the section ID as well as the thickness, description, and strength index or property for each layer. Flexural strength is reported for any PCC layer. The description can range from a general layer description (e.g., drainage layer or stabilized base) to a USCS when soil laboratory testing was performed. The table may include the backcalculated modulus value as shown in Figure 10-19 or a strength index like CBR or k for soil layers as shown in Figure 10-20. When testing includes coring and DCP tests, it is typical to report the CBR and k values. Reporting modulus values is typically done when only HWD data is collected although there may be instances when a PPD table may include both, e.g., some sections had coring, DCP, and HWD data collected because they were new or when the impulse stiffness modulus was below 400, making an airfield pavement analysis (APE) analysis preferable for that section.

Figure 10-19 PPD Table with Modulus

10-7 BACKCALCULATION RESULTS.

Backcalculation results are presented in a layered elastic modulus table. This table may include either the backcalculated modulus values for each section or the modulus values used for Layered Elastic Evaluation Program (LEEP) analysis for each section, the distinction being that the latter shows values that were manually set for analysis as in the case of capping PCC modulus values or using the temp option for asphalt modulus values in analysis. At a minimum, a modulus table shows the section ID and the modulus for each layer. It may also include information on the layer type (e.g., PCC or AC), the layer thickness (including depth to bedrock), or the percent error of closure for reported backcalculated modulus values. Figure 10-21 shows a layered elastic modulus value generated by the Pavement-Transportation Computer Assisted Structural Engineering (PCASE) application.

10-8 ANALYSIS RESULTS.

Analysis results are typically in tables but the results from these tables may also be displayed on maps. At a minimum, analysis results tables will include the section ID, allowable passes, allowable gross load (AGL), Pavement Classification Number (PCN), and the basis of the PCN. These results are reported in one or more tables, e.g., PCNs may be reported in a separate table than allowable passes and AGLs. These tables may also include other data, such as overlay requirements, critical aircraft, Aircraft Classification Number (ACN, and the structural index (ACN/PCN ratio). The presentation of the results is largely defined by whether the analysis is done based on standard, mission, or mission/representative aircraft groups as well as whether an individual or mixed traffic analysis was performed.

10-8.1 Aircraft/Gear Type Load Table.

An analysis results table may be organized based on specified loads for specific aircraft or gear types. In this case, the report in Figure 10-22 shows the PCN and design passes (basis of the PCN) as well as the allowable passes.

Figure 10-22 Aircraft/Gear Type PCN – Allowable Pass Table

10-8.2 Aircraft Group Allowable Gross Load (AGL) Table.

An aircraft group AGL table is organized by groups of aircraft with similar characteristics. AGLs are reported for specified pass levels of each group. These tables may be color-coded to indicate when the AGL is above the maximum aircraft load for the group (green), when it is between the maximum and minimum load for the group (yellow), and when it is below the minimum load for the group. The AGL table is accompanied by a separate table that defines the aircraft in each group and the pass levels. Figure 10-23 shows an AGL table from PCASE.

Figure 10-23 Aircraft Group AGL Table

10-8.3 Controlling Aircraft AGL Table.

A controlling aircraft AGL table is organized by section like the other tables but defines the controlling aircraft load and passes and reports the AGL and PCN. The example in Figure 10-24 also shows overlays.

Figure 10-24 Controlling Aircraft AGL Table

10-8.4 Pavement Classification Number (PCN) Table.

As with other reports, PCN tables are organized by section and show the PCN for each respective section. These tables may also show the structural index (ACN/PCN ratio) for the controlling aircraft or may show the controlling PCN for a branch with multiple sections. Figure 10-25 shows an example of a basic PCN table from PCASE.

Figure 10-25 PCN Table

PAVEMENT CLASSIFICATION NUMBER Normal Period

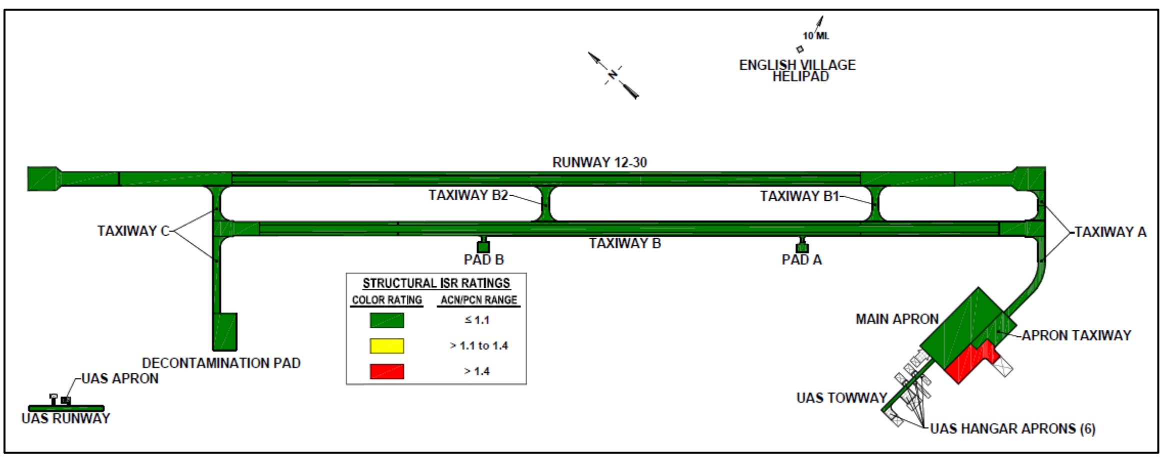
10-8.5 Structural Index (ACN/PCN) Ratio.

As described in paragraph 9-5.1, the structural index (SI) is used to define whether a pavement is structurally adequate to sustain mission traffic. As mentioned in paragraph 10-8.4, the SI can be incorporated in other tabular reports as shown in the example in Figure 10-26 in which it is included in the PCN table or it can be displayed in a map as shown in Figure 10-27. This objective is to indicate whether each pavement section is structurally capable of supporting the anticipated mission traffic for the expected life of the pavement. The concept can be extended to address the issue of service life, which is discussed in paragraph 10-8.6.

Figure 10-26 SI Example

SECTION	PRIMARY AIRCRAFT	ACN	PCN	STRUCTURAL INDEX
A01B	T-6A	3/R/B	21/R/B/W/T	0.14
A02B	T-6A	3/R/C	23/R/C/W/T	0.13
A03B	T-6A	3/R/B	31/R/B/W/T	0.10
A04B	T-6A	3/R/B	33/R/B/W/T	0.09
A05B	T-6A	3/R/B	18/R/B/W/T	0.17

Figure 10-27 Pavement Life Expectancy Based on SI



10-8.6 Pavement Life Expectancy.

The ACN/PCN ratio concept can be extended to similar Service-specific criteria as described below and shown in the color-coded example map in Figure 10-28. In this example, the ACN of the critical aircraft at various load levels (loaded, half-loaded, and unloaded aircraft) is compared to the PCN for the section. These ACN/PCN relationships correspond to the color codes shown below:

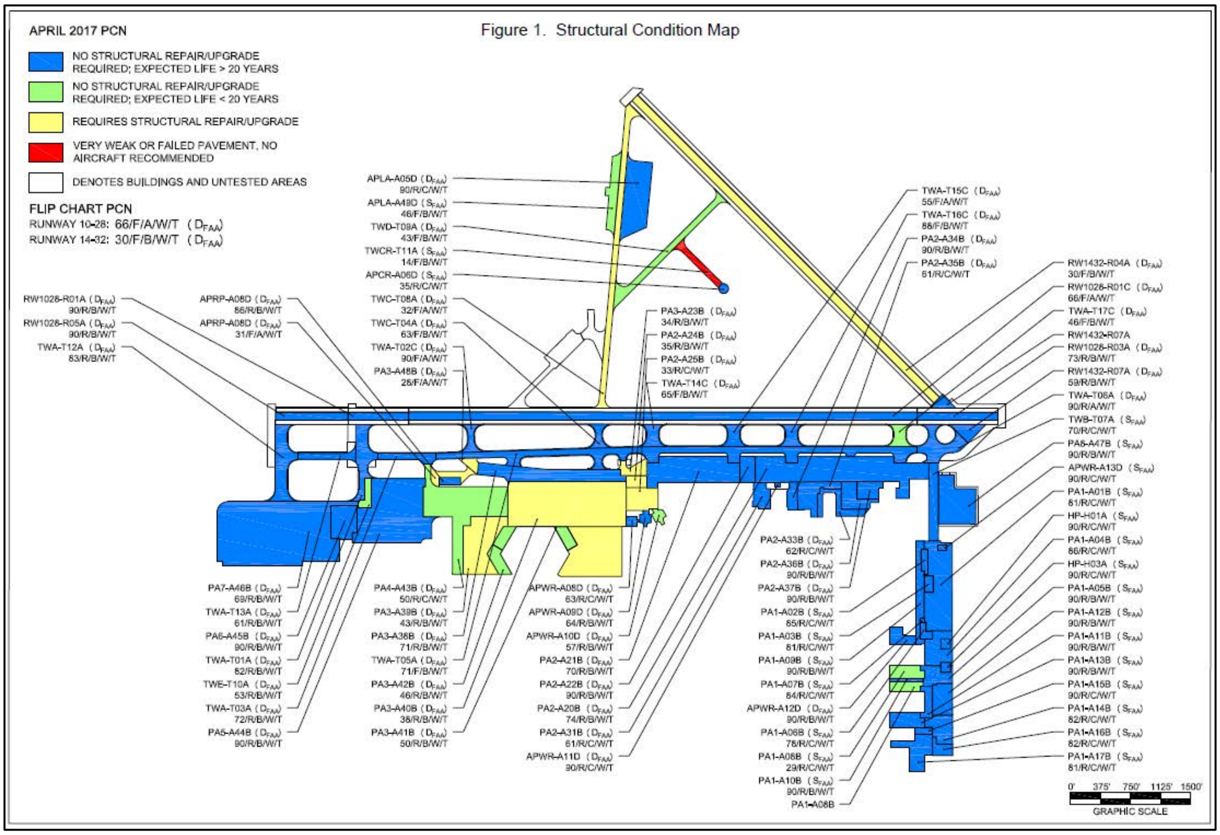
- B (BLUE): $ACN_{\text{fully loaded}} \leq PCN$
- G (GREEN): $ACN_{\text{half-loaded}} \leq PCN \leq ACN_{\text{fully loaded}}$
- Y (YELLOW): $ACN_{\text{empty}} \leq PCN \leq ACN_{\text{half-loaded}}$

- R (RED): PCN ≤ ACN_{empty}.

Figure 10-28 depicts this 4-color structural condition map in terms of life expectancy:

- B (BLUE): Expected pavement life is greater than 20 years
- G (GREEN): Expected pavement life is less than 20 years
- Y (YELLOW): Pavement in need of structural repair/upgrade
- R (RED): Very weak or failed pavement, limit or cease aircraft operations

Figure 10-28 Pavement Life Expectancy Based on Service-Specific Criteria



10-8.6.1 Life Expectancy Weight Restrictions.

The example map in Figure 10-28 also identifies weight restrictions based on the color code. The color codes below define the limitations necessary (at the original level of passes) to ensure the section will provide a service life of twenty years.

- B (BLUE): No weight restriction
- G (GREEN): Reduce departure weights by 50 percent
- Y (YELLOW): Reduce use to unloaded aircraft
- R (RED): Aircraft traffic operations suspended until pavement is repaired.

10-8.6.2 Life Expectancy Pass Level Restrictions.

The colors in the map in Figure 10-28 also imply pass level restrictions (at the original weight) necessary to ensure that the Section provides a 20-year service life. Areas with a blue color code can accommodate pass level increases up to 50 percent without significantly affecting the pavement service life.

APPENDIX A SAMPLING AND TESTING METHODS

A-1 INTRODUCTION.

The Table A-1 provides a summary of the sampling and testing procedures used in pavement evaluation and published standards for the respective tests. The remainder of this appendix provides an overview of some of the commonly used test methods and details on procedures that do not have established standards.

Table A-1 Sampling and Testing Procedures

Testing or Sampling Procedure	Publication
General Testing	
Pavement condition index (PCI) inspection	UFC 3-260-16 ASTM D5340
Falling weight deflectometer (FWD)	ASTM D4694 and D4695
Ground penetrating radar (GPR)	ASTM D6432
Pavement coring	Paragraph A-2.4
Dynamic cone penetrometer	TM 3-34.48-2
Asphalt Testing	
Sampling bituminous paving mixtures	ASTM D979
Unit weight, Marshall stability, and flow of bituminous mixtures	CRD-C 649
Density and percent voids of compacted bituminous paving mixtures	CRD-C 650
Recovery of asphalt from solution by Abson method	ASTM D1856
Extraction of bitumen from bituminous paving mixtures	ASTM D2172
Asphaltic concrete recompaction	Paragraph A-3.1
Penetration of bituminous materials	ASTM D5
Ductility of bituminous materials	ASTM D113
Softening point of asphalt and tar materials	ASTM D36
Test for bitumen	ASTM D4

Testing or Sampling Procedure	Publication
Concrete Testing	
MIRA ultrasonic tomography	ASTM C597

Deep, quasi-static, cone, and friction-cone penetration tests of soils	ASTM D3441

Note: ASTM is the designation of standards and test methods issued by the American Society for Testing and Materials.

A-2 GENERAL PAVEMENT EVALUATION TESTING.

A-2.1 Pavement Condition Index (PCI) Inspection.

UFC 3-260-16 implements the PCI inspection procedures in ASTM D5340 for DoD. Additional details are found in the PAVER User manual and Distress Identification Manuals posted on the Tri-Service Pavement-Transportation site, https://transportation.erdc.dren.mil/paver/Manuals.htm

A-2.2 Falling Weight Deflectometer (FWD).

Chapter 3 provides DoD-specific procedures on use of the FWD. This guidance supplements that found in the Dynatest user manual, ASTM D4694, and ASTM D4695.

A-2.3 Ground Penetrating Radar (GPR).

Chapter 3 provides a general description on DoD GPR use. Appendix B addresses GPR use for void detection. This guidance supplements the manufacturer's user manual and ASTM D6432.

A-2.4 Pavement Coring and Drilling.

Chapter 3 provides general DoD guidance on the number and locations for taking pavement core samples.

A-2.5 Dynamic Cone Penetrometer (DCP).

Chapter 3 provides a general overview of the types of DCP devices used by DoD as well as guidance on the number and locations for drilling pavement to perform DCP testing.

The DCP (or automated DCP) consists of a rod that is driven into the soil using a 17.6-pound hammer dropped from a constant height of 22.6 inches (574 millimeters). The manual system is portable and has options that automate data collection so testing is performed by a single operator. DCPs are designed to penetrate to a depth of 36 to 48 inches (900 to 1,220 millimeters), which is typically sufficient to test weak areas for voids.

A-2.6 Standard Penetration Test.

The standard penetration test (SPT) is also called the split-spoon test because of the split-barrel used for soil sampling. The test (ASTM D1586) provides a representative soil sample and a measure of the soil resistance to penetration by driving a split-barrel sampler using a 140-pound mass from a 30-inch height. The number of blows is recorded for each 6-inch increment of penetration and is assumed to be representative of the soil strength. Typically, the DCP has been easier to conduct than the SPT.

A-3 ASPHALT TESTING.

A-3.1 Recompaction of Asphaltic Concrete.

Samples of existing pavements may be recompacted in the laboratory for comparison with the in-place conditions. Pavement samples should be approximately 10-inch (254-millimeter) maximum dimension so the various layers or course can be identified. If the pavement consists of more than one course, the courses should be separated and treated individually. The courses may be separated by heating the pieces of pavement and driving a hot knife between the layers or by other similar methods. After a course has been separated, break it into small pieces and heat it to a temperature of 240 °F to 260 °F (115 °C to 127 °C) as rapidly as possible in an oven or on a hotplate, with constant stirring to ensure uniform heating. Thoroughly mix the material during heating and compact the hot mixture in accordance with the standard Marshall method procedures. Compact samples with 50 or 75 blows on each side of the specimen for comparison with criteria for tire pressures of 100 psi and 200 psi (0.7 MPa and 1.4 MPa), respectively. Compact six to eight specimens with each effort and test in accordance with standard procedures for the Marshall method. Note that reheating produces a hardening of the asphalt cement. This hardening causes somewhat higher stability values but has little effect on the other test values when analyzing the test data.

A-3.2 All-Bituminous Concrete and Flexible Overlays.

Use the same procedures described in paragraph A-3.1 when testing all-bituminous concrete base-course material and flexible overlays except when the all-bituminous concrete or flexible overlay exists between two thicknesses of rigid pavement (composite pavement). In this case, the only test necessary on the bituminous concrete portion of the overlay is an extraction test to determine the gradation of the aggregate and the bitumen content, so only one or two samples of the bituminous concrete are needed from each test pit. Take a large enough sample of the base course portion of the flexible overlay for a gradation test.

A-3.3 AC Layer Separation by Construction.

Split the cores at the interface of each AC layer (or lift) when a flexible pavement consists of more than one AC layer so that each layer can be tested separately. Test each layer for Marshall stability, flow, percentage of asphalt by weight, penetration of bitumen, aggregate type, shape and gradation, specific gravity of bitumen and aggregate, and density (CRD-C 649). Evaluate each course of the cores for percentage of asphalt by weight, aggregate gradation, and specific gravity according to ASTM D2172, ASTM D2726, and ASTM D5444 when the pavement was designed according to Superpave criteria. Compute the voids in the total mix and the percentage of voids filled with asphalt from the test results (CRD-C 650, ASTM D2041 and ASTM D2726).

A-3.4 AC Core Extraction Analysis.

Determine aggregate gradation, specific gravity of bitumen and aggregate, and penetration, ductility, and softening point of the bitumen from a portion of the samples. Other samples are recompacted as described in paragraph A-3.1 to determine Marshall stability, flow, density, and their voids relations. The stability of the cores cut from the pavement will often be lower than the recompacted sample. A part of this difference is due to differences in density since the field cores seldom have density as high as the laboratory-compacted samples. A major part of this variation in stability is due to differences in the structure of the field and laboratory samples and also the fact that the asphalt hardens some during reheating. Since the stability value is not the sole criterion for evaluating the mix, the lack of correlation between the stability of the field and laboratory samples is not particularly significant.

A-3.5 Resistance to Fuel Spillage.

There are currently no standard tests to determine resistance to spillage. However, spilling a small amount of jet fuel on one of the samples from each test pit to see if the fuel penetrates the samples quickly or if it “puddles” on the surface gives an indication of resistance to fuel spillage.

A-3.6 AC Separation Tests between PCC Layers.

The gradation and bitumen content of the bituminous concrete and the gradation of the base-course material, if any, are the only tests required when the non-rigid overlay is between two thicknesses of rigid pavement.

A-4 CONCRETE TESTING.

Retain all concrete cores collected and all test specimens cut from test pits for laboratory tests to determine the flexural strength. Visually examine concrete samples to determine the type of aggregate and estimate the maximum size of aggregate. Determine flexural strength from cores by conducting tensile splitting tests on 6-inch (152-millimeter) -diameter cores. Ensure the test specimens from pits are three times as long and three times as wide as the pavement thickness except when cutting 6- by 6-

inch (152- by 152-millimeter) beams from the top and bottom of the specimens for three-point load beam tests.

A-4.1 Flexural Strength Test.

Determine the flexural strength of rigid pavement using the third-point loading procedure set forth in ASTM C78, with the following modifications.

A-4.1.1 Test Specimens.

The test specimens should have a square section with the width and thickness equal to the pavement thickness for pavement thicknesses less than or equal to 12 inches (305 millimeters). For pavement greater than 12 inches (305 millimeters), either cut a square section with width and thickness equal to the pavement thickness or cut 6- by 6-inch (152- by 152-millimeter) beams from the top and bottom of the slab then average test to obtain a strength representative of the full section. When cutting 6- by 6-inch (152- by 152-millimeter) beams from the top and bottom of the slab, ensure the length of the specimen is three times the thickness of the specimen plus approximately 6 inches (152 millimeters).

A-4.1.2 Procedure.

Place the specimen in the third point loading apparatus and test it in the as-cast position. That is, apply the load at the third points on the surface of the beam that represents the pavement surface. Locate the load reaction on the bottom of the beam, which represents the bottom of the pavement.

A-4.2 Splitting Tensile Strength Tests.

The splitting tensile test can be conducted in the laboratory or in the field in accordance with ASTM C496 standard practices and uses the correlation in Equation A-3 to measure concrete flexural strength. Portable field splitting tensile test equipment is a modified version of the laboratory test equipment shown in Figure A-1.

Figure A-1 Portable Split Tensile Tester

The test involves laying a concrete core with its longitudinal axis horizontal and then applying a vertical compressive load at a constant rate along the longitudinal until the core fails in tension across the diameter from stresses induced by the compression load. Figure A-1 shows a failed specimen following a splitting tensile test. Record the diameter and the length of the core and maximum load at failure. Use Equation A-3 to calculate the tensile splitting strength and use the empirically developed relationship (WES, 1974) in Equation A-1 to compute flexural strength (Equation A-2 is a variation of Equation A-1).

Equation A-1 Flexural Strength

$$f = \left[\frac{2p}{\pi \cdot ld} \right] 1.02 + 210$$

Where:

f = *flexural strength (pounds per square inch)*

p = *applied load (pound-force)*

l = *length of the sample (inches)*

d = *diameter of the sample (inches)*

Equation A-2 Flexural Strength

$$F = 1.02T + 210$$

Where:

F = flexural strength in psi

T = tensile splitting strength in psi

The splitting tensile strength T is then computed from the equation:

Equation A-3 Tensile Splitting Strength

$$T = \frac{2P}{\pi l d}$$

Where:

P = maximum load at rupture, pounds-force (Newtons)

l = length of core, inches (millimeters)

d = diameter of core, inches (millimeters)

A-5 SOIL TESTING.

Conduct laboratory testing on samples of the base course, subbase course, and subgrade materials to classify them using the USCS in accordance with ASTM D2487. The size of the samples depends on the type of sampling and laboratory tests performed.

A-5.1 Disturbed Sampling.

Auger borings and bag samples are the two types of disturbed sampling used for airfield pavement evaluation.

A-5.1.1 Auger Borings.

The most suitable method of obtaining samples of the foundation materials for developing soil profiles is by auger borings. These borings are taken in test pits or through small 4- or 6-inch (102-millimeter or 152-millimeter) -diameter holes cored through the pavement. Take samples of the foundation materials at each 6-inch (152-millimeter) vertical increment to a depth of 2 feet (610 millimeter) and for each 12-inch (305-millimeter) increment thereafter to the desired depth. Take additional samples whenever there is a change in materials or moisture conditions. Seal the samples in clearly marked jars before transporting to the laboratory for moisture content testing and soil classification.

A-5.1.2 Bag Samples.

Bag samples of the foundation materials from test pits are used for compaction tests. Take samples of each type of material encountered. The size of the bag samples required depends on the type of material and the type of test to be performed. Collect a 100-pound (45 kilogram) sample of fine-grained soil for determining moisture-density. Collect a 450-pound (204-kilogram) sample of fine-grained soil when developing the moisture-density-CBR relationship. Increase the sample size to 200 pounds (90 kilograms) for the moisture-density tests and 600 pounds (272 kilograms) for moisture-density-CBR tests of granular soils.

A-5.2 Undisturbed Sampling.

Undisturbed samples may be required for laboratory CBR tests if the subgrade is composed of a fine-grained cohesive material. There is no prescribed method for obtaining undisturbed samples of subgrade material. Any method that provides enough material and maintains it in its existing condition is satisfactory. The method most widely used for undisturbed sampling is to trim a sample by hand to fit into a split cylinder of galvanized metal approximately 8 inches (203 millimeters) in diameter and at least 12 inches (305 millimeters) high. Seal the sample at the sides and ends with paraffin to prevent moisture loss.

A-5.3 Soil Testing for Rigid Pavements.

Collect bag samples of base and subbase courses underlying rigid pavements for classification and compaction tests. In general, a 200-pound (91 kilograms) sample is sufficient. However, when laboratory CBR tests are necessary, which may be the case when evaluating a non-rigid overlay on rigid pavements, a minimum 600-pound (272 kilogram) base-course sample is required. Determine gradation, Atterberg limits, specific gravity, and moisture-density relations. The moisture-density and CBR values may be required when evaluating a non-rigid overlay on rigid pavements. Perform an adaptation of the consolidation test on undisturbed samples of the subgrade to determine the correction for saturation of the plate-bearing test results. The undisturbed samples may also be used for density determinations. Soaked laboratory CBR tests on undisturbed subgrade material may be required when evaluating a non-rigid overlay on rigid pavement.

A-5.4 Soil Testing for Flexible Pavement.

Conduct tests on samples of base course, subbase, and subgrade materials, including Atterberg limits, gradation, dry soil color, and specific gravity, to classify the soil. Table A-2 summarizes testing requirements for project design that UFC 3-260-02 describes in more detail. Determine moisture-density and CBR relations from available data or from samples of base course, subbase, and subgrade materials remolded at three compaction efforts as described in CRD-C 653 and CRD-C 654. Take the base and subgrade samples in a manner that assures representative materials.

Table A-2 Flexible Pavement Sampling Requirements

Material	Samples Per Pit	Remarks
Pavement	8 cores, 200 pounds (91 kilograms) per sample	Samples should be 8 to 10 inches (203 to 254 millimeters) in minimum dimension to permit separation of courses
Base and subbase courses	600 pounds (272 kilograms)	Disturbed sample
	3 samples	Undisturbed cylinders to be taken of material with plastic fines where applicable
Subgrade	450 pounds (204 kilograms)	Disturbed sample; increase to 600 pounds (272 kilograms) if much coarse material is present
	3 samples	Undisturbed cylinders

A-5.5 Subgrade Soil Testing.

Collect a 100-pound (45-kilogram) bag sample of fine-grained material when samples of the subgrade are required. Obtain a 200-pound (91-kilogram) bag sample when the subgrade is composed of a granular material. If laboratory CBR tests are required, which may be the case in the evaluation of a non-rigid overlay on rigid pavements, increase the bag samples of subgrade material to 450 pounds (204 kilograms) and 600 pounds (272 kilograms) for fine-grained and granular materials, respectively.

A-5.6 Field Density Tests.

A-5.6.1 Field Density Frequency.

When taking samples of 0.5 cubic foot (0.014 cubic meter) volume or less, make three density determinations at each elevation tested. When taking larger samples, decrease the number of density determinations to two. When there is not a reasonable agreement between the tests results, perform two additional tests. A reasonable agreement is a tolerance of 5 pounds per cubic foot (80 kilograms per cubic meter) wet density. For example, test results of 108, 111, and 113 pounds per cubic foot (1,730, 1,778, and 1,810 kilograms per cubic meter) wet density are in reasonable agreement, and their average is 111 pounds per cubic foot (1,778 kilograms per cubic meter).

A-5.6.2 Field Density Test Procedure.

Field density tests are performed on the base course and subgrade materials. The most satisfactory methods of obtaining the density are by the sand-displacement or balloon methods when the base course or subgrade is composed of granular materials. These tests are described in ASTM D1556 and ASTM D2167, respectively. If the subgrade is composed of a fine-grained cohesive material, the density is best obtained either by drive-sampling (ASTM D2937) or balloon methods (ASTM D2167) or by the undisturbed sampling that may be required in connection with the plate-bearing test. Conduct all field density tests adjacent to the area that was loaded during the plate-bearing test. When the overlay portion of a non-rigid overlay on rigid pavement is composed of a bituminous concrete and base course, conduct density tests on the base-course portion of the overlay.

A-5.7 Moisture Content Tests.

The strength of base courses composed of substantial portions of fine materials is governed by the moisture content of the fine fraction. Therefore, moisture-content determinations are made on the fine-grained portion of the soil. The fine fraction is that portion passing any of several sieve sizes ranging from No. 200 to No. 4. For the purposes of this UFC, material passing the No. 40 sieve is the critical sieve size. This is the same sieve used for separations for liquid and plastic limit determinations. Determine the moisture content of both the material passing the No. 40 sieve and the total sample and recorded in the test data tables. If it is impractical to separate the material at the No. 40 sieve without affecting the moisture present, perform an absorption test following ASTM C127. The percentage of absorption thus determined is considered the moisture content of the coarse fraction. It is used to determine the moisture content of the remainder (assuming all other moisture to be in this finer fraction) mathematically. Comparing the moisture content of the material passing the No. 40 sieve with the liquid limit of the material is an indication of the stability of the base-course material. If the moisture content is near the liquid limit, the material is considered unstable. When the moisture content exceeds the liquid limit, the base material becomes more unstable as the percentage of fines increase.

A-5.8 California Bearing Ratio (CBR) Test.

A-5.8.1 CBR Test Locations within Test Pit.

When selecting CBR test locations in the test pit, place the CBR piston at a location that represents an average condition of the surface being tested, ensuring it is not set on unusually large pieces of aggregate or other unusual materials. The general practice is to space the CBR tests in the pit where the areas covered by the surcharge weights of the individual tests do not overlap. Perform these tests on the surface and at each full 6-inch (152-millimeter) depth (especially if a strength problem is suspected) in the base and subbase courses, on the surface of the subgrade, and on underlying layers in the subgrade as needed. Make density and moisture-content determinations in the subgrade at 1-foot (0.3 meter) intervals to a total depth of 4 feet (1 meter) below the surface of the subgrade. Use the results of the density and moisture tests at these depths to ascertain whether there is a need for additional CBR tests. Make density determinations between adjacent CBR tests. Perform three in-place CBR tests in test pits at each elevation tested. However, if the results of these three tests do not show reasonable agreement, make three additional tests. Reasonable agreement means a tolerance of 3 between three tests when the CBR is less than 10; a tolerance of 5 when the CBR is from 10 to 30; and a tolerance of 10 when the CBR is from 30 to 60. Variations in the individual readings are not as important for CBR values greater than 60. For example, actual test results of 6, 8, and 9 are reasonable and their average is 8; results of 23, 18, and 20 are reasonable and their average is 20. If the first three tests do not fall within this tolerance, then perform three additional tests at the same location and use the numerical average of the six tests as the CBR for that location. Round off CBR values below 20 to the nearest point. For example, round off 18.7 to 19. Round off to the nearest five points for CBR values above 20. For example, round off 23.4 to 25. Obtain a moisture content at the point of each penetration.

A-5.8.2 Using CBR Tests for Rigid Pavements.

In-place CBR tests may be required on the subgrade materials in addition to plate-bearing tests to evaluate a non-rigid overlay on rigid pavement. When the k value of the subgrade material is greater than 200 pci (5,536 g/cm3) or the concrete flexural strength is less than 400 psi (2.8 MPa), the load-carrying capability for the non-rigid overlay or rigid pavement should be evaluated using both rigid and flexible pavement evaluation procedures. In the latter case, assume the rigid pavement is a high-quality base course material and conduct in-place CBR tests on the base and subgrade materials in addition to the plate-bearing tests. Conduct the in-place CBR tests the same as if it was for a flexible pavement evaluation.

A-5.8.3 Moisture-Density-CBR Relations.

Develop the moisture-density-CBR relationships of the foundation materials as outlined in UFC 3-260-02 when required to evaluate a non-rigid overlay on rigid pavement.

A-5.9 Plate-Bearing Tests.

A-5.9.1 Estimating the Subgrade k Value.

Determine the modulus of subgrade reaction of the subgrade or base course using the plate-bearing test for rigid pavements as discussed in CRD-C 655. Conduct the plate-bearing test on the surface of the unbound material immediately beneath the pavement, that is, on the granular base course or on the subgrade when there is no base course. When the plate-bearing test cannot be conducted, determine an approximate k value by determining CBR values of each layer in the pavement structure using the DCP and use the procedure outlined in paragraph 7-3.4 to determine the effective k. When the pavement structure includes a high-quality stabilized base course as defined in UFC 3-260-02, conduct the plate-bearing test on the layer beneath the stabilized layer and test the stabilized layer to determine its modulus.

A-5.9.2 Plate-Bearing Tests on Rigid Overlays of Flexible Pavement.

When evaluating a rigid overlay of a flexible pavement, conduct the test in a pit with the concrete overlay removed. When the temperature of the existing asphalt pavement surface is above 75 °F (24 °C), remove the asphalt concrete pavement and run the plate bearing test on the base, then use the effective k procedure in paragraph 7-3.4 to determine the effective k at the top of the asphalt and use that value for the analysis. When the temperature of the existing asphalt pavement surface is below 75 °F (24 °C), run the tests on the asphalt concrete pavement and use that value for the analysis. Place load reaction far enough away from the plates so the stresses created by the load reaction will not influence the results of the plate-bearing tests. In general, place the load reactions on slabs adjacent to the slab being tested and not less than 12.5 feet (3.8 meters) from the bearing plate.

A-5.9.3 Plate Bearing Tests on Composite Pavements.

A composite pavement is composed of rigid overlay over a rigid base pavement with 4 inches (102 millimeters) or more of flexible or all-bituminous overlay. If the flexible overlay is less than 4 inches (102 millimeters), evaluate the rigid overlay using the unbonded overlay equation. When evaluating a composite pavement, perform the plate-bearing test on the surface of the granular base course beneath the rigid pavement layer or on the subgrade when there is no base course. Place load reaction far enough away from the plates so the stresses created by the load reaction will not influence the results of the plate-bearing tests. In general, place the load reactions on slabs adjacent to the slab being tested and not less than 12.5 feet (3.8 meters) from the bearing plate.

APPENDIX B VOID DETECTION UNDER AIRFIELD PAVEMENTS

B-1 GENERAL.

This appendix outlines a reliable, cost-effective method to detect subsurface voids under airfield pavements to minimize the risk of premature airfield pavement failure. The Services determine whether to perform airfield void detection surveys as part of regularly scheduled evaluation or as required based on the airfield location and history of issues with voids. The term void encompasses actual voids, voids filled with water, or pockets of very loose subgrade with low bearing capacity.

B-2 BACKGROUND.

Past aircraft accidents and airfield pavement failures due to subsurface voids increase the risk of future accidents and threats to life safety, especially given aging DoD facilities and scarce M&R resources. A pavement failure under the front gear of a trainer aircraft at NAS Pensacola in 1999 prompted a review of available pavement evaluation technology and procedures to detect subsurface weakness. The resulting approach outlined below uses a combination of visual, nondestructive, and destructive testing and targets pavements above drainpipe crossings, but the same method is applied for any airfield pavement where there is the potential for a void.

B-3 VOID DETECTION.

B-3.1 Visual Inspection.

Perform visual inspection of the airfield pavements with sufficient frequency to locate potential problem areas and satisfy the airfield manager of their operational safety. Base testing frequency on local physical conditions and operational tempo. Monitor pavements for conditions that may affect aircraft movement, with a focus on depressions and cracking that are indicative of subsurface deterioration. Depressions are evident in flexible pavements after a rainfall or by the concentric marks left by the evaporated water. Concrete slabs cracked into two or more pieces or slabs that exhibit faulting at joints may indicate underlying voids or loss of support. Carefully inspect areas above drainpipe crossings since most problems appear above or near drainage structures. Inspect unpaved areas adjacent to the pavement above drainage structures. Problems observed in these areas are early warning signs of problems in nearby paved areas. Depressed pavement or shattered slabs surrounding drainage structures (catch basins) indicate infiltration of soil materials into the structure or pipe. Use UFC 3-260-16 (ASTM D5340 and ASTM D6433) for visual inspections.

B-3.2 Heavy-Weight Deflectometer (HWD) Testing.

After performing a visual inspection, evaluate areas of concern using an HWD. Test all drainage structure crossings and any other areas that have visual indications of voids or loss of subgrade support.

B-3.2.1 Data Collection.

- The following outlines the data collection procedure for drainage structures under asphalt pavements. The procedure for concrete pavements is the same, with adjustments for performing HWD tests at the center of each slab.
  - o Identify the location of each pipe and mark it on the pavement.
  - o Test at 10-foot (3-meter) intervals, offset 10 feet (3 meters) to the left of the drainage structure. This is “Line A” for reporting purposes.
  - o Test at 10-foot (3-meter) intervals above the drainage structure in the same direction as Line A. This is “Line B” for reporting purposes.
  - o Test at 10-foot (3-meter) intervals, offset 10 feet (3 meters) to the right of the drainage structure in the same direction as Line A. This is “Line C” for reporting purposes.
- This procedure typically produces three sets of readings at 10-foot (3-meter) intervals along the drainage structure except for the case where the pipe falls just in between two rows of concrete slabs, then only two sets of readings are needed. The procedure uses 10-foot (3-meter) intervals based on the assumption the HWD cannot “sense” loss of pavement support beyond a 5-foot (1.5-meter) radius.
- A single drop at each location is typically sufficient to compare successive drops at adjacent locations. Configure the HWD with seven geophones numbered D1 though D7, where D1 is the deflection under the load point and D2 through D7 are typically at 12 inches (305 millimeters) (15 inches [381 millimeters] for some configurations), 24, 36, 48, 60, and 72 inches (381, 610, 914, 1219, 1524, and 1829 millimeters) from D1, respectively. This results in seven deflection measurements at each test location.
- Use the deflection data to determine the impulse stiffness modulus (ISM), which is a measure of the relative pavement strength at each test location. Calculate ISM1 by dividing the load by the deflection at D1. Determine ISM2 through ISM7 using the same procedure: ISM(X) = load/deflection at D(X).
- D1 primarily indicates the state of the pavement itself, whereas D7 primarily indicates the state of the subgrade. Therefore, using D1 alone is not sufficient to successfully detect voids under the pavement.

B-3.2.2 Data Analysis.

Analyze data during data acquisition and mark weak areas immediately for penetrometer testing. Plot ISM1 through ISM7 results for each test along the drainage structure. Normalize the data by dividing each plot by the highest value in the plot to determine relative effects of pavement weaknesses on each sensor. Once the ISM plots are completed, use the following rules to determine potentially weak areas.

- An absolute ISM1 value below about 300 kips/inch is of concern for asphalt pavements.
- An absolute ISM1 value below 1000 kips/inch is of concern for concrete pavements.
- A relative ISM decay indicates an unexpected weakness.
    - A relative weakness in ISM1 indicates it is shallow.
    - A relative weakness in ISM7 indicates it is deep (3 to 20 feet [1 to 6 meters]).
    - A relative weakness in both ISM1 and ISM7 indicates a general lack of support.

B-3.2.3 Load-Carrying Capacity.

Use the HWD data to determine the effect of any subgrade weakness (or void) on the load-carrying capacity of the pavement using the layered elastic evaluation procedure in paragraph 5-3.

B-3.2.4 Frequency.

When an airfield has a history of problem with voids, perform void detection procedures at all drainage structures as outlined in paragraphs B-3.1 and B-3.2, in conjunction with regularly scheduled structural evaluations.

B-3.2.5 Large Area Testing.

When large areas may be subject to voids, such as where karst formations are prevalent, adjust the procedure on asphalt pavement by testing at 10- to 20-foot (3- to 6-meter) intervals along a linear structure (e.g., a runway) at 10-foot (3 meters) offsets on both sides of the centerline. Perform testing at each slab center (e.g., 15-foot (4.6 meters) spacing for Navy airfields) on PCC pavements. Test composite pavements as asphalt pavements when overlaid joints are not visible. Perform testing with the concrete procedure when the overlaid concrete joints are visible. Test outer portions of the linear structures with GPR if deemed necessary. GPR testing is faster but less reliable. Perform HWD testing on any anomalies found with GPR.

B-3.3 Penetrometer Testing.

Test weak areas revealed by the HWD (or the GPR and the HWD) with DCP or SPT as outlined in Chapter 3 and Appendix A to determine the depth of the weakness and identify the type of repair needed. Ensure there are no buried utilities present prior to testing.

Use PCASE or a spreadsheet to plot CBR or k (modulus of subgrade reaction) versus depth. A low CBR value (less than 3) or a low k (less than 75) indicates a weak layer or an actual void. When coring concrete pavement, the core may drop, indicating a void between the concrete pavement and the underlying base. When drilling the pavement, this separation is more difficult to observe, so a bore scope may be used to assess the existing void.

B-3.4 Capture Drainage Structure Video.

When testing and/or visible failure is evident near or around drainage structures, capture video of the interior of these drainage structures to help pinpoint the location of potential problem areas and define the need for M&R. Give special attention to assessing pipe joints because accumulations of fines near joints or other penetrations are a good indicator of a loss of subgrade material and concurrent subgrade strength loss.

B-3.5 Alternative Nondestructive Testing (NDT).

As described in paragraph 3-4.2, GPR is an alternate nondestructive void detection technique. Acoustic reflection sounding is another technique. Based on testing, neither is as effective for detecting voids in all circumstances as the procedures outlined in paragraph B-3.2. However, they can provide useful complementary information.

B-3.5.1 Ground Penetrating Radar (GPR).

GPR provides a cost-effective and nondestructive means of examining subsurface conditions. On the airfield, GPR can be used to detect utilities, pavement reinforcement, and anomalies in base and subgrade material, such as voids. There are distinct advantages and disadvantages to using GPR in lieu of the HWD. GPR techniques will never provide an estimate of the pavement strength. However, GPR methodologies are very fast and accurate if used in areas suitable for GPR technology. It is essential to make sure GPR is suitable for the site. The United States Department of Agriculture’s Natural Resources Conservation Service Ground-Penetrating Radar Soil Suitability Maps are an essential resource in early planning to determine if GPR is the correct approach to take in a pavement void detection analysis. The GPR works by sending a tiny pulse of energy into a material and recording the strength and the time required for the return of any reflected signal. A series of pulses make up what is called a scan. Reflections are produced whenever the energy pulse enters a material with different electrical conduction properties or dielectric permittivity. The strength, or amplitude, of the reflection is determined by the contrast in dielectric constants and conductivities of the two materials. The GPR displays the changes in dielectric constant on the screen, indicating changes in material type. The display allows interpretation of data in the field. Subsurface features can be identified with the GPR by how fast the energy can travel though the material type. Air has a dielectric constant of 1 and energy travels very quickly through materials with a dielectric constant of 1. Water has a dielectric constant of 81 and energy travels slowly through water. Metal has a dialectic constant of infinity and acts as a reflector. The dielectric constant of subsurface soils typically ranges from

4 to 32, depending on the soil type and saturation. With the knowledge of pavement, base, and material types, unanticipated anomalies and changes in scan response can be identified as weak base or subgrade or air- and water-filled voids.

The following procedures are used for effective void detection using GPR.

- The GPR will first be calibrated to accurately measure stations along the storm drainage lines. This is done at each pavement type to account for the roughness in the pavement surface.
- At each differing pavement and geological condition, the dielectric constant of the cross-section of pavement, base, and subgrade must be determined for accurate depth calculations and appropriate contrast while performing the scan onsite. This can be done by either identifying the soil type or ground truthing to known underground structure depths. The dielectric constants and the GPR data are recorded at each run.
- Once the storm drainage structures have been identified and the approximate location of the storm drainage line to be tested is known, the GPR unit will make several perpendicular scans to determine the exact location of the storm pipe. The pipe will then be marked on the pavement surface for future data collection. Sometimes, as with concrete or PVC pipes, it is difficult to locate the pipe due to the dielectric constant being similar to the in situ soil. In these instances, the field team uses maps and locations of drainage structures to determine the most likely place for the pipe to be located and the tests are run along those alignment locations.
- Once the location of the pipe is properly identified, collection of data is taken parallel to the storm pipe approximately 12 inches (305 millimeters) left and right of the pipe edge. Another pass is made directly over the pipe. Data is collected in the same direction each time so the stations of each run are comparable.
- Based on the observed pavement conditions and the observations made with the GPR scans, suspicious void locations may be marked on the pavement for further testing to verify the presence of a void or soft subgrade.
- The identified areas could be voids or could be utilities. Before proceeding with soil penetration techniques, it is best to locate the utilities and ensure the suspect areas are not utilities. If the suspect areas are not utilities, then they can be investigated using one of the soil penetration techniques such as the DCP.

B-3.5.2 Acoustic Reflection Sounding

Acoustic reflection sounding (ASTM D4580, *Standard Practice for Measuring Delaminations in Concrete Bridge Decks by Sounding*) has been used to detect concrete bridge deck delamination. In some instances, a person walking alongside the HWD can hear a difference in the sound of the pavement when it is spanning a shallow void, especially with thin concrete pavements. This provides another tool in detecting potential voids just under the slab. Once coring or drilling is complete, a borescope is useful to assess the existence of voids.

B-4 VOID REPAIR AND PREVENTION.

- Prior to proceeding with repair, determine if an actual void (or very loose area) is present or if a deep layer of weak material is responsible for the readings, using FWD/HWD testing.
- Void repair methods include pressure grouting, polymer injection, and removal and replacement. If an actual void is present, lightweight polymer or grout injection is generally preferred to removal and replacement because of the minimal impact on aircraft operations.
    - Pressure grouting and polymer injection may successfully fill a void (or compact a locally loose area) but may only have very limited success for a deep layer of weak material.
    - When a void or weak layer is deep, injection may simply create polymer (or grout) lenses (i.e., thin layers) that will lift the pavement but not provide additional support.
    - When pavement surface integrity is sound and load-carrying capacity is adequate, pressure grouting or polymer injection can be used to lift pavement and re-establish ride quality.
    - Once set, grout provides a stiff material typically usable for any type of subgrade and can also be used to fill gaps just under the slab.
    - If no void is present and a weak subgrade is undermining the load carrying capacity, remove and replace the weak layer. If the weak layer is under the water table, removal and replacement can become very difficult.
- Lightweight polymer injection has some advantages over grout injection.
    - Polymer injection adds less weight when dealing with soft subgrades and large voids.
    - A properly mixed polymer typically reaches most of its strength in a few minutes.
    - Quick-setting polymer can seal large cracks in drainpipes or fill deep sinkholes, while grout could flow down the sinkhole and proceed into the pipes.
- If polymer injection is used, the modulus of elasticity of the polymer needs to exceed the stiffness of the layer where it is injected; therefore, it should typically only be injected into the subgrade. Even then, tests on some limited data indicate that this requires a minimum density of:

  - o 6 pcf (96 kg/m^3) for subgrades with elastic modulus of 6,000 psi (41 MPa)
  - o 10 pcf (160 kg/m^3) for subgrades with elastic modulus of 15,000 psi (103 MPa)
  - o 15 pcf (240 kg/m^3) for subgrades with elastic modulus of 25,000 psi (172 MPa)

- If lightweight polymer or grout injection is not available, then use pavement and base removal and replacement down to the prescribed depth. When pipe deterioration is extensive, consider internal pipe repair, jacketing, or pipe replacement.

APPENDIX C AIRCRAFT GEAR CONFIGURATION NOMENCLATURE

C-1 PURPOSE.

This appendix outlines the standard convention for naming and characterizing aircraft landing gear configurations. It is primarily intended for fixed-wing aircraft but is applicable to any aircraft using wheels for landing. This appendix is used in conjunction with FAA Order 5300.7, *Standard Naming Convention for Aircraft Landing Gear Configurations*.

C-2 BACKGROUND.

Landing gear configuration and aircraft gross weight are an integral part of airfield pavement design and evaluating pavement strength. Historically, most aircraft used relatively simple gear geometries such as a single wheel per strut or two wheels side by side on a landing strut. As aircraft became larger and heavier, they required additional wheels in groups or placed side-by-side and in tandem configurations to prevent excessively high individual wheel loads that impart high stresses on the pavement structure.

C-2.1 Typical Gear Configurations.

Originally, most civilian and military aircraft used three basic gear configurations: the “single wheel” (one wheel per strut), the “dual wheel” (two wheels side by side on a strut), and the “dual tandem” (two wheels side by side followed by two additional side-by-side wheels). As aircraft gross weight increased, manufacturers added additional landing struts to the aircraft. For example, Boeing used four landing struts with dual tandem configurations on the B-747 to reduce its impact on airfield pavement.

C-2.2 Complex Gear Configurations.

Other aircraft used gear configurations with multiple wheels in arrangements that could not be described by the three simple gear configurations. There was no coordinated effort between the FAA and the Services to provide a uniform naming convention resulting in naming systems that were not easily cross-referenced.

C-3 DEFINITIONS.

C-3.1 Main Gear.

“Main gear” means the primary landing gear that is symmetrical on either side of an aircraft. When multiple landing gears are present and are not in line with each other, the outermost gear pair is considered the main gear. Multiples of the main gear exist when a gear is in line with other gears along the longitudinal axis of the aircraft.

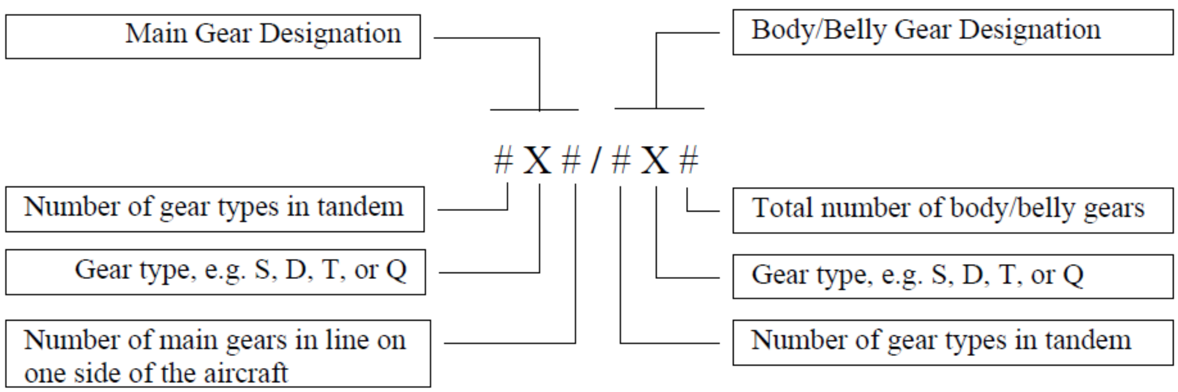
C-3.2 Body/Belly Gear.

"Body/belly gear" refers to an additional landing gear or gears in the center portion of the aircraft between the main gears. Body/belly gears may be different than the main gear and may be asymmetric.

C-4 INTENDED USE.

DoD is adopting the naming convention used by the FAA, as shown in Figure C-1.

Figure C-1 Aircraft Gear Naming Convention



C-5 AIRCRAFT GEAR GEOMETRY NAMING CONVENTION.

C-5.1 Basic Name for Aircraft Gear Geometry.

As shown in Figure C-1, abbreviated aircraft gear designations may include up to three variables. The two primary variables are the main gear configuration and the body/belly gear configuration if body/belly gears are present. An optional tire pressure code can also be used.

C-5.2 Basic Gear Type.

Gear type for an individual landing strut is determined by the number of wheels across a given axle (or axle line) and whether wheels are repeated in tandem. There are instances when multiple struts are in close proximity and are best treated as a single gear, e.g., the Antonov AN-124 (see Figure C-14). If body/belly gears are not present, the second portion of the name is omitted. For aircraft with multiple gears, such as the B-747 and the A380, the outer gear pair is treated as the main gear.

C-5.3 Basic Gear Codes.

The naming convention in Figure C-1 uses the gear designation codes in Table C-1.

Table C-1 Gear Designations

S	Single
D	Dual
T	Triple
Q	Quadruple

C-5.4 Use of Historical Tandem Designation.

Note that while the verbal description continues to use the term “tandem” to describe tandem gear configurations, the tandem designation “T” no longer appears in the gear name. “T” now indicates triple wheels.

C-5.5 Main Gear Portion of Gear Designation.

As shown in Figure C-1, the first portion of the aircraft gear name is the main gear designation that may consist of up to three characters. The first character indicates the number of tandem sets or wheels in tandem and the second character indicates the gear code (S, D, T, or Q). If a tandem configuration is not present, the leading value of “1” is omitted. Typical names are S = single, 2D = two dual wheels in tandem, 3D = three dual gears in tandem, 5D = five dual wheels in tandem, and 2T = two triple wheels in tandem.

The main gear designation indicates the number of gears on one side of the aircraft but assumes the gear is present on both sides (symmetrical) of the aircraft. The third character of the gear designation is a numeric value that indicates multiples of gears. An aircraft with one gear on each side of the aircraft has a value of 1 but, for simplicity, it is omitted from the main gear designation. Aircraft with more than one main gear on each side of the aircraft and where the gears are in line will use a value indicating the number of gears in line. For example, as shown in Figure C-20, the Ilyushin IL-76 has two gears containing quadruple wheels on each side of the aircraft and has the designation Q2.

C-5.6 Body/Belly Gear Portion of Gear Designation.

The second portion of the aircraft gear name is used when body/belly gears are present. If body/belly gears are present, the main gear designation is followed by a forward slash (/), then the body/belly gear designation. For example, the B-747 aircraft has two dual wheels in tandem main gear and two dual wheels in tandem body/belly gears. The full gear designation for this aircraft is 2D/2D2. The body/belly gear designation is similar to the main gear designation except that the trailing numeric value denotes the total number of body/belly gears present, e.g., 2D1 = one dual tandem body/belly gear; 2D2 = two dual tandem body/belly gears. Because body/belly gear arrangement may not be symmetrical, the gear code must identify the total number of gears present; a value of 1 is not omitted if only one gear exists.

C-5.7 Extension of Naming Convention.

Future aircraft might require additional body/belly gears that are nonsymmetrical and/or non-uniform. In these instances, the body/belly gear designation will contain a hyphen to indicate the non-uniform gear geometry. For demonstration purposes, consider adding one dual wheel body/belly gear to the existing 2D/2D2 gear configuration. The resulting gear name would be 2D/2D2-D.

C-5.8 Unique Gear Configurations.

The Lockheed C-5 Galaxy has a unique gear type and is difficult to name using this method. This aircraft will continue to be referred to directly as the C5. Gear configurations such as those on the Boeing C-17, Antonov AN-124, and Ilyushin IL-76 might also cause some confusion. In these cases, it is important to observe the number of landing struts and the proximity of the struts. In the case of the AN-124, it is more advantageous to address the multiple landing struts as one gear, i.e., 5D or five duals in tandem, rather than use D5 or dual wheel gears with five sets per side of the aircraft. Due to wheel proximity, the C-17 gear is more appropriately called a 2T as it appears to have triple wheels in tandem. In contrast, the IL-76 has considerable spacing between the struts and has a Q2 designation.

C-5.9 Gear Geometry Naming Convention Examples.

Table C-1 and paragraphs C-5.3 to C-5.8 provide examples of generic gear types in individual and multiple tandem configurations. Figures C-2 through C-20 provide examples of known gear configurations.

C-5.10 Tire Pressure Information.

The gear naming convention includes a third variable to report tire pressure using ICAO codes. While tire pressure effects on airfield pavements are secondary to aircraft load and wheel spacing, they can have a significant impact on the ability of the pavement to accommodate a specific aircraft.

C-5.10.1 ICAO codes associated with the ACN and the PCN system categorize aircraft tire pressures into four groups for reporting purposes. Table C-2 lists tire pressure codes by category.

Table C-2 Standard Tire Pressure Categories

Category	Range		Code Designation
	psi	MPa	
Unlimited	No limit	No limit	W
High	182–254	1.26–1.75	X
Medium	74–181	0.51–1.25	Y
Low	0–73	0.0–0.5	Z

C-5.10.2 Include the ICAO tire pressure in parentheses after the standard gear name. Table C-3 shows sample gear names with and without the additional tire pressure code.

Table C-3 Sample Gear Names with and without Tire Pressure Codes

Gear Name without Tire Pressure	Gear Name with Tire Pressure
S	S(W)
2S	2S(X)
2D/2D1	2D/2D1(Z)
Q2	Q2(Y)
2D/3D2	2D/3D2(Z)

C-5.11 Historical Naming Convention Comparison.

Table C-4 provides a comparison of the naming convention outlined in this UFC and past FAA, Air Force, and Navy methods. Note that while the old Air Force methodology addresses nose gear configuration, the new method does not due to the minimal impact of the nose gear on the pavement load.

Table C-4 Naming Convention with Historical FAA, U.S. Air Force, and U.S. Navy Nomenclatures

		Historic FAA Designations					U.S. Air Force Designations				U.S. Navy Designations			
Proposed Nomenclature	Reference Figure	FAA Name	Main Gear	Belly Gear	# Belly Gear	Total # Wheels, Excluding Nose	Air Force Designation	Air Force Types	Air Force Name	Nose Gear	Navy Name	Navy Designation	DOD Flight Information	Typical Aircraft

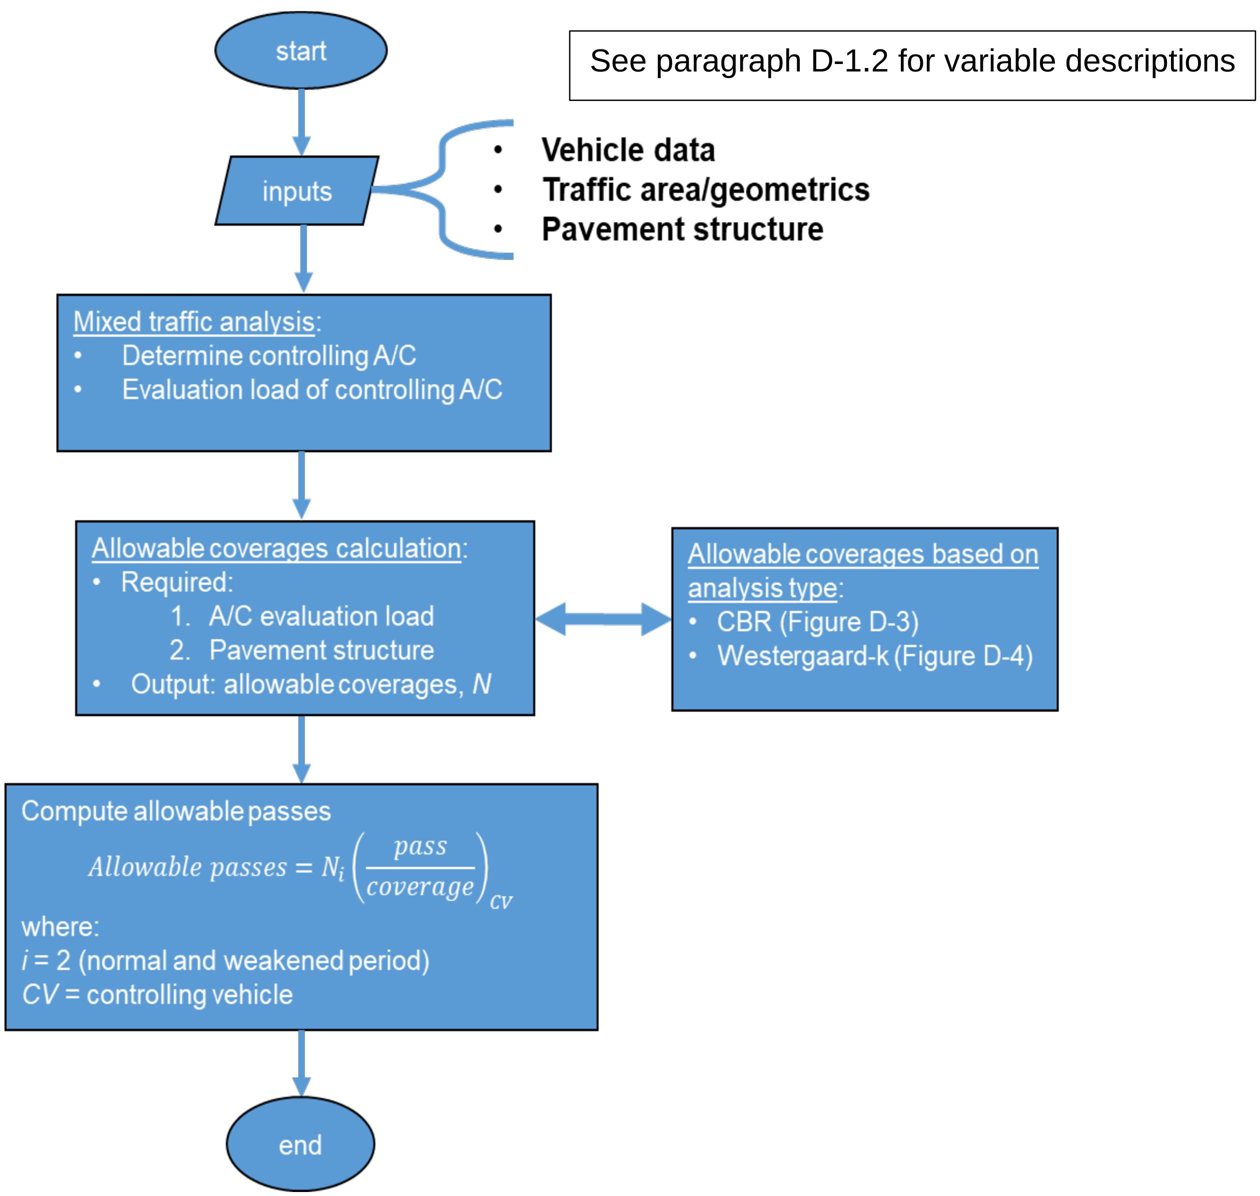
APPENDIX D STRUCTURAL ANALYSIS PROCESS

D-1 CBR-K PAVEMENT ANALYSIS PROCESS FLOW.

D-1.1 Overall CBR-k Analysis Process Flow.

The general process flows for each of the analysis models, Alpha-Beta Hybrid (CBR), and Westergaard (k) are the same. The objective of the first process flow shown in Figure D-1 is to determine the allowable passes. The second, shown in Figure D-2, is to determine the allowable load. Each of these process flows call the CBR procedure for flexible pavement analysis in Figure D-3 and the Westergaard procedure for rigid pavement analysis shown in Figure D-4.

Figure D-1 CBR-k Procedure for Allowable Passes Computation



D-1.2 Analysis Variables for Figure D-1.

- A/C = aircraft
- AGL = allowable gross load of controlling aircraft
- AGL_{trial} = the trial AGL assumed by PCASE during a given iteration
- CBR = California Bearing Ratio (evaluation methodology for flexible pavements)
- CDF = cumulative damage factor, a ratio of applied coverages to allowable coverages of the controlling aircraft
- CV = controlling vehicle (aircraft) determined from mixed traffic analysis
- k = Modulus of subgrade reaction (evaluation methodology for rigid pavements)
- N = Allowable coverages of controlling aircraft at trial AGL
- n = applied coverages of controlling aircraft based on equivalent evaluation passes
- N_i = the number of allowable coverages determined for the controlling aircraft, where the subscript i = 2 for a normal period and a weakened (typically due to thawing) period
- pass/coverage = the ratio of passes to coverage for the controlling aircraft for a specified traffic area

Figure D-2 CBR-k Procedure for Allowable Gross Load Computation

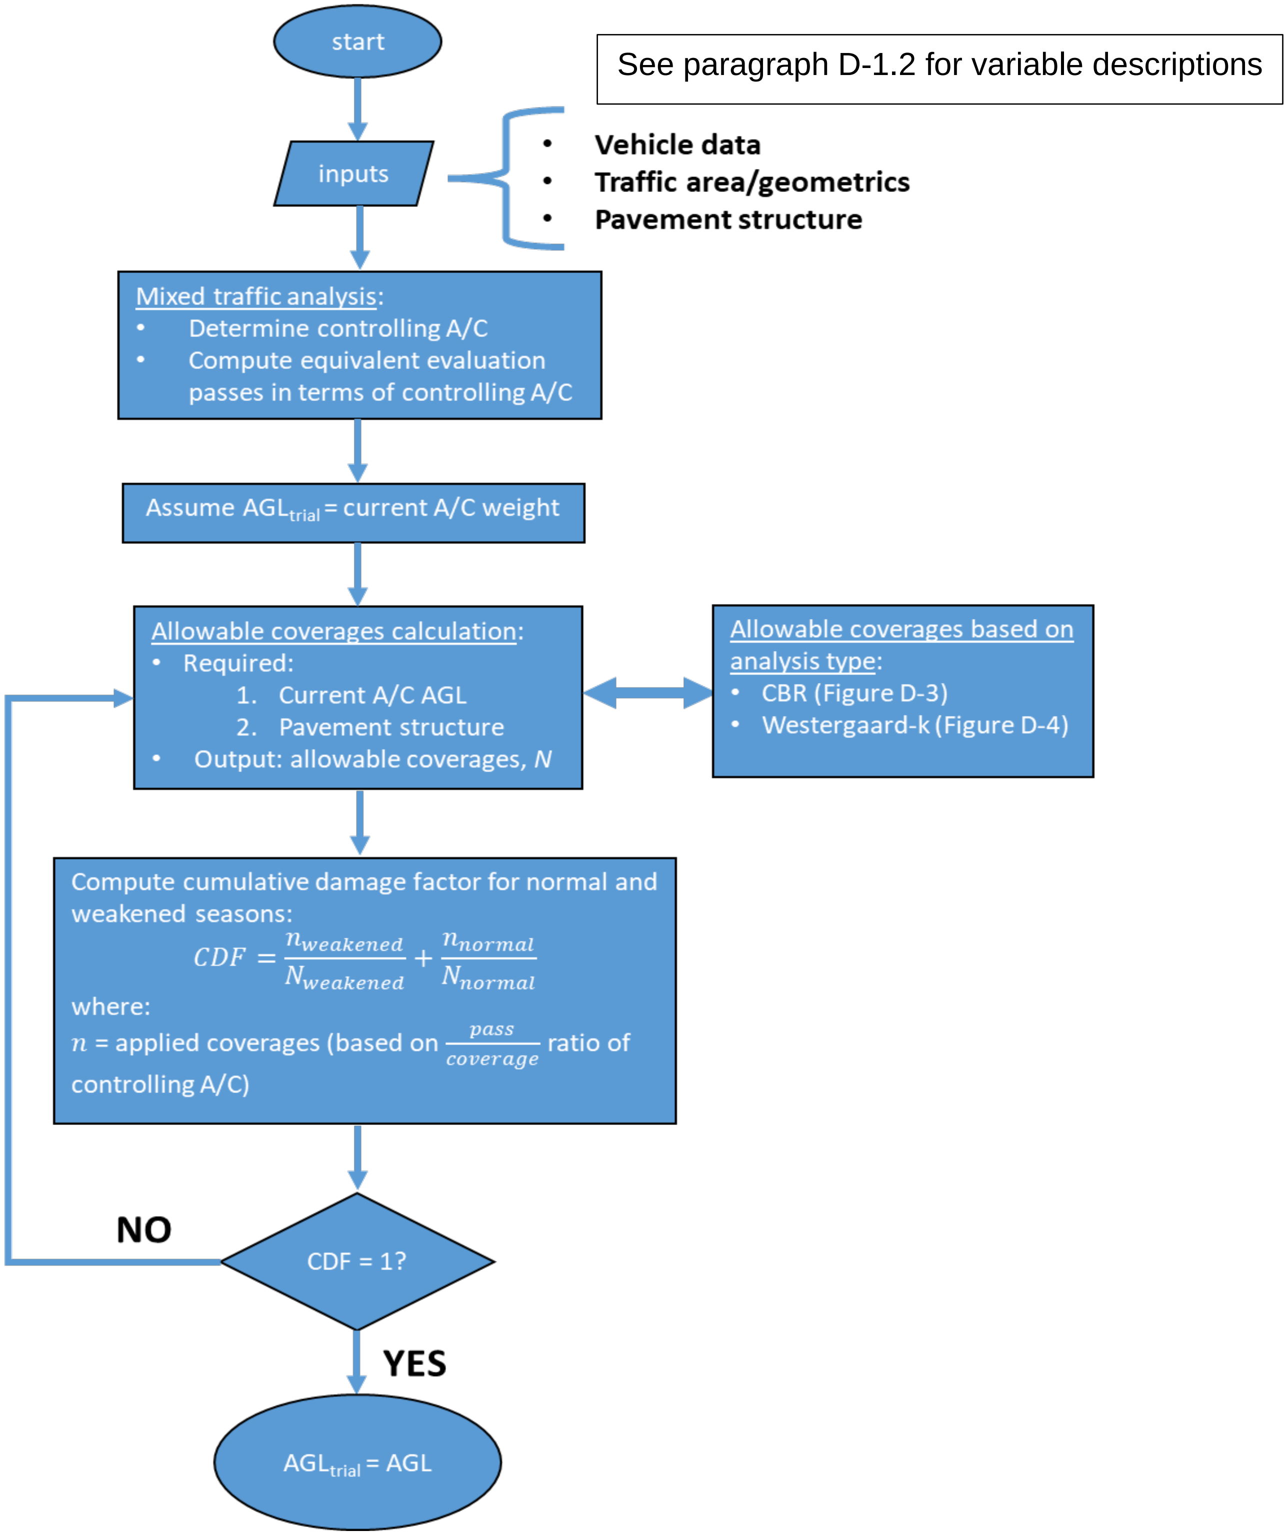


Figure D-3 CBR Procedure for Allowable Coverage Computation

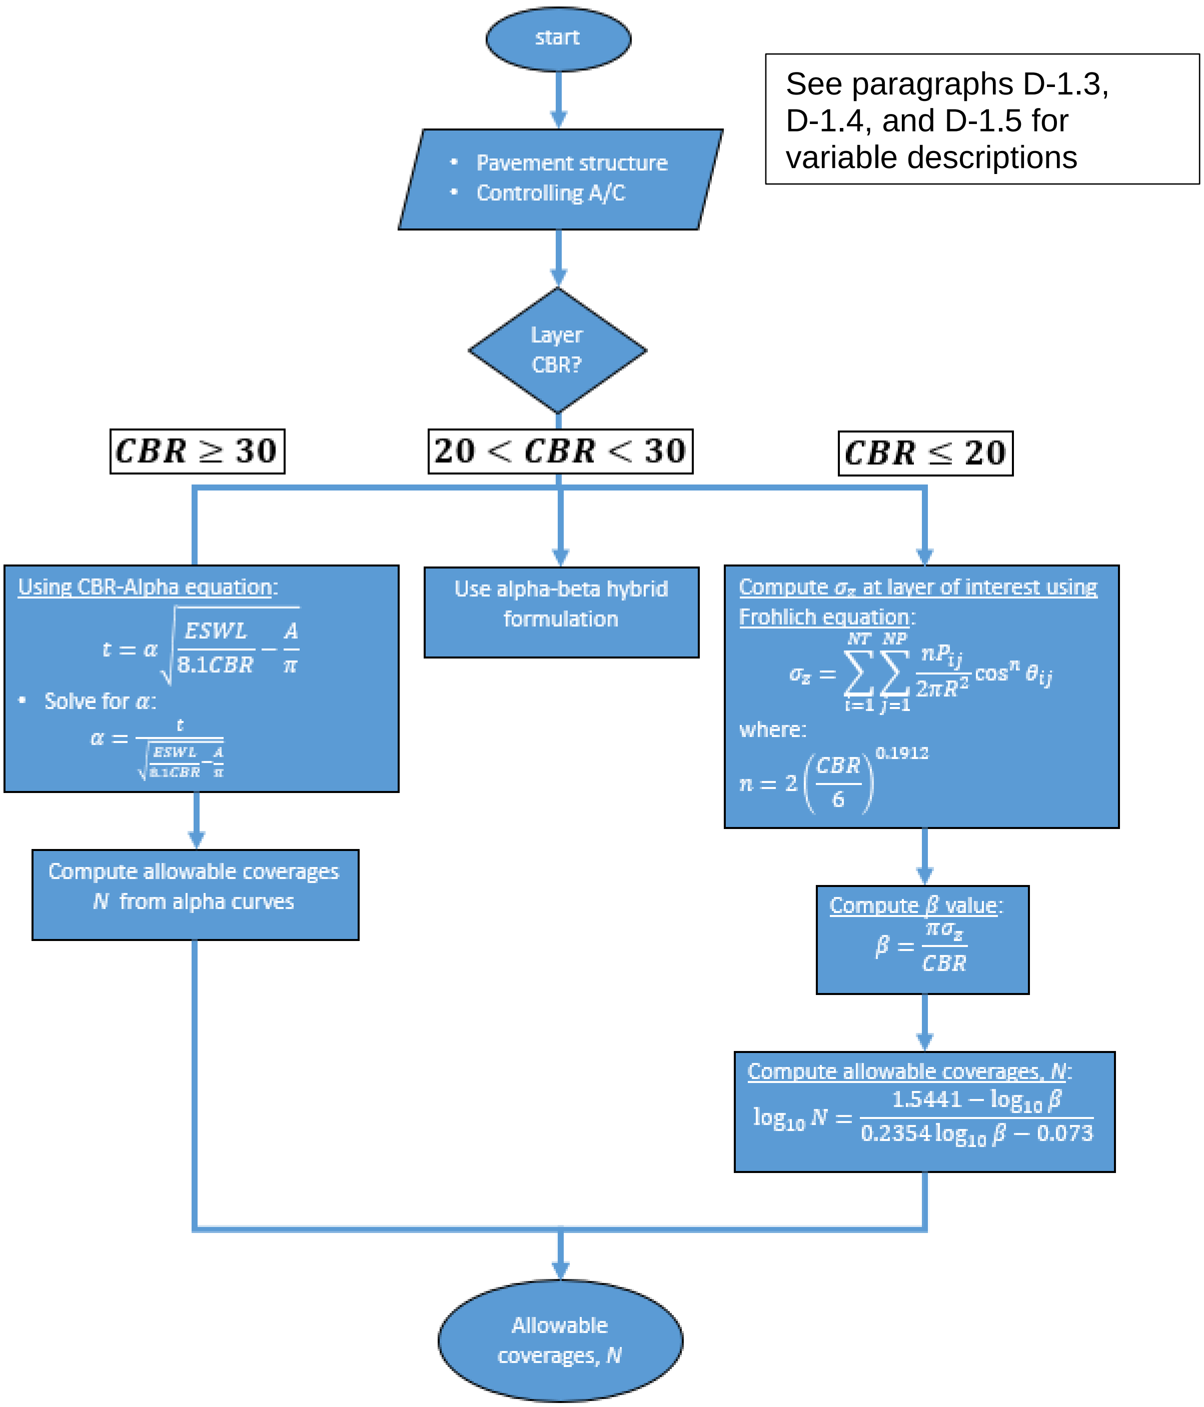


D-1.3 CBR-Alpha Equation Variables in Figure D-3.

- t = total thickness of pavement structure above layer of interest
- α = thickness reduction factor, from alpha curves (function of number of tires in controlling vehicle)
- ESWL = equivalent single wheel load of controlling vehicle
- CBR = California Bearing Ratio of layer of interest
- A = contact area of controlling vehicle

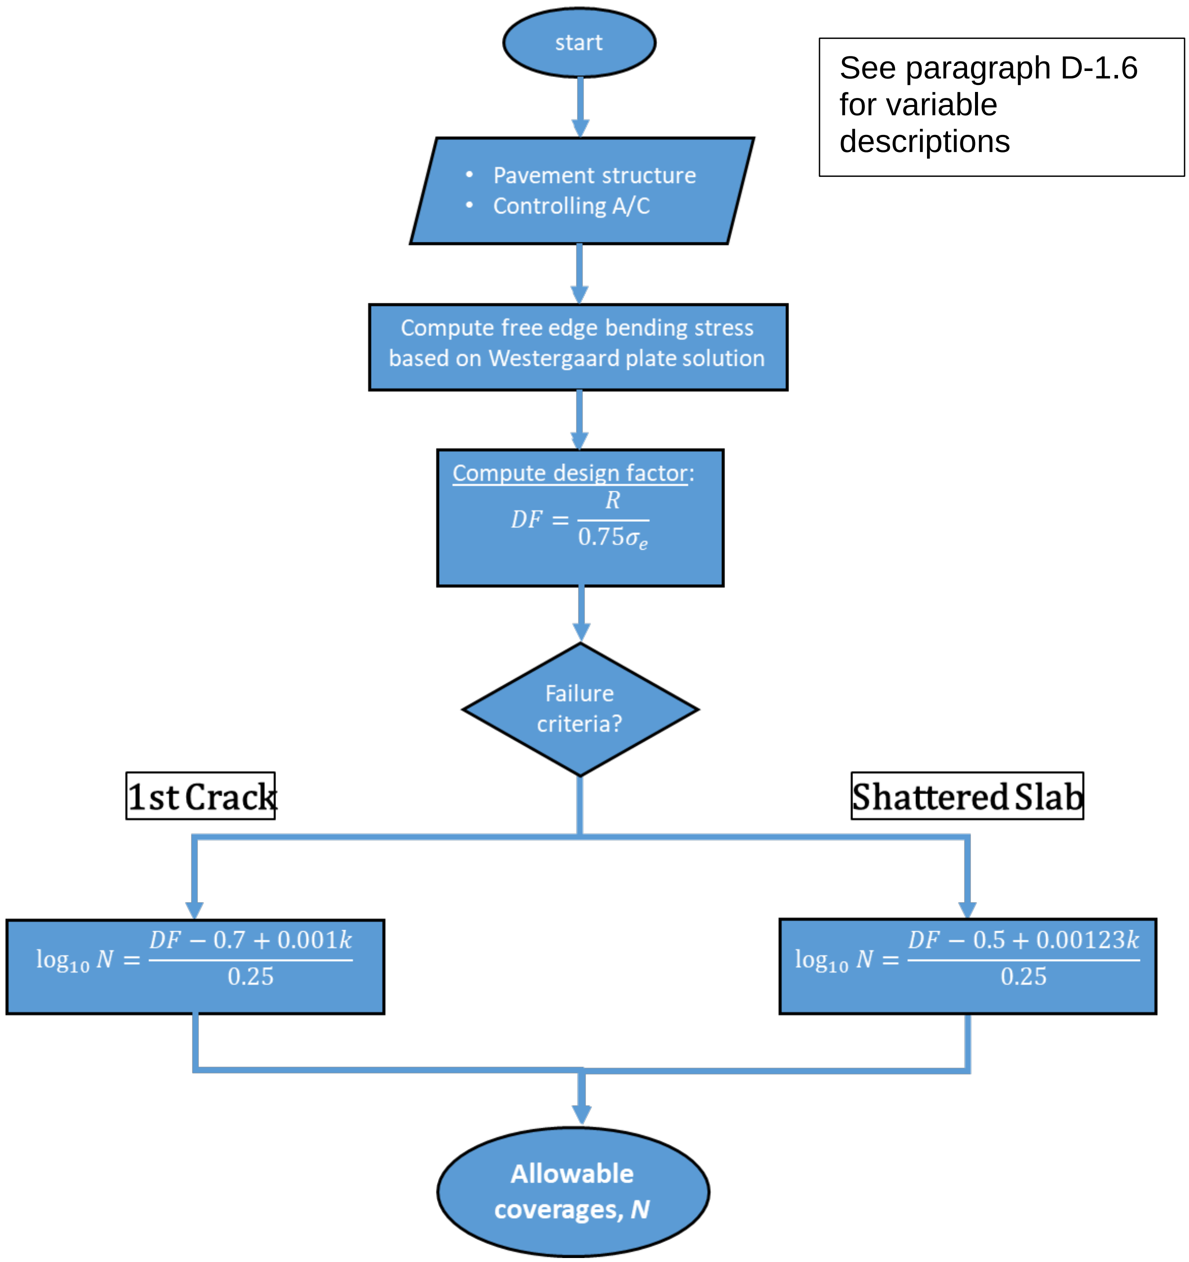
D-1.4 CBR-Beta Frohlich Equation Variables in Figure D-3.

- σ_z = vertical stress computed at the top of the layer of interest
- NT = number of tires in the controlling vehicle main landing gear
- NP = as the Frohlich equation is a *point load solution* (as opposed to a uniform pressure over a circular area solution), the inner summation is conducted over a given number of point loads NT used to estimate the tire inflation pressure in the shape of an elliptical contact area
- i,j subscripts = “i” is the current tire number in the outer summation and “j” is the current point load number in the inner summation
- n = Frohlich stress concentration factor, an empirical value which modifies the vertical stress distribution with depth
- P_{ij} = j^{th} point load in the i^{th} main landing gear tire of the controlling vehicle
- θ_{ij} = horizontal angle between the (x,y) coordinate of point load P_{ij} and the (x,y) coordinate of the calculation point at the top of the layer of interest
- R_{ij} = straight line distance from the z coordinate of the surface point load P_{ij} and the z coordinate of the calculation point at the top of the layer of interest
- β = Beta parameter, a function of the computed Frohlich σ_z and layer CBR, used to compute the allowable coverages of the controlling vehicle

D-1.5 Alpha-Beta Hybrid Formulation.

To compute the allowable gross load for a given flexible pavement structure with CBR > 20 and < 30, the Alpha-Beta Hybrid formulation must be used. This requires the CBR-Beta procedure to be used to compute the AGL at CBR = 20 and the CBR-Alpha procedure to compute the AGLs at CBR = 25 and CBR = 30 to establish a bilinear approximation of the nonlinear relationship between the two formulations. Interpolation is then used to compute the AGL at a specified CBR. This is only an interim solution to address the problems that arise when evaluating contingency structures with thin asphalt layers and marginal base materials.

Figure D-4 Westergaard-k Procedure for Allowable Coverage Computation



D-1.6 Variables for Figure D-4.

- σ_e = “free edge bending stress” = the maximum tensile stress at the bottom edge of the slab due to loading on the slab’s free edge (i.e., no joint) computed from Westergaard plate solution
- *DF* = design factor, a function of concrete flexural strength and the free edge stress reduced by 25 percent considering joint load transfer, used to compute the allowable coverages of the controlling vehicle
- *R* = concrete flexural strength
- *k* = modulus of subgrade reaction used to characterize entire supporting structure beneath slab

Figure D-5 Layered Elastic Procedure for Allowable Passes Computation

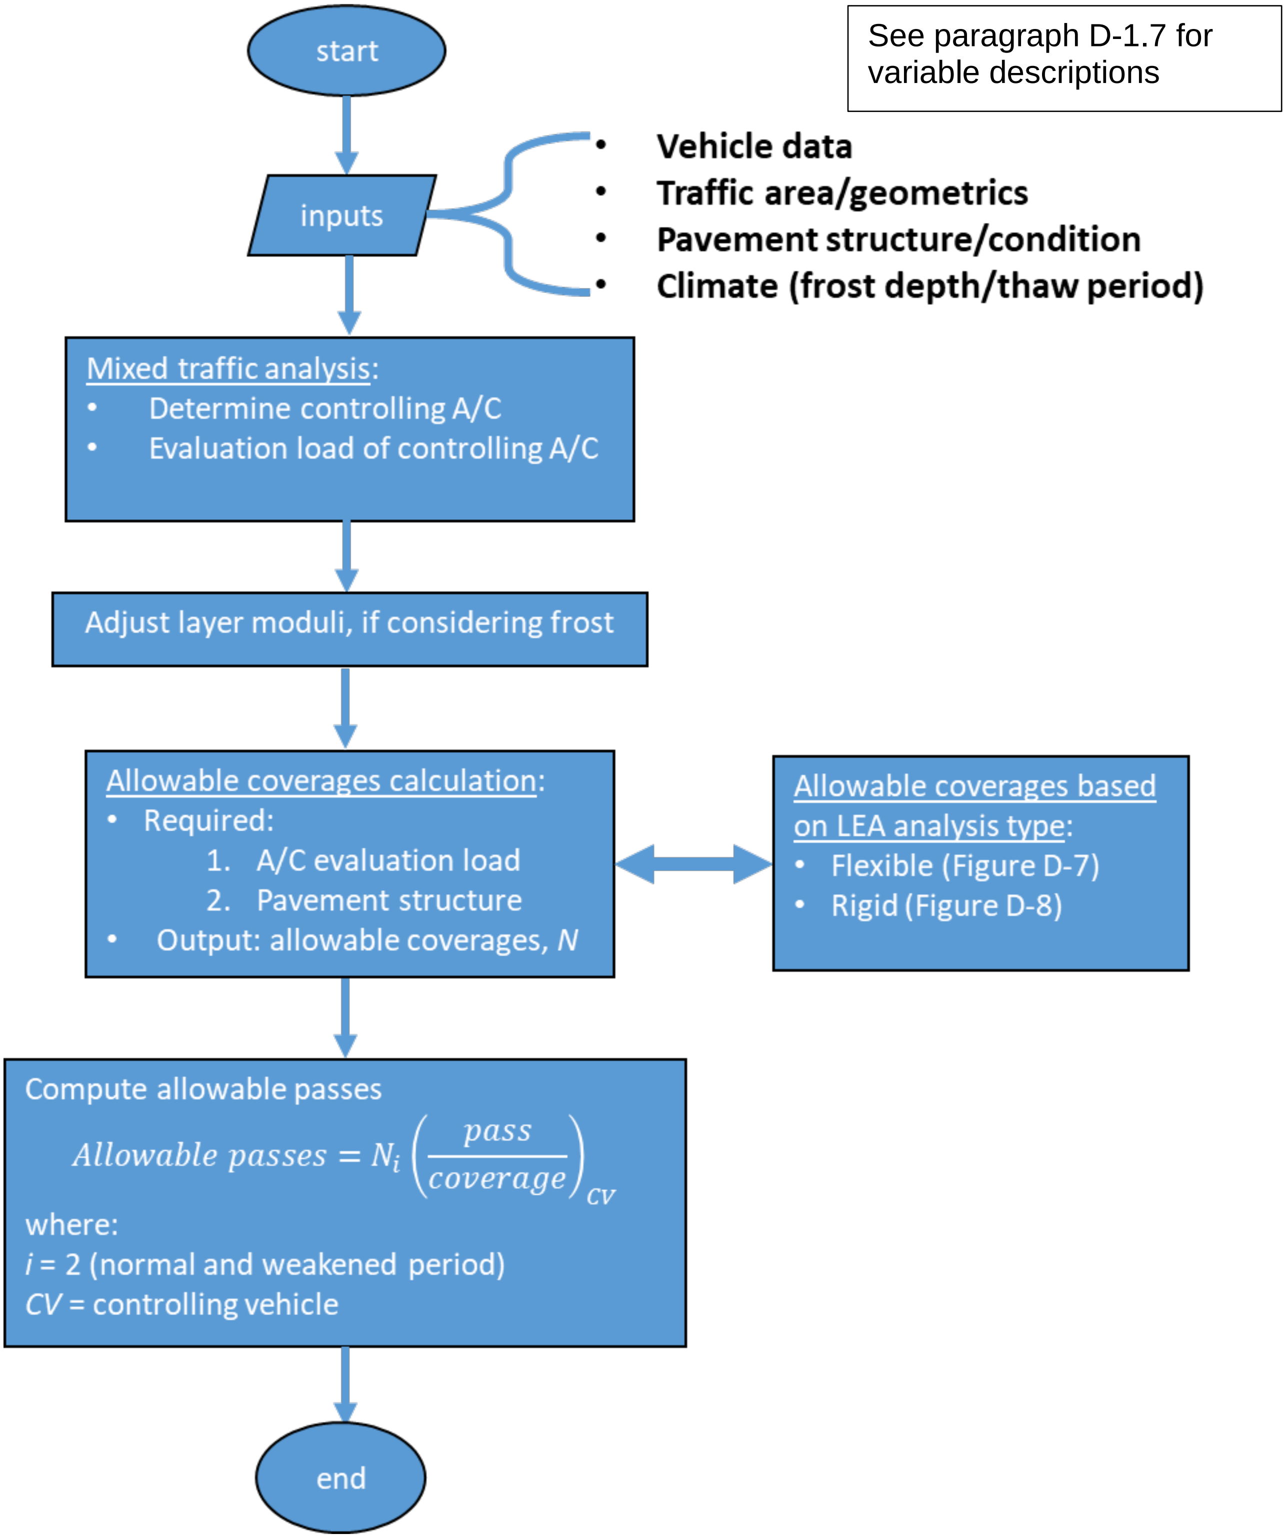


Figure D-6 Layered Elastic Procedure for Allowable Gross Load Computation

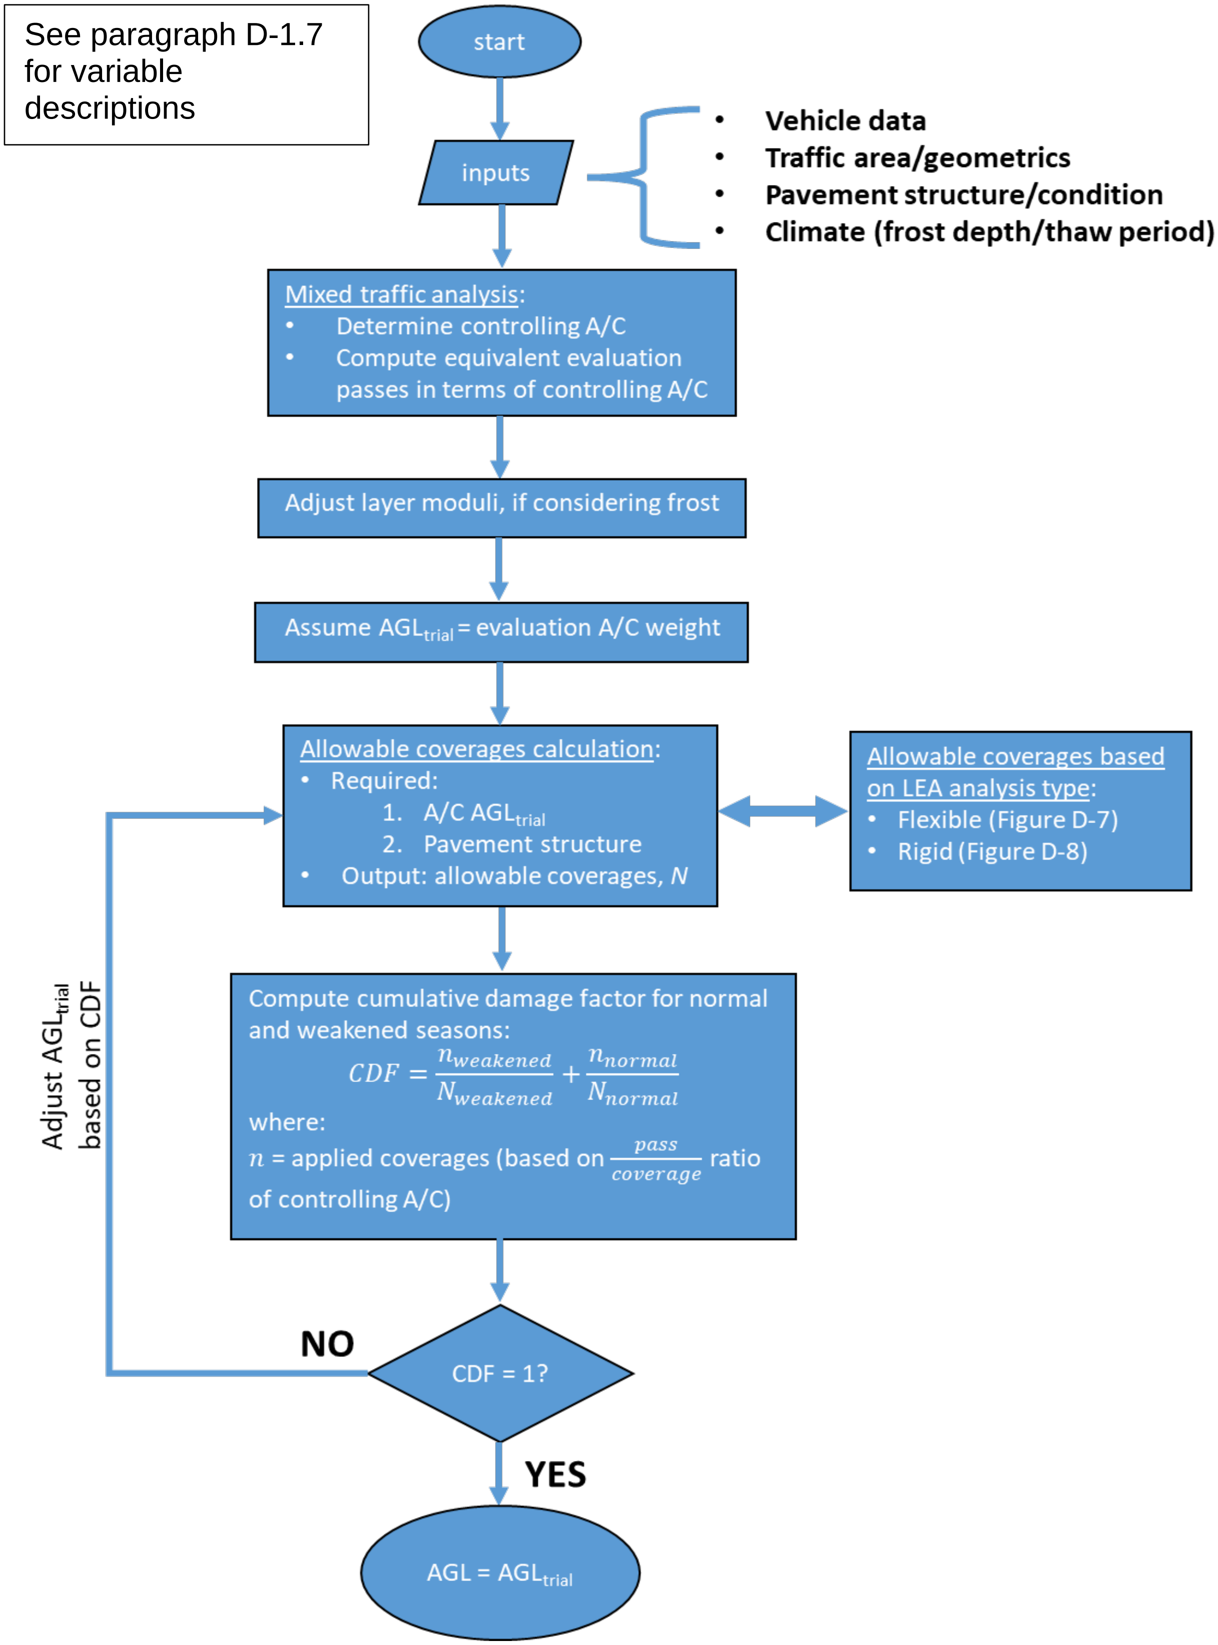
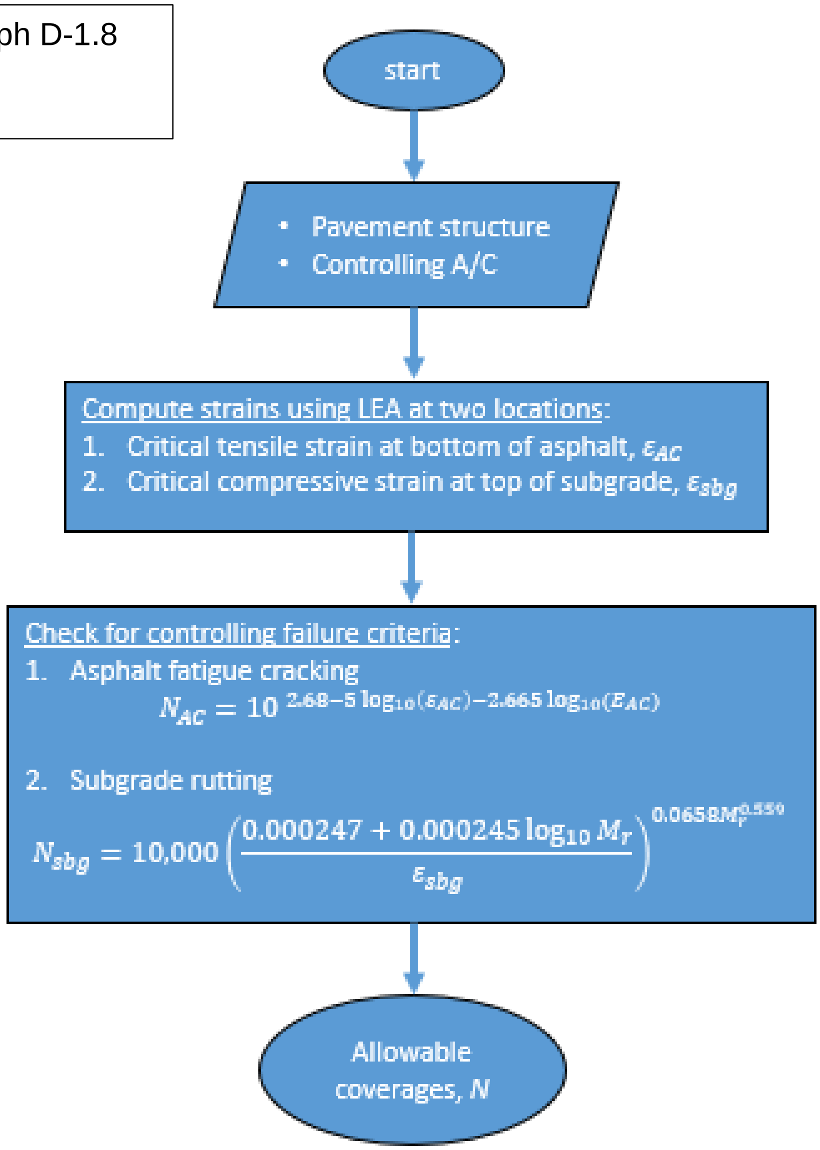


D-1.7 Variables for Figures D-5 and D-6.

- n_{thaw} = the number of applied coverages during the thaw period
- n_{normal} = the number of applied coverages during the normal period
- N_{thaw} = computed allowable coverages from performance model during thaw period
- N_{normal} = computed allowable coverages from performance model during normal period

Figure D-7 Layered Elastic Analysis Flexible Pavement Allowable Coverage Computation

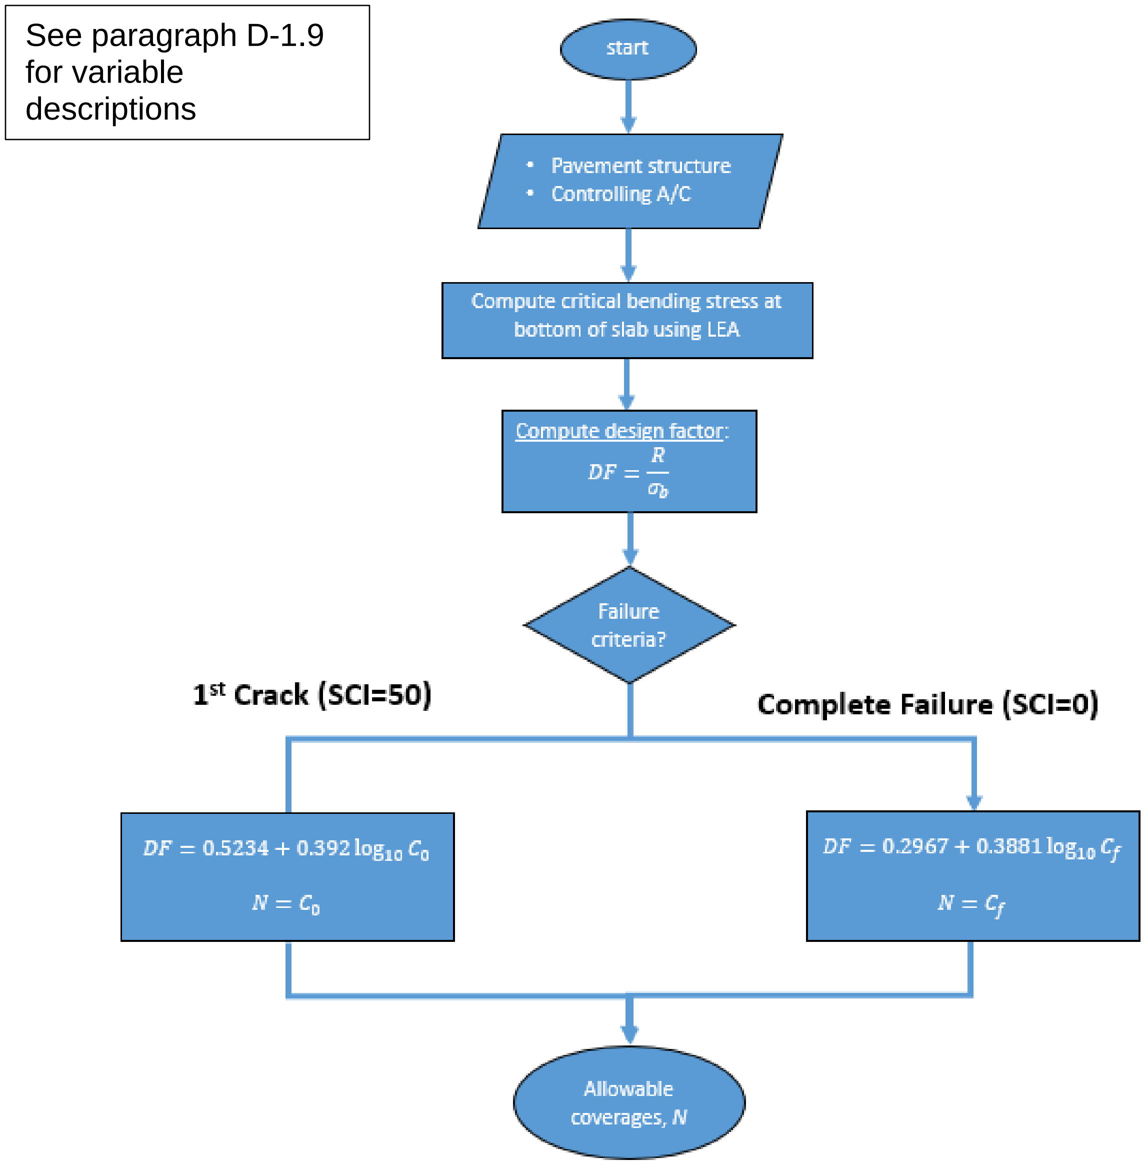
See paragraph D-1.8 for variable descriptions



D-1.8 Variables for Figure D-7.

- ε_{AC} = tensile strain at the bottom of the asphalt layer (in/in)
- ε_{sbg} = compressive strain at the top of the subgrade layer (in/in)
- N_{AC} = computed allowable coverages using asphalt fatigue cracking performance model
- N_{sbg} = computed allowable coverages using subgrade rutting performance model
- E_{AC} = asphalt layer Young's modulus of elasticity (psi)
- Mr = subgrade layer resilient modulus (psi)

Figure D-8 Layered Elastic Analysis Rigid Procedure for Allowable Coverage Computation



D-1.9 Variable for Figure D-8.

- σ_b = interior bending stress in slab
- SCI = structural condition index
- C_0 = computed allowable coverages before first crack failure criteria (SCI = 50)
- C_f = computed allowable coverages before complete failure criteria (SCI = 0)

APPENDIX E PCASE PAVEMENT EVALUATION APPLICATION

E-1 BACKGROUND.

The Services use the Pavements-Transportation Computer Assisted Structural Engineering (PCASE) application to design and evaluate airfield and road and parking pavements. The program is managed Jointly by the US Army Corps of Engineers Transportation Systems Center (TSC) and Engineer Research and Development Center (ERDC) Geotechnical and Structures Lab, with support from a Tri-Service governance working group. TSC and ERDC continuously update, expand, and improve the application and provide technical assistance, consulting services, and training. PCASE training is highly encouraged to ensure the latest criteria and technology is used to design and evaluate pavements. TSC contact information is below:

U.S. Army Corps of Engineers
Transportation Systems Center
1616 Capitol Ave.
Omaha, NE 68102-4901
Telephone: 402-995-2399

E-2 USING PCASE.

Details on PCASE installation and use for design and evaluation are available in the *PCASE User Manual.* The guide and latest version of the application are available at:

https://transportation.erdc.dren.mil/pcase/

F-2 DEFINITION OF TERMS.

Average Daily Temperature: The average of the maximum and minimum temperatures for one day, or the average of several temperature readings taken at equal time intervals, generally hourly, during a day.

Combined Base Thickness: Term used in frost analysis that means the combined thickness of base, subbase, drainage layer, and separation layer.

Critical Weakening Period: Interval during the period of thaw weakening when the base, subbase, or subgrade are at their lowest strength.

Degree-Days: The Fahrenheit degree days for any given day equal the difference between the average daily air temperatures and 32 degrees F (0 degrees C). The Centigrade degree hours for any given day equal the average daily temperatures (degrees C) multiplied by 24 hours. The degree-days or degree-hours are negative when the average daily temperature is below 32 degrees F (0 degrees C) (freezing degree-days or hours) and positive when above (thawing degree-days or hours). Usually, the degree-days or hours are reported in terms of their absolute values and the distinction is made between freezing and thawing.

Design Freezing Index: The average air freezing index of the three coldest winters in the latest 30 years of record. If 30 years of record are not available, the air freezing index for the coldest winter in the latest 10-year period may be used. The design freezing index at a site need not be changed more than once in 5 years unless the more recent temperature records indicate a significant change in thickness requirements for frost protection.

Discipline Working Group: Representatives from the DoD components responsible for the unification and maintenance of criteria documents. (MIL-STD-3007)

Freezing Index: The number of degree-days between the highest and lowest points on a curve of cumulative degree-days versus time for one freezing season. It is used as a measure of the combined duration and magnitude of below-freezing temperatures occurring during any given freezing season. The index is determined from air temperatures measured approximately 4.5 feet (1 meter) above the ground and is commonly designated as the air freezing index.

Frost Action: A general term for freezing and thawing of moisture in materials and the resultant effects on these materials and on structures of which they are a part, or with which they are in contact.

Frost Area Soil Support Indices (FASSI): The weighted average of CBR values for the annual cycle. These values are used in flexible pavement evaluation for the frost-melt period, as if they are true CBR values.

Frost Area Index of Reaction (FAIR): The weighted average of k values for the annual cycle. These values are used for rigid pavement evaluation for the frost-melt period, as if they are true k values.

Frost Susceptible Soil: Soil in which significant detrimental ice segregation will occur when the requisite moisture and freezing conditions are present. These soils will lose a substantial portion of their strength upon thawing.

Frost Heave: The raising of the pavement surface due to formation of ice lenses in the underlying soil.

Frost-melting (Thaw) Periods: Intervals of the year when the ice in the base, subbase, or subgrade returns to a liquid state. A period ends when all the ice in the ground has melted or when the previously frozen material is refrozen. In general, there may be several significant frost-melting periods during the winter months prior to the spring thaw.

Mean Daily Temperature: The mean of the average daily temperatures for a given day, usually calculated over a period of several years.

Mean Freezing Index: The freezing index determined based on mean daily temperatures. The period of record over which average daily temperatures are averaged is usually a minimum of the latest 10 years, preferably 30.

Non-frost Susceptible Materials: Cohesionless materials such as crushed rock, gravel, sand, slag, and cinders that do not experience significant detrimental ice segregation under normal freezing conditions. Cemented or stabilized materials that do not experience significant detrimental ice segregation, loss of strength upon thawing, and freeze thaw degradation are also considered to be non-frost susceptible materials.

Normal Period: Interval during the year when the base, subbase, and subgrade strengths are at their normal strength.

Recovery Period: Interval from the end of the critical weakening period to the beginning of the normal period. During this time the base, subbase, and subgrade strengths are recovering to normal strength from their lowest strength.

Surface Freezing Index: The n factor * Design Freezing Index = the Surface Freezing Index.

Thaw-Weakened Periods: Intervals of the year when the base, subbase, or subgrade strength are below normal summer values. These intervals correspond to thaw periods. The period ends when either the material is refrozen or when the subgrade strength has returned to the normal summer value at the end of the spring thaw-weakening period.

Change No.	**Date**	**Location**

This UFC supersedes Air Force ETL 04-2, *Standard Airfield Pavement Marking Schemes*, 19 July 2004; Army TM 5-823-4 C1, *Marking of Army Airfield-Heliport Operational and Maintenance Facilities*, July 1987; UFC 3-260-05A, *Marking of Army Airfield Heliport Operational and Maintenance Facilities,* 16 January 2004*;* Army Engineering and Construction Bulletin*, Marking of Army Airfields and Heliports,* 1 October 2012; and Army ETL 1110-3-512, *Army Airfield and Heliport Markings*, 30 September 2015.

FOREWORD

The Unified Facilities Criteria (UFC) system is prescribed by MIL-STD 3007 and provides planning, design, construction, sustainment, restoration, and modernization criteria, and applies to the Military Departments, the Defense Agencies, and the DoD Field Activities in accordance with USD (AT&L) Memorandum dated 29 May 2002. UFC will be used for all DoD projects and work for other customers where appropriate. All construction outside of the United States is also governed by Status of Forces Agreements (SOFA), Host Nation Funded Construction Agreements (HNFA), and, in some instances, Bilateral Infrastructure Agreements (BIA.) Therefore, the acquisition team must ensure compliance with the most stringent of the UFC, the SOFA, the HNFA, and the BIA, as applicable.

UFC are living documents and will be periodically reviewed, updated, and made available to users as part of the Services' responsibility for providing technical criteria for military construction. Headquarters, U.S. Army Corps of Engineers (HQUSACE), Naval Facilities Engineering Command (NAVFAC), and Air Force Civil Engineer Center (AFCEC) are responsible for administration of the UFC system. Defense agencies should contact the preparing Service for document interpretation and improvements. Technical content of UFC is the responsibility of the cognizant DoD working group. Recommended changes with supporting rationale should be sent to the respective Service proponent office by the following electronic form: Criteria Change Request. The form is also accessible from the Internet site listed below.

UFC are effective upon issuance and are distributed only in electronic media from the following source:

- Whole Building Design Guide web site http://dod.wbdg.org/.

Refer to UFC 1-200-01, *DoD Building Code (General Building Requirements)*, for implementation of new issuances on projects.

UNIFIED FACILITIES CRITERIA (UFC)
NEW DOCUMENT SUMMARY SHEET

Document: UFC 3-260-04, *Airfield and Heliport Marking*

Superseding: Air Force Engineering Technical Letter (ETL) 04-2, *Standard Airfield Pavement Marking Schemes*, 19 July 2004; Army TM 5-823-4 C1, *Marking of Army Airfield-Heliport Operational and Maintenance Facilities*, July 1987; UFC 3-260-05A, *Marking of Army Airfield Heliport Operational and Maintenance Facilities*, 16 January 2004; and Army Engineering and Construction Bulletin, *Marking of Army Airfields and Heliports*, 1 October 2012, and Army ETL 1110-3-512, *Army Airfield and Heliport Markings*, 30 September 2015

Description: The purpose of this document is to provide standard dimensions, colors, retro-reflectivity requirements, layout, placement, and orientation standards for marking airfield pavements. It gives the minimum level of marking necessary for paved surfaces of fixed and rotary wing runways, taxiways, helipads, and landing lanes. It also provides authority to mark hazards to air navigation as obstructions in accordance with national standards or military agreements within host countries. See TM 3-34.48-2, *Theater of Operations: Roads, Airfields, and Heliports – Airfield and Heliport Design*, Volume II, for landing zone marking requirements. This document applies to all Department of Defense (DoD) activities except those operating at airports owned and controlled by an authority other than the DoD. For airports under Federal Aviation Administration (FAA) jurisdiction, use FAA Advisory Circular (AC) 150/5340-1, *Standards for Airport Markings*. For DoD facilities overseas, if a written agreement exists between the host nation and DoD that requires application of North Atlantic Treaty Organization (NATO), International Civil Aviation Organization (ICAO), or FAA standards, those standards apply as stipulated within the agreement. For cases where a Status of Forces Agreement (SOFA) specifically requires international standards, use ICAO Annex 14, Volume I, *Aerodromes* (for fixed wing runways), or Annex 14, Volume II, *Heliports* (for rotary wing helipads and runways), as appropriate. Air Force tenant organizations on civil airports use these standards on the military portion of the airfield to the maximum extent practicable.

Reasons for Document: This document combines and consolidates standards for the Services to ensure uniformity in visual guidance aids on DoD airfields.

Impact: Impacts of implementing these updated standards have been minimized by allowing existing markings to remain pending a need to remark pavement due to age or normal wear.

Unification Issues: Naval Air Systems Command (NAVAIR) is the Office of Primary Responsibility for airfield marking on U.S. Navy facilities. The NAVAIR standard is NAVAIR 51-50AAA-2, *General Requirements for Shore Based Airfield Marking and Lighting*. Additionally, the NAVAIR publication includes airfield lighting standards which are not unified with UFC 3-535-01, *Visual Air Navigation Facilities*. The Pavements Discipline Working Group (DWG) continues to work with NAVAIR to unify airfield marking standards across DoD. Waiver processing differs among the Services due to differences in organizational structure.

TABLE OF CONTENTS

TABLES

This Page Intentionally Left Blank

CHAPTER 1 BACKGROUND AND GENERAL INFORMATION

1-1 BACKGROUND.

These criteria are a compilation of U.S. and international standards, adopted from the International Civil Aviation Organization (ICAO) standards, North Atlantic Treaty Organization (NATO) agreements, and Federal Aviation Administration (FAA) standards, as well as individual Service- or aircraft-specific technical orders. Prior to publication of this UFC, each Service component promulgated independent airfield marking standards based upon mission needs and operational doctrine, none of which fully complied with NATO, ICAO, or FAA criteria. Because DoD Service components operate worldwide, it is desirable and necessary that visual aids be commonly recognized and universally accepted by all DoD personnel and our allies.

1-2 GENERAL INFORMATION.

Pavement markings are provided to enable and enhance safe and informed aircraft and vehicle operation on the airfield and roadways. They are required to be prominent and of uniform configuration so they are clearly understood. Do not place locally devised non-standard markings without authorization from the appropriate authority. Such markings confuse aviators and ground personnel and cause runway incursions and accidents.

1-3 PURPOSE AND SCOPE.

This UFC provides standards for marking DoD airfields and heliports. This UFC also requires use of the Federal Highway Administration's (FHWA) *Manual of Uniform Traffic Control Devices* (MUTCD) for marking roadways, vehicular traffic routes on airfields, and airfield service roads maintained and operated by the designated authority. It gives the minimum level of markings necessary for paved surfaces of fixed and rotary wing runways, taxiways, helipads, and landing lanes as well as unique apron or hard stand markings necessary for maintenance or calibration of aircraft. It refers to FAA or ICAO standards for marking the surfaces of obstructions when deemed necessary by the designated authority. For additional airfield facility types, such as the F-35 vertical landing (VL) pad, landing helicopter deck (LHD) simulated deck facilities, and other fixed-wing short takeoff and vertical landing (STOVL) facilities, see UFC 3-260-01.

1-4 APPLICABILITY.

These criteria apply to all DoD activities except those operating at airports owned and controlled by an authority other than DoD. U.S. Navy and Marine Corps pavement marking details for shore-based installations are provided in NAVAIR 51-50AAA-2, *General Requirements for Shore Based Airfield Marking and Lighting*. Download a copy at http://www.wbdg.org/ffc/dod/supplemental-technical-criteria (designated TSEWG NAVAIR 51-50111-2, *General Requirements for Shorebased Airfield Marking and Lighting*) or contact the management authority for NAVAIR 51-50-AAA-2 at: Commanding Officer Naval Air Warfare Center Aircraft Division, Lakehurst Logistics, Code 6.8.5.1, Lakehurst, NJ, 08733, phone (732) 323-5073.

Base the marking criteria used upon ownership of the facility or official agreements with the host nation or host aviation authority. For example, DoD-owned and -controlled facilities are marked in accordance with DoD criteria and municipally owned airfields and airports are marked in accordance with FAA or ICAO criteria, as applicable.

It is recommended that noncompliant markings be updated to comply with this UFC at the next painting cycle. However, existing markings are not required to be changed to comply with the updated criteria in this UFC until it is appropriate and economically feasible to remove and replace all noncompliant markings on a significant feature of the airfield. An entire runway, the taxiway system, or an individual apron are examples of significant features of an airfield for the purpose of complying with this UFC.

1-5 JOINT USE FACILITIES.

1-5.1 Within the Continental United States (CONUS).

A joint use facility is one where a written agreement between the U.S. military and a government agency authorizes use of the military runways for public transportation. For airports operated under FAA jurisdiction, use FAA AC 150/5340-1.

1-5.2 Outside the Continental United States (OCONUS).

For DoD facilities overseas, if a written agreement exists between the host nation and DoD that requires application of NATO or ICAO standards, those standards apply as stipulated within the agreement. For cases where a Status of Forces Agreement (SOFA) specifically requires international standards, use ICAO Annex 14, Volume I, *Aerodromes* (for fixed wing runways), or Annex 14, Volume II, *Heliports* (for rotary wing helipads and runways), as appropriate. DoD tenant organizations on civil airports use these standards on the military portion of the airfield to the maximum extent practicable.

1-6 GENERAL BUILDING REQUIREMENTS.

UFC 1-200-01 provides applicability of model building codes and government-unique criteria for typical design disciplines and building systems, as well as for accessibility, antiterrorism, security, sustainability, and safety. Use this UFC in addition to UFC 1-200-01 and the UFCs and government criteria referenced therein.

1-7 REFERENCES.

Appendix A contains a list of references. The publication date of the code or standard is not included in this UFC. In general, the latest available issuance of the reference is used.

1-8 SUMMARY OF BEST PRACTICES IN APPENDIX B.

1-8.1 Airfield Marking Handbook.

Appendix B-1 contains best practices for installation and maintenance of airfield and heliport markings documented by the Innovative Pavement Research Foundation (IPRF) in Project 05-1.

1-8.2 Maintenance of Marking Patterns from Previous Standards.

Appendix B-2 contains the layout and dimension details for airfield markings previously used on Air Force and Army installations prior to publication of this UFC. Details for Navy and Marine Corps pavement marking details for shore-based installations are provided in NAVAIR 51-50AAA-2. The details and reference information provided facilitates maintenance of existing markings.

1-8.3 Use of Metrics for Markings.

Appendix B-3 is a matrix of dimensional equivalencies for various line segments, markings, and distances to or from specific geographic or feature reference points identified or referenced in this UFC.

1-9 GLOSSARY.

Appendix C contains acronyms, abbreviations, and terms.

This Page Intentionally Left Blank

CHAPTER 2 WAIVERS

2-1 REQUIREMENTS AND PROCEDURES.

Do not design, specify, provide, construct, or apply any airfield marking that does not comply with this UFC without first requesting and obtaining a waiver in accordance with Military Standard (MIL-STD) 3007 and agency, DoD, and Service department airfield waiver procedures. However, design markings to the extent needed to determine if a waiver is required and to prepare the waiver. Prepare and obtain separate waivers from the senior airfield authority and airfield manager if they are not included in the current agency waiver procedure. Refer to the current agency airfield markings waiver procedures in Tri-Service Pavements Working Group (TSPWG) Manual 3-260-04.18-02, *Airfield Marking Waiver Procedures*.

This Page Intentionally Left Blank

CHAPTER 3 TOLERANCES, MATERIALS, APPLICATION RATES, AND COLORS

3-1 PATTERN SIZE ALLOWANCES.

3-1.1 Tolerances for New Markings and Remarking.

Apply all markings in the standard dimensions provided in the drawings. New markings are allowed to deviate a maximum of 10 percent larger than the standard dimension. The maximum deviation allowed when painting over an old marking is up to 20 percent larger than the standard dimension. Do not use less than standard dimensions.

3-1.2 Paint.

Mark flexible and rigid pavements with lead-free pavement-marking paints, available under Federal Specification TT-P-1952. Select Type I for use under normal conditions, Type II for use under adverse conditions, or Type III for increased durability. See the latest revision of Federal Specification TT-P-1952 for additional information on applications. Apply glass beads to the paint immediately after application of paint to incorporate retro-reflective properties into the markings.

3-1.2.1 Permanent Painted Markings.

Apply markings at 12 to 14 mils (0.310 to 0.360 millimeters) wet-film thickness for coverage of 121 (± 6) square feet per gallon (2.970 square meters [± 165 square millimeters] per liter). Apply beads to permanent painted markings at the rate recommended for the type beads used. (The wet film thickness of the paint is increased when the larger diameter Type IV beads are used. See paragraph 3-3.3 for details.) It is undesirable for painted markings to build up beyond a total thickness of approximately 40 mils (1.02 millimeters). This occurs after about five marking cycles unless surface abrasion (e.g., caused by snow-removal equipment) reduces this buildup. Repeated over-painting increases stresses at the initial bond with the pavement and eventually causes the marking to crack and peel.

3-1.2.2 Temporary Painted Markings.

Apply markings at 4 to 6 mils (0.100 to 0.150 millimeter) wet-film thickness in cases where new pavements need to be opened early or for temporarily displaced thresholds. Apply beads to temporary painted markings at half the normal rate; this provides markings of sufficient prominence to allow operations. Touch up the marking in case of bleeding and remark the pavement at the normal application rate after the pavement is at least 30 days old. For temporary markings, first apply a pavement-curing compound; this makes the markings easier to remove. A lime and water solution or sea-marker dyes are also used for temporary markings; however, these materials are best suited to dirt surfaces or snow-covered pavements. Temporary marking tape is also used for temporary taxi routes or for temporarily displaced threshold markings if the pre-threshold area is only planned for operation at normal taxiing speeds. High-speed operations, turning traffic, rotor-wash, or jet blast might dislodge these materials, creating a potential for foreign object damage (FOD) to jet engines. Do not use these materials on runways for this reason.

3-1.3 Alternate Marking Materials.

Thermoplastics or preformed materials such as tape are allowed for use on taxiways and aprons, but these type materials are not used on runways or helipads because of the potential FOD to aircraft if they delaminate from the pavement. Apply these materials in accordance with the manufacturer's recommendations. Pre-mix glass beads with thermoplastic materials and post-apply beads to the surface of the marking at the same application rate as noted above to provide initial retro-reflectivity. The beads are uniformly suspended throughout the material to ensure continuing retro-reflectivity as the marking wears from the effects of traffic. Add beads at a rate equivalent to that noted above for each 10 mils (0.250 millimeter) of overall application thickness.

3-1.4 Alternate Visual Aids.

When appropriate, lighted barricades, traffic cones, or portable edge markers are used instead of pavement markings during short periods of construction if addressed in the construction waiver and the construction phasing plan (see Appendix B of UFC 3-260-01). Use edge markers for daytime use or expedient airfield markings such as are used on a minimum operating strip (MOS) or a landing zone (LZ). Lighted visual aids are used for night operations or instrument flight rule (IFR) operations. Fasten or weight down all such devices to prevent them from becoming dislodged by jet blast or prop wash. Use frangible markers designed and constructed of materials that collapse if struck by an aircraft. They are colored to present a sharp contrast with the surrounding terrain.

3-1.5 Contrasting Markings to Increase Conspicuity.

If needed, use a non-reflectorized black border to outline markings on light-colored pavements (portland cement concrete [PCC] or oxidized asphaltic concrete [AC]). This makes the markings more prominent. The border is uniformly 6 inches (152 millimeters) wide (no variation in width beyond standard tolerances) and borders all edges of the marking

3-1.6 Obliteration of Extraneous Markings.

Use black paint, or a color blend of black and white to match pavement color, to temporarily hide extraneous markings rather than risk damaging the pavement during paint removal. **Note:** This method is only used temporarily because the underlying paint shows through when illuminated at night after the black paint begins to wear off the top of the previously applied glass beads. For effective guidance, remove the old paint completely by hydro-blast, grinding, or some other method, or pave over the old marking to eliminate potential confusion from obsolesced or extraneous surface markings. Take care when obliterating old markings so the resulting pattern no longer presents the appearance of a usable marking. This requires additional scarifying or overpainting for effective obfuscation of the pattern.

3-2 COLORS FOR PAVEMENT AND OBSTRUCTION MARKINGS.

3-2.1 Airfields and Roadways.

For airfield pavement applications, use the following color chip numbers from SAE-AMS-STD-595 when ordering or specifying paint. See the specific layout schemes in Chapters 5 through 8 for the specific color and retro-reflective requirements for the applicable marking.

3-2.1.1 White – 37925.

Generally, retro-reflective white is used for all runway, helipad, towway, and rotary wing runway or landing lane markings. However, there are some exceptions, such as for aircraft arresting system (AAS) warning markings, runway shoulder markings, hold short runway hold position markings, taxiway lead-in and lead-out lines, and hospital helipad markings.

3-2.1.2 Yellow – 33538.

Generally, retro-reflective yellow is used for all taxiway and apron markings, as well as displaced threshold areas used only as a taxiway and for the arrowheads and chevrons when the displacement is temporary. Exceptions: Restricted area markings and legends on some surface painted taxiway and apron signs are marked in other colors. Non-reflective yellow is used in overruns and for shoulder markings.

3-2.1.3 Red – 31136.

Red is normally used to mark restricted area boundaries and some of the legend on the restricted area signs required by AFI 31-101.

3-2.1.4 Black – 37038.

Black is used as a border to increase the conspicuity of markings on light-colored pavements. It is also mixed with white (to better match pavement surface color) and used to obliterate extraneous markings. **Note:** Covering obsolete or extraneous markings with paint is a temporary solution. The only means for permanent obliteration is to grind, scarify, burn, or hydro-blast the pavement surface or place a new surface material over the old markings.

3-2.1.5 Green – 34108.

Green is used to identify obstacle clearance boundaries at U.S. Army facilities.

3-2.2 Colors for Marking Obstructions.

For obstruction marking applications, use the following color chip numbers from SAE-AMS-STD-595 when ordering or specifying paint to mark obstructions.

- White – 17875
- Orange – 12197

3-3 RETRO-REFLECTIVE PAVEMENT MARKINGS.

3-3.1 Painted Pavement Markings.

Painted pavement markings are very difficult to see at night or during rain if they have no retro-reflective properties. Markings without beads also have a lower coefficient of friction. For these reasons, use of glass beads is encouraged for all surface painted markings. Do not place beads on black borders. Other less-expensive materials are available to improve the coefficient of friction on black painted pavement surfaces.

Note: Because thermoplastic materials are applied at a greater film thickness, these materials also have spherical beads premixed into the colored binder prior to application.

3-3.2 Post Applied Retro-Reflective Media.

Post-apply retro-reflective media (glass beads) specified under Federal Specification TT-B-1325D (or later revision) to make surface painted markings retro-reflective. Retro-reflective runway, taxiway, and apron markings are identified in the layout scheme descriptions in Chapters 5 through 8.

3-3.3 Material Selection.

Select the most appropriate material manufactured in accordance with the most current version of Federal Specification TT-B-1325D, as follows:

- Type I, Gradation A, Drop-On, Low Index of Refraction, for use on any airfield or roadway marking pattern applied with paint procured to comply with Federal Specification TT-P-1952E. Apply a minimum of 7 pounds per gallon (0.85 kilogram per liter) of paint. In accordance with the National Defense Authorization Act (NDAA) for Fiscal Year 2018, complete a life-cycle cost analysis of the beads which appropriately considers local site conditions, life-cycle cost maintenance, environmental impact, operational requirements, and the safety of flight before specifying or using beads with a refractive index of 1.6 or less, including Type I beads.
- Type II has been deleted and is no longer specified or used.
- Type III, Gradation A, Drop-On, High Index of Refraction, intended for applications where increased retro-reflectivity is needed. Apply a minimum of 10 pounds per gallon (1.2 kilograms per liter) of paint.

- Type IV Gradation A – Large coarse, direct-melt, low-index glass beads for drop-on applications are intended for highways and all airfield markings applied with paint procured to comply with Federal Specification TT-P-1952E, Type III. Apply a minimum of 8 pounds per gallon (1 kilogram per liter) of paint. A wet film paint thickness of 18 to 25 mils (0.457 to 0.635 millimeter) is specified when Type IV gradation A beads are used.
- Type IV Gradation B – Medium coarse, direct-melt, low-index glass beads for drop-on applications are intended for highways and all airfield markings applied with paint procured to comply with Federal Specification TT-P-1952E, Type III. Apply a minimum of 8 pounds per gallon (1 kilogram per liter) of paint. A wet film paint thickness of 15 to 18 mils (0.381 to 0.457 millimeter) wet film paint thickness is specified when Type IV gradation B beads are used.

3-3.4 Lifecycle Cost Analysis

In accordance with the NDAA of 2016, perform a lifecycle cost analysis at every individual location to determine what type of reflective media (glass bead) to use at the installation. This is reiterated in Unified Facilities Guide Specification (UFGS) 32 17 23. In accordance with the NDAA for fiscal year (FY) 2018, complete a lifecycle cost analysis of the beads which appropriately considers local site conditions, lifecycle cost maintenance, environmental impact, operational requirements, and the safety of flight before specifying or using beads with a refractive index of 1.6 or less, including Type I beads. TSPWG Manual 3-260-04.18-01, *Life-Cycle Cost Analysis of Retroreflective Glass Beads,* provides guidance on how to accomplish a lifecycle cost analysis (LCCA) comparing Type I to Type III retroreflective glass beads in accordance with NDAA FY 2018, Section 2872(b).

This Page Intentionally Left Blank

CHAPTER 4 UNIQUE MARKING PRACTICES

4-1 PRACTICES FOR SPECIAL CIRCUMSTANCES.

Striated markings are substituted for any solid marking pattern that is 3 feet (0.9 meter) wide or wider to reduce the effects of frost heave or improve surface friction characteristics. Do not striate markings on runways intended to support operations in instrument categories II and III. Striated markings are created by painting multiple longitudinal stripes 6 inches (152 millimeters) wide with gaps from 4 to 6 inches (102 to 152 millimeters) wide.

4-2 OPEN GRADED WEARING SURFACES AND CLEANING EXISTING MARKINGS.

4-2.1 Painting Porous Pavements.

On porous friction surfaces or other open aggregate wearing surfaces, it is desirable, or in some cases necessary, to apply painted markings twice, approaching the area to be marked from opposite directions. Glass beads, necessary to add retro-reflective characteristics to the markings, are applied during each pass.

4-2.2 Cleaning Markings.

When contaminated by fuel, oil, dirt, or other impurities, clean pavement markings using high-pressure water or a combination of applying an environmentally friendly soap and sweeping with a truck- or tractor-mounted sweeper, followed by a clear-water rinse. Sweeping new markings immediately after the paint cures also improves retro-reflectivity by abrading the overspray deposited on adjacent surface-exposed beads during subsequent paint applications.

4-3 MAXIMUM PAINT THICKNESS.

Each time a surface is over-painted, the initial stress at the bond between the paint binder and the pavement increases. For this reason, remove painted markings before they build up more than about 40 mils (1 millimeter) total thickness. This occurs after about five marking cycles with Type I or Type II paints, and even more rapidly with the more heavily applied Type III (high-build) paints unless surface abrasion such as that caused by heavy accelerating, stopping, or turning traffic, or snow removal operations with plows and/or brooms, reduces the buildup by abrasion. Over-painting to excessive thickness also eventually causes the marking to prematurely crack and peel.

4-4 OBSTRUCTION MARKING.

Obstacles or obstructions defined by UFC 3-260-01, Federal Aviation Regulations (FAR) Part 77, or ICAO Annex 14, Volume I and Volume II, as applicable, are marked according to the following guidance:

- For installations in CONUS or its territories, use FAA AC 70/7460-1.

- For OCONUS installations, use the current edition of ICAO Annex 14, or the standard defined by the SOFA, Host Nation Funded Construction Agreement (HNFA), or Bilateral Infrastructure Agreement (BIA).

4-5 ROADWAY MARKING.

Markings and signs of roadways are configured in accordance with UFC 3-201-01, SDDCTEA Pamphlet 55-17, SDDCTEA Pamphlet 55-14, and the FHWA MUTCD.

CHAPTER 5 RUNWAY MARKINGS

5-1 GENERAL INFORMATION.

All markings of any color on light-colored pavement are optionally highlighted by marking a black, non-reflectorized 6-inch (152-millimeter) border (see paragraph 3-1.5).

5-2 RUNWAY MARKING SCHEMES.

5-2.1 Runway Marking Elements Based on Highest Intended Use.

There are three marking patterns for manned, fixed-wing runways; visual flight rules (VFR), non-precision instrument approach, and precision instrument approach. These are shown in Figure 5-1. Unmanned aircraft systems (UAS) are marked differently if constructed to support UAS-only operations. Determine the extent of runway markings based on the level of operations planned during day, night, and instrument meteorological conditions (IMC). Also consider available electronic navigation and visual approach lighting aids. Closed runways are marked to reflect their non-operational status. Engineers consult with the airfield managers to determine what markings are needed for each runway.

5-2.2 Additional Markings.

Installation/garrison commanders authorize additional standard markings. Non-standard markings are approved by the USAF Major Command Director of Operations (MAJCOM/A3) or U.S. Army Aeronautical Services Agency (USAASA), publicized in the DoD Flight Information Publication (FLIP). Interference with standard runway markings is not allowable. Non-standard markings are those not defined within any USAF or other DoD Service standard, Department of Transportation (FAA and FHWA), ICAO, Air Standardization Coordinating Committee (ASCC), or NATO standard appropriate for application at the given installation.

5-2.3 Unmanned Aircraft System (UAS) Runways.

For UAS-only runways, mark runway designation, centerline marking, and the letters “UAS” (without black borders), threshold bar, and runway edge stripes in retroreflective white, all centered on the runway width. These type runways are identified with the letters “UAS” on each end of the runway as shown in Figure 5-5.

5-2.3.1 Shadow (RQ-7A/B) -only runways are only marked with “UAS” without a designation number and centerline marking**.**

5-2.3.2 Global Hawk, Predator, and Reaper UAS-only runways are marked based on standard Class B airfield marking schemes and precedence (VFR, non-precision, or precision instrument; see Figure 5-1) and the standards provided herein.

5-2.4 Basic Visual Flight Rule (VFR) Runway.

For a VFR runway intended for use only during visual meteorological conditions (VMC), provide the following minimum markings (see Figures 5-1, 5-2, and 5-7):

- Centerline stripes
- Designation numbers (and letters, if appropriate)
- AAS warning markings (Runway only; do not mark these for emergency arresting systems located in overruns.)
- Runway/runway hold positions (if the runway intersects another runway and is used as a taxiway or is approved for simultaneous land and hold short operations [LAHSO] with the intersecting runway)
- Overrun chevrons
- Fixed distance (aiming point) marking (if the runway is 4,000 feet [1,200 meters] or longer and potentially used by jet aircraft)
- Add side stripes to all non-precision instrument runways and basic VFR runways where the shoulder pavement is the same as the full-strength runway pavement. On airfields where the width of the runway was reduced, creating a full-strength shoulder, the use of edge stripes is optional except that they must be used to mark the location of any non-full-strength pavement such as the shoulders of the previously wider runway.

5-2.5 Non-Precision Instrument Runways.

For an instrument, non-precision approach runway, also mark threshold bars and expand the centerline width to 3 feet (0.9 meter). See Figures 5-1 and 5-3 for examples.

Figure 5-1 Runway Marking Schemes

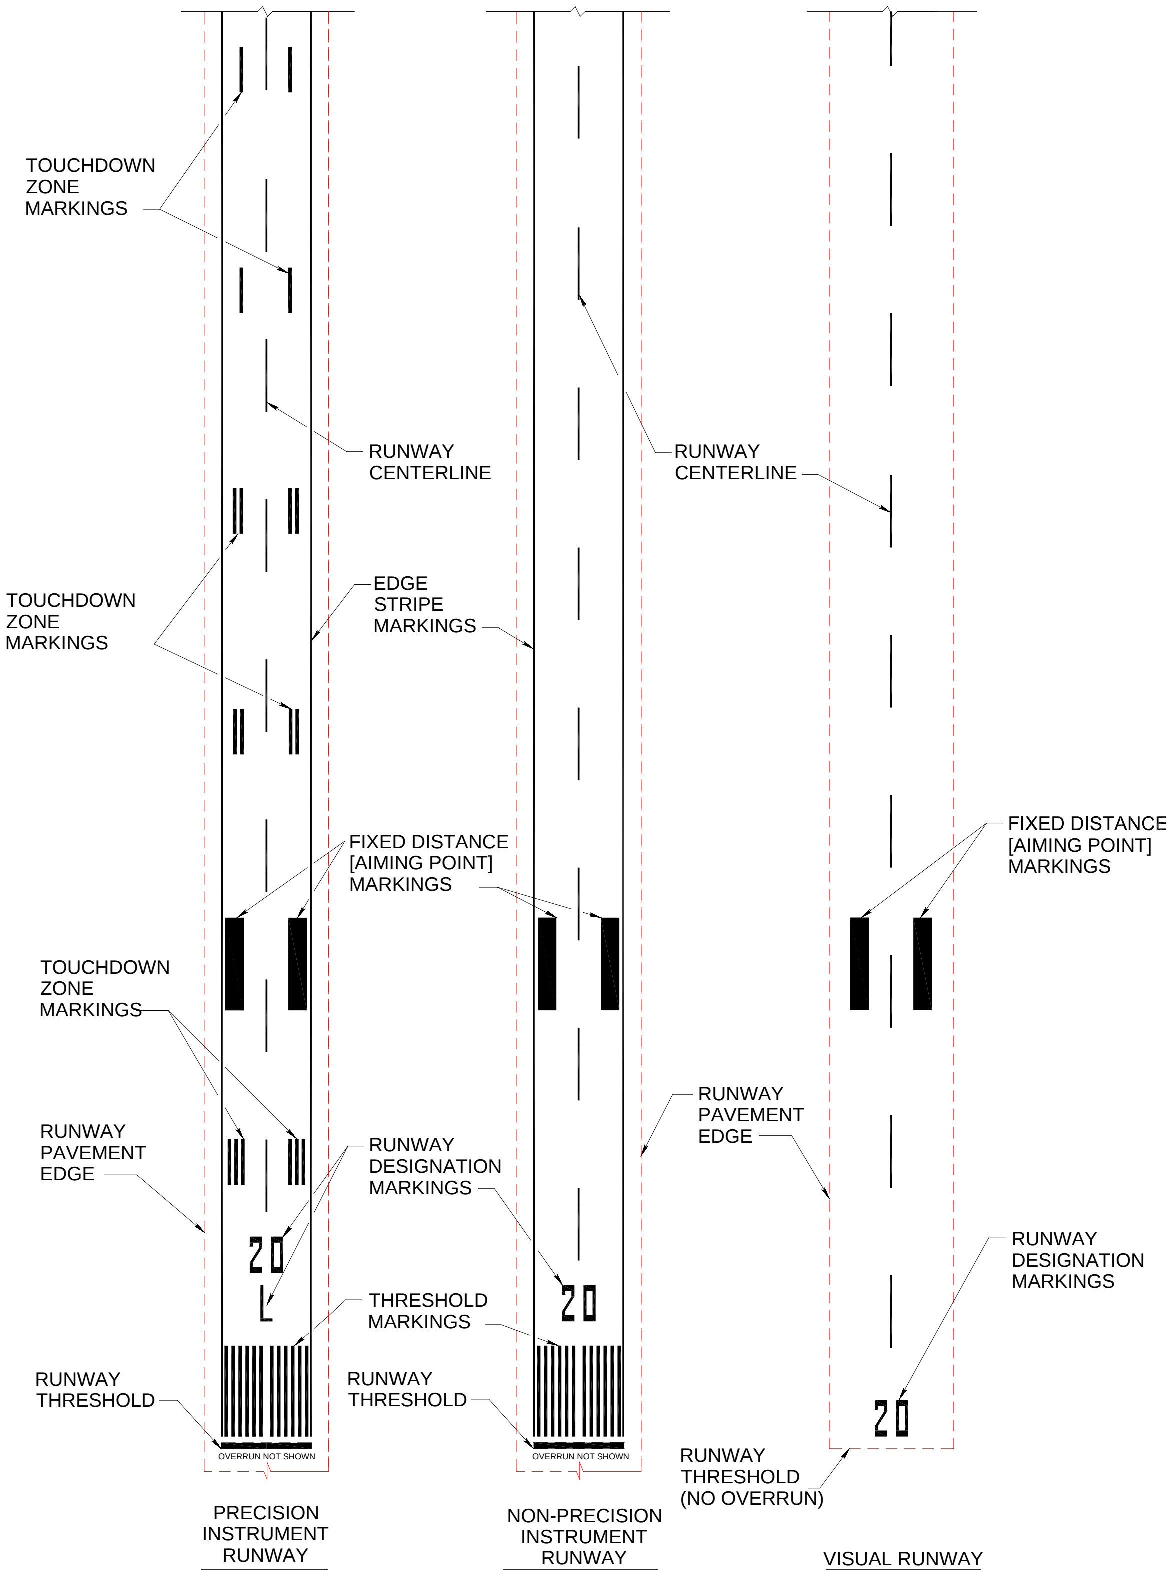

Figure 5-2. VFR Runway Markings

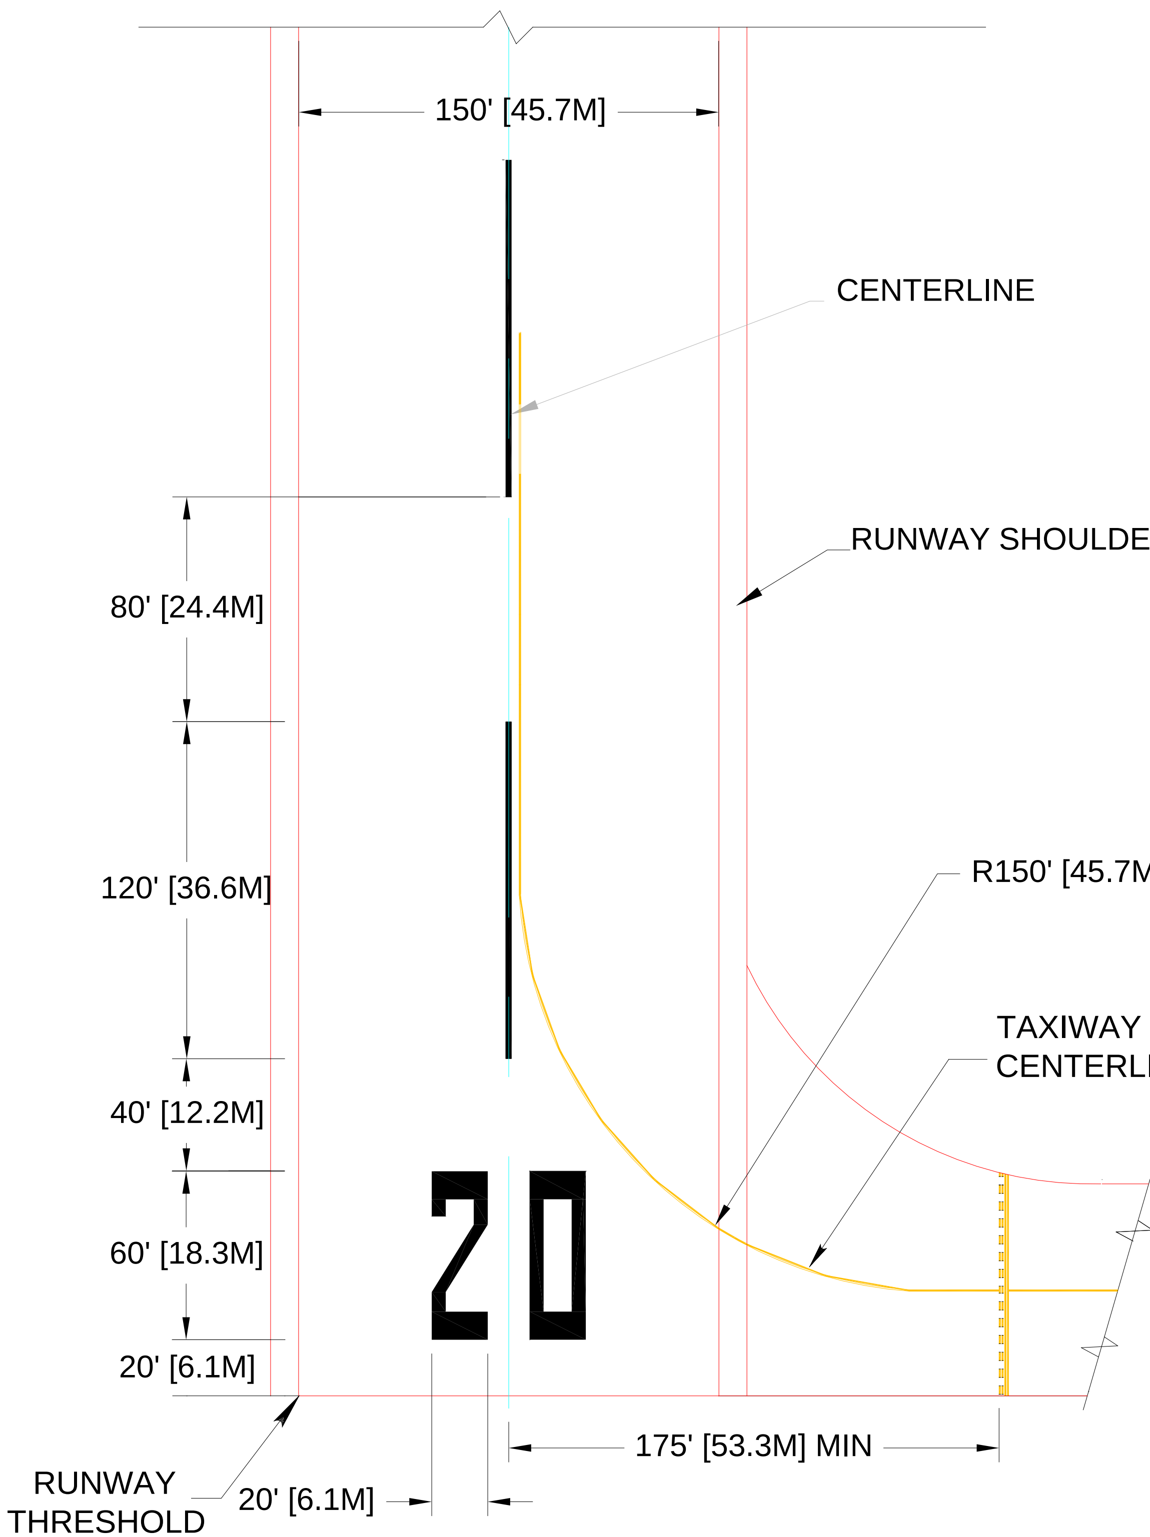

Figure 5-3. Non-Precision Instrument Runway Markings

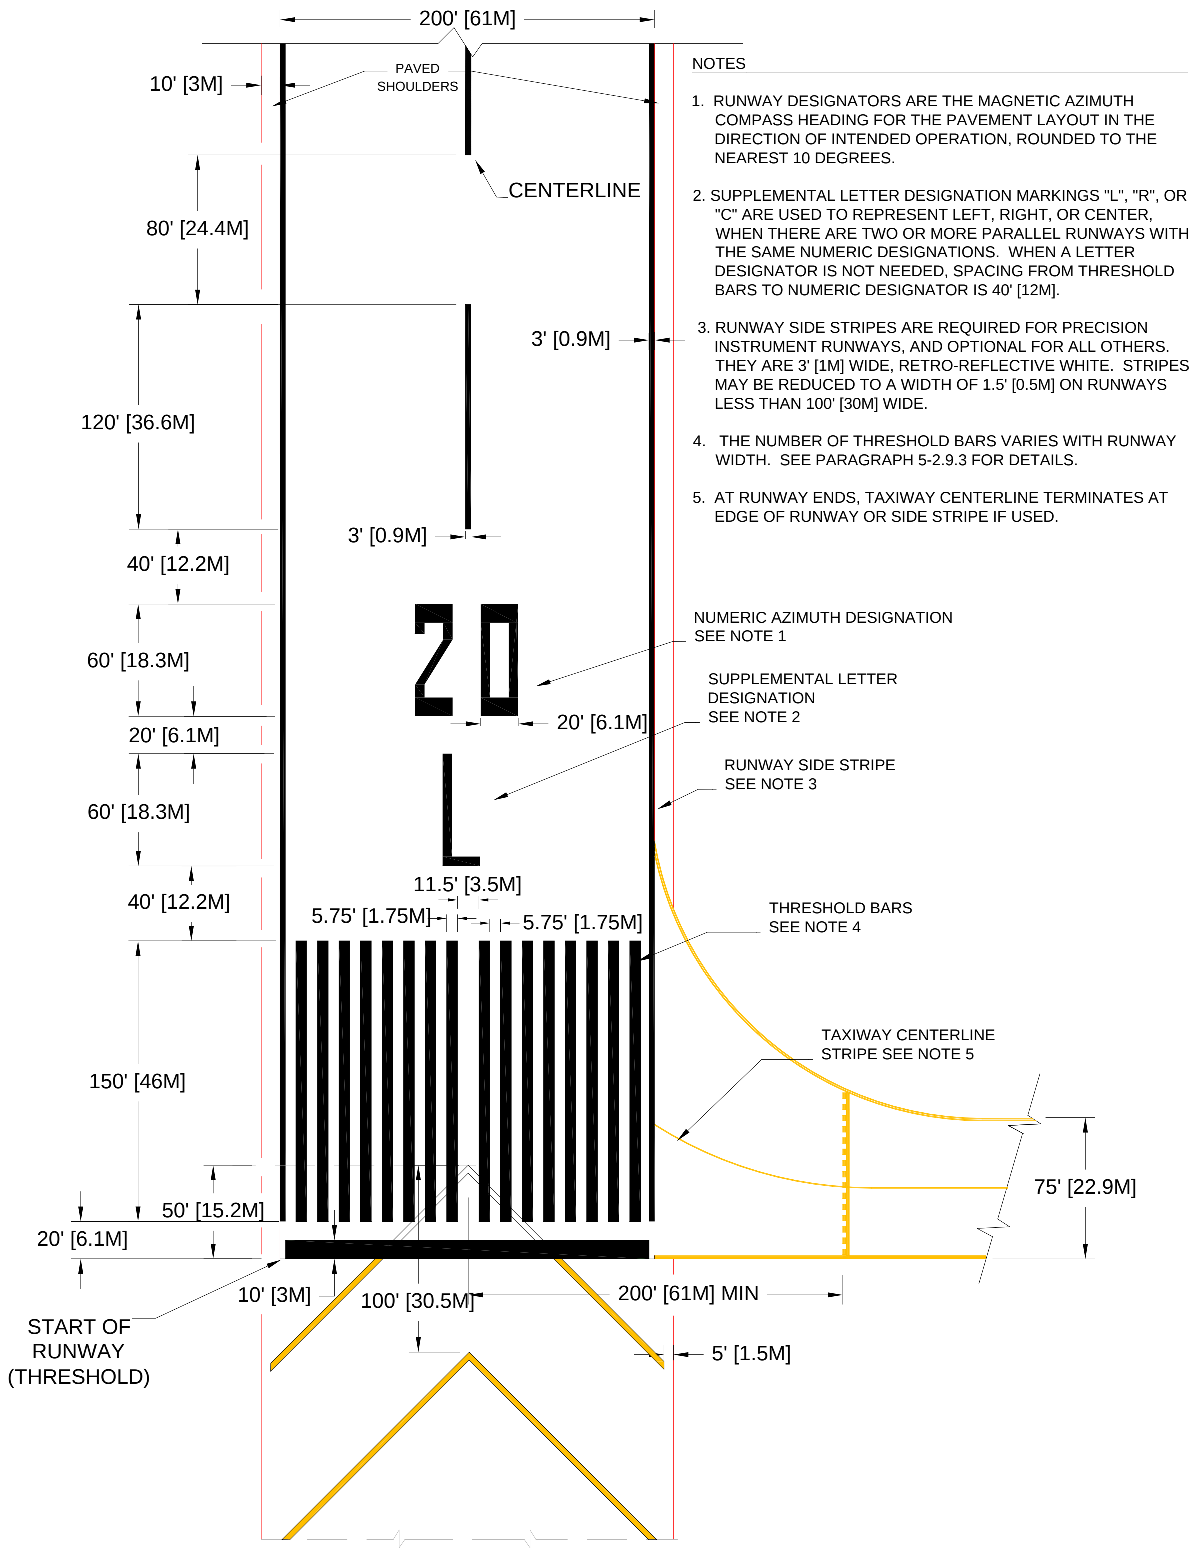


NOTES

1. RUNWAY DESIGNATORS ARE THE MAGNETIC AZIMUTH COMPASS HEADING FOR THE PAVEMENT LAYOUT IN THE DIRECTION OF INTENDED OPERATION, ROUNDED TO THE NEAREST 10 DEGREES.
2. SUPPLEMENTAL LETTER DESIGNATION MARKINGS "L", "R", OR "C" ARE USED TO REPRESENT LEFT, RIGHT, OR CENTER, WHEN THERE ARE TWO OR MORE PARALLEL RUNWAYS WITH THE SAME NUMERIC DESIGNATIONS. WHEN A LETTER DESIGNATOR IS NOT NEEDED, SPACING FROM THRESHOLD BARS TO NUMERIC DESIGNATOR IS 40' [12M].
3. RUNWAY SIDE STRIPES ARE REQUIRED FOR PRECISION INSTRUMENT RUNWAYS, AND OPTIONAL FOR ALL OTHERS. THEY ARE 3' [1M] WIDE, RETRO-REFLECTIVE WHITE. STRIPES MAY BE REDUCED TO A WIDTH OF 1.5' [0.5M] ON RUNWAYS LESS THAN 100' [30M] WIDE.
4. THE NUMBER OF THRESHOLD BARS VARIES WITH RUNWAY WIDTH. SEE PARAGRAPH 5-2.9.3 FOR DETAILS.
5. AT RUNWAY ENDS, TAXIWAY CENTERLINE TERMINATES AT EDGE OF RUNWAY OR SIDE STRIPE IF USED.

5-2.6 Precision Instrument Runway.

For precision approach runways, in addition to the non-precision instrument approach and VFR runway marking elements, provide side stripes and touchdown zone (TDZ) markings (and instrument hold lines, if appropriate). Substitute fixed distance (aiming point) markings for the second pair of TDZ markings on each end of the runway (see Figures 5-1 and 5-4).

5-2.7 Runway Marking Precedence.

For runways that intersect or share a common end, interrupt or adjust markings on the runway with the lower priority. Give precedence in this order:

- Category III
- Category II
- Category I
- Non-precision instrument runway markings
- VFR runway markings

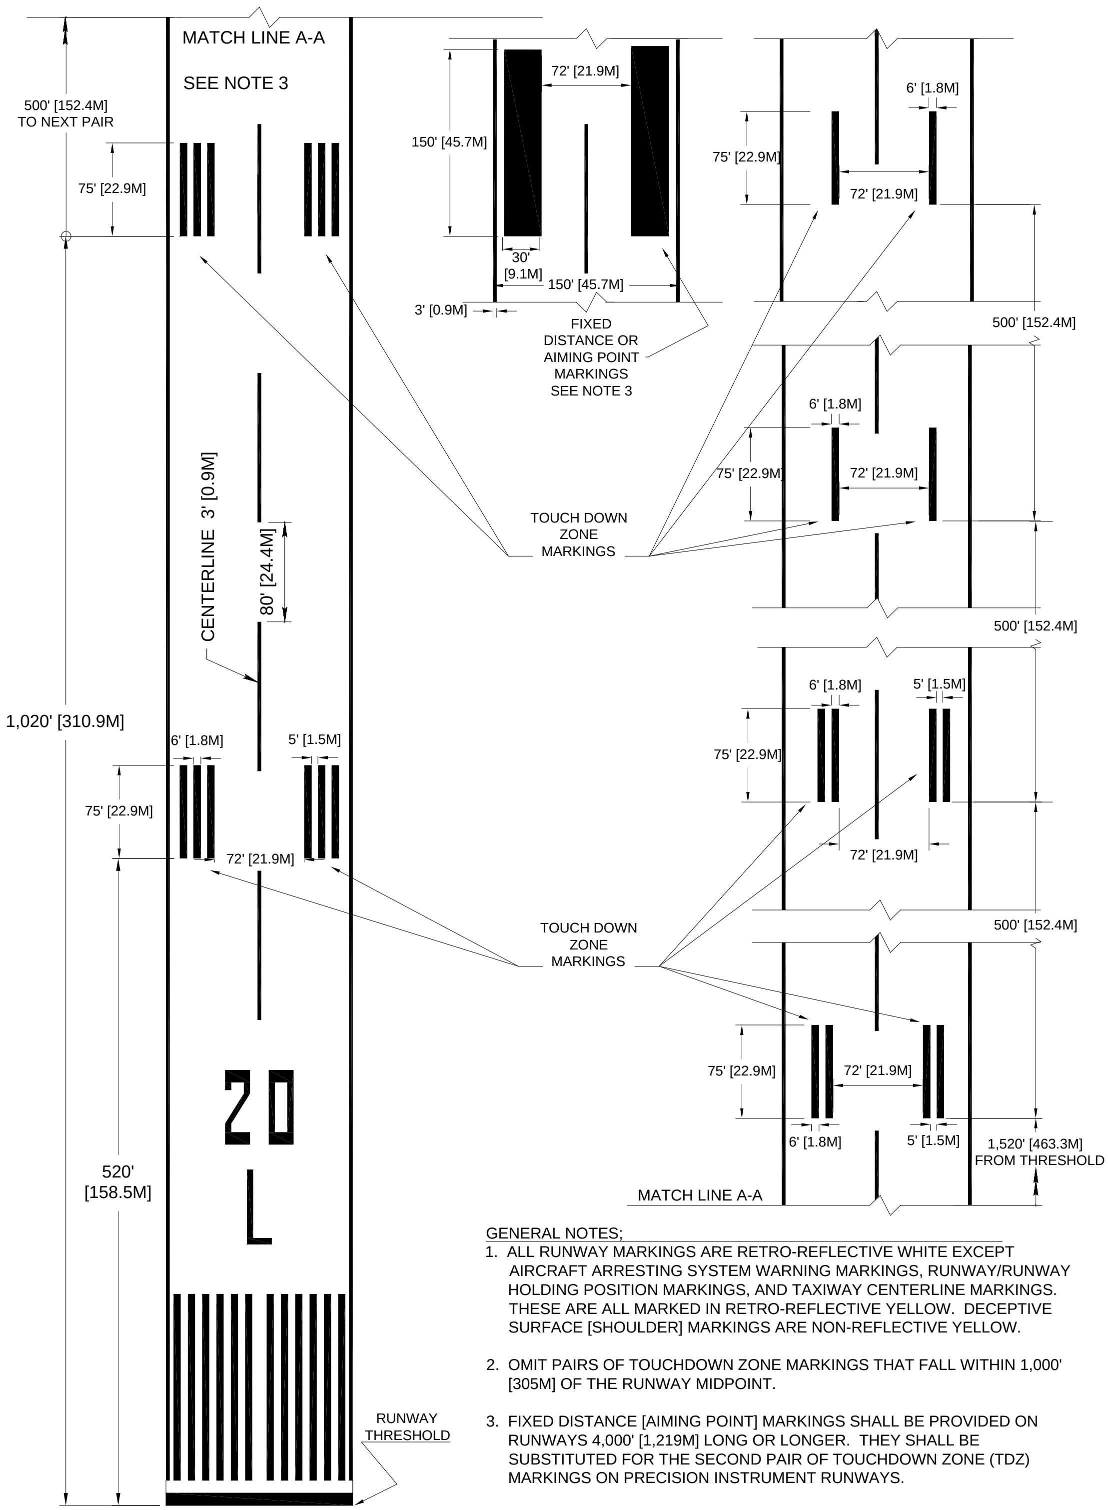
5-2.7.1 Where a need exists to mark a taxiway centerline across a runway, interrupt the marking 3 feet (0.9 meter) on either side of the runway marking.

5-2.7.2 Taxiway centerline is interrupted 5 feet (1.5 meters) either side of threshold markings or numbers.

5-2.8 Runway Centerline.

Runway centerlines are marked with a series of uniformly spaced retro-reflective white longitudinal stripes, 3 feet (0.9 meter) wide on instrument runways and at least 12 inches (305 millimeters) wide for VFR runways. Begin layout of centerline markings 40 feet (12.2 meters) from the runway designation (numeral[s]) and continue to the midpoint of the runway. Uniformly adjust the lengths of two stripes and three gaps or three stripes and two gaps (depending on which of the two falls at the center of the runway length) near the runway midpoint. See Figures 5-2 and 5-3.

Figure 5-4. Touchdown Zone and Fixed Distance (Aiming Point) Markings



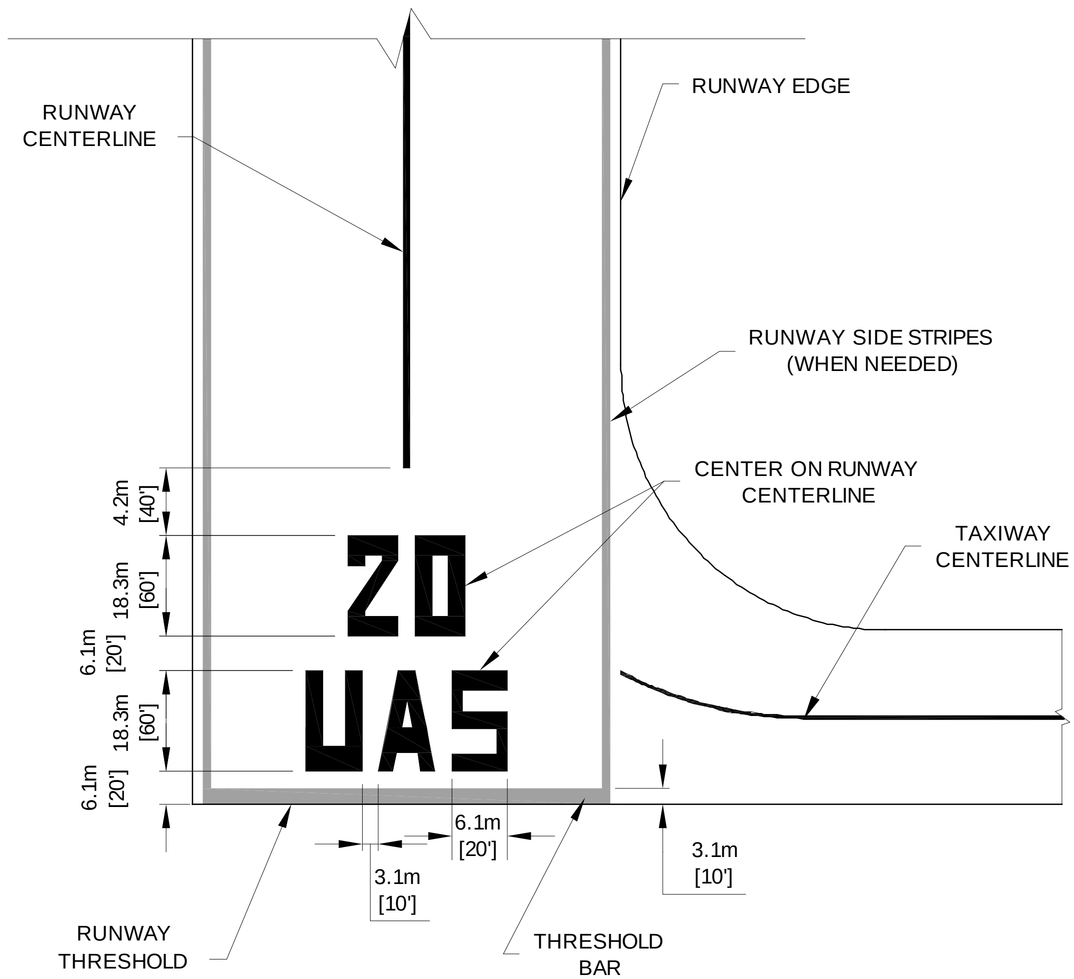
GENERAL NOTES;

1. ALL RUNWAY MARKINGS ARE RETRO-REFLECTIVE WHITE EXCEPT AIRCRAFT ARRESTING SYSTEM WARNING MARKINGS, RUNWAY/RUNWAY HOLDING POSITION MARKINGS, AND TAXIWAY CENTERLINE MARKINGS. THESE ARE ALL MARKED IN RETRO-REFLECTIVE YELLOW. DECEPTIVE SURFACE [SHOULDER] MARKINGS ARE NON-REFLECTIVE YELLOW.

2. OMIT PAIRS OF TOUCHDOWN ZONE MARKINGS THAT FALL WITHIN 1,000' [305M] OF THE RUNWAY MIDPOINT.

3. FIXED DISTANCE [AIMING POINT] MARKINGS SHALL BE PROVIDED ON RUNWAYS 4,000' [1,219M] LONG OR LONGER. THEY SHALL BE SUBSTITUTED FOR THE SECOND PAIR OF TOUCHDOWN ZONE (TDZ) MARKINGS ON PRECISION INSTRUMENT RUNWAYS.

Figure 5-5. UAS Runway Markings



NOTES:

1. SEE FIGURE 5-6 FOR DESIGNATION NUMBER AND LETTER MARKING DIMENSIONS.
2. WHEN THESE MARKINGS ARE BEING USED ON RUNWAYS FOR RQ-7A/B ONLY (50' WIDE), THEN ALL DIMENSIONS SHOWN ON THIS DETAIL SHALL BE REDUCED BY ONE HALF. RUNWAYS FOR THESE AIRCRAFT WILL NOT HAVE THE CENTERLINE OR NUMERICAL DIRECTION MARKINGS EITHER.

5-2.9 Threshold Marking.

The runway threshold is the beginning of the full-strength pavement. The 10-foot (3 meter) wide threshold bar is marked at the threshold, and the designation number(s) or longitudinal threshold bars begin 20 feet (6.1 meters) inward from the threshold.

5-2.9.1 Visual Flight Rule (VFR) Runways.

Figures 5-1 and 5-2 provide the layout details for a VFR runway. Figure 5-6 provides layout dimensions and spacing details for designators.

5-2.9.2 Instrument Runways.

Precision and non-precision instrument runway thresholds are marked with a group of retro-reflective white longitudinal stripes, and a transverse threshold bar when there is any type of pavement preceding the runway pavement. The longitudinal threshold bars are spaced symmetrically about the runway centerline on 11.5-foot (3.5-meter) centers, configured of 5.75-foot (1.75-meter) -wide stripes and gaps, except at the center of the runway, where the gap dimension is doubled to 11.5 feet (3.5 meters*).* The transverse runway threshold bar is 10 feet (3 meters) in width and extends between the runway edges (as published in the DoD FLIP or between the runway side stripes, whichever is less). Figure 5-3 provides layout details for the threshold bars and longitudinal spacing for the runway designators, and Figure 5-6 provides layout dimensions and horizontal spacing details for designators.

5-2.9.3 Variances in Longitudinal Threshold Patterns.

The number of longitudinal stripes in a threshold pattern varies for different-width runways. Threshold bar length and widths are the same in all cases. The appropriate numbers of longitudinal stripes to be used are as follows:

- Four for 60-foot (18.3-meter) -wide runways;
- Six for 75-foot (22.9-meter) -wide runways;
- Eight for 100-foot (30.5-meter) -wide runways;
- Ten for 125-foot (38.1-meter) -wide runways;
- 12 for 150-foot (45.7-meter) -wide runways, and;
- 16 for 200-foot (61-meter) -wide or wider runways

5-2.9.4 Non-standard Width Runways.

For non-standard runway widths, the same stripe-gap pattern is continued from the runway centerline until the outermost longitudinal stripe is no closer than 4 feet (1.2 meters) from the runway edge or side stripes. Do not mark more than 16 threshold bars, even for runways wider than 200 feet (61 meters).

5-2.10 Runway Designations.

Designators for runways are retro-reflective white numeric characters that indicate the magnetic azimuth of the runway centerline to the nearest 10-degree increment. The designation consists of one or two numbers, or in the case of parallel runways, the numeric designator and a retro-reflective white letter (“L” for left, “C” for center, or “R” for right) to indicate the lateral position of the runway with respect to any others with the same numeric designator on the same airfield. See Figure 5.3 for placement on the runway pavement and Figure 5-6 for letter and numeral dimensions.

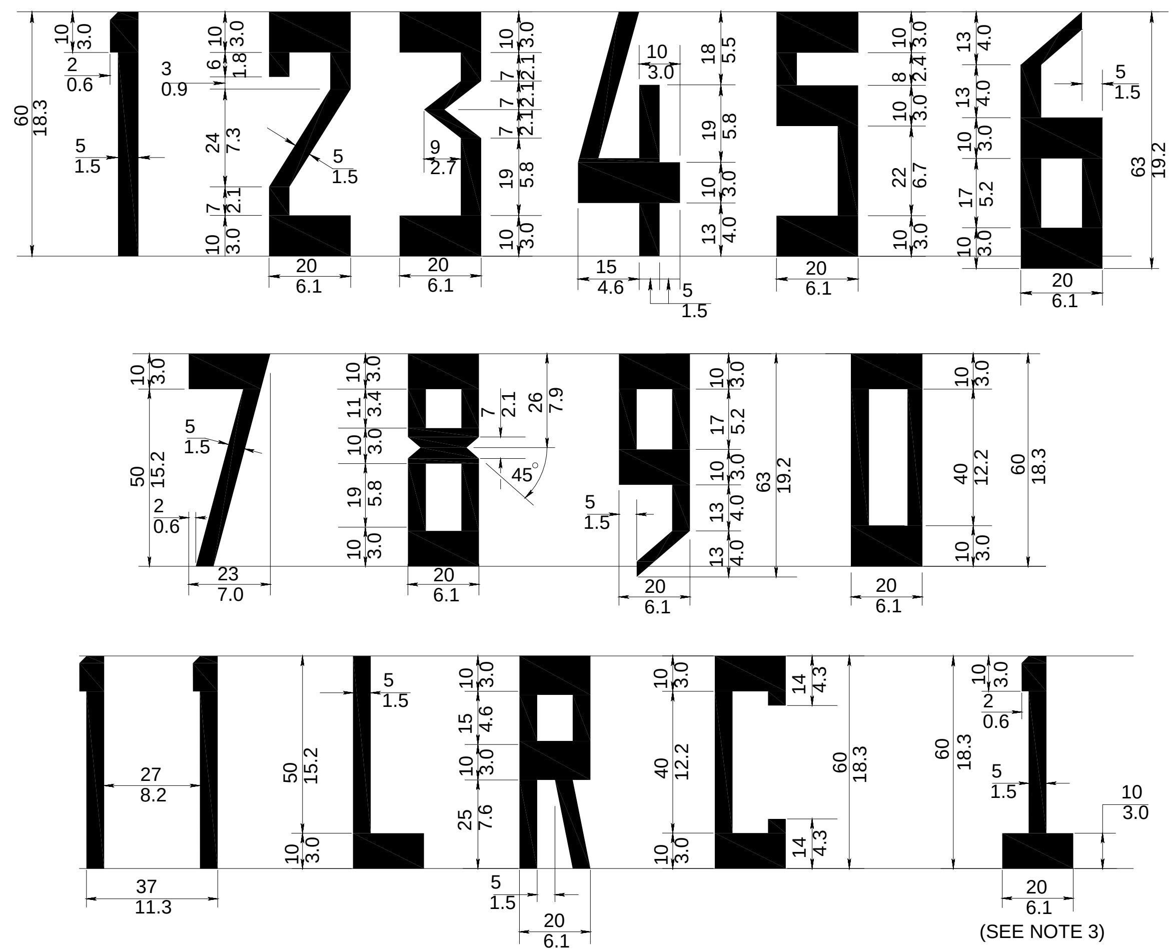
5-2.11 Dimensions for Designation Numbers and Letters.

Numbers are formed with 5-foot (1.5-meter) -wide vertical stripes and 10-foot (3-meter) -wide horizontal stripes. A zero (0) is marked to precede single-digit numbers on Class B runways except those subject to NAVAIR 51-50AAA-2. Lateral spacing between the numbers is 15 feet (4.6 meters), except for the number "11." Spacing between these numerals is 27 feet (8.2 meters). The dimensional layout is shown in Figure 5-6.

5-2.12 Runway Overruns.

Non-reflective yellow chevron markings are used on overruns to indicate the area is not a normal operational surface. For layout, the apex of the chevron is laid out (but not painted) 50 feet (15.2 meters) inward of the runway threshold. Only the portions of the chevron legs that are outward from the runway threshold are painted. Subsequent chevrons are placed at 100-foot (30.5-meter) intervals along the overrun, measured from chevron apex to chevron apex. The legs of the chevrons intersect the centerline at a 45-degree angle. The chevron legs extend laterally to within 5 feet (1.5 meters) of the paved surface edge or to align with the lateral limits of the runway shoulder markings (deceptive surface markings), if used. A typical layout plan and dimensions for these markings are shown in Figure 5-7.

Figure 5-6 Runway Designators



NOTES:

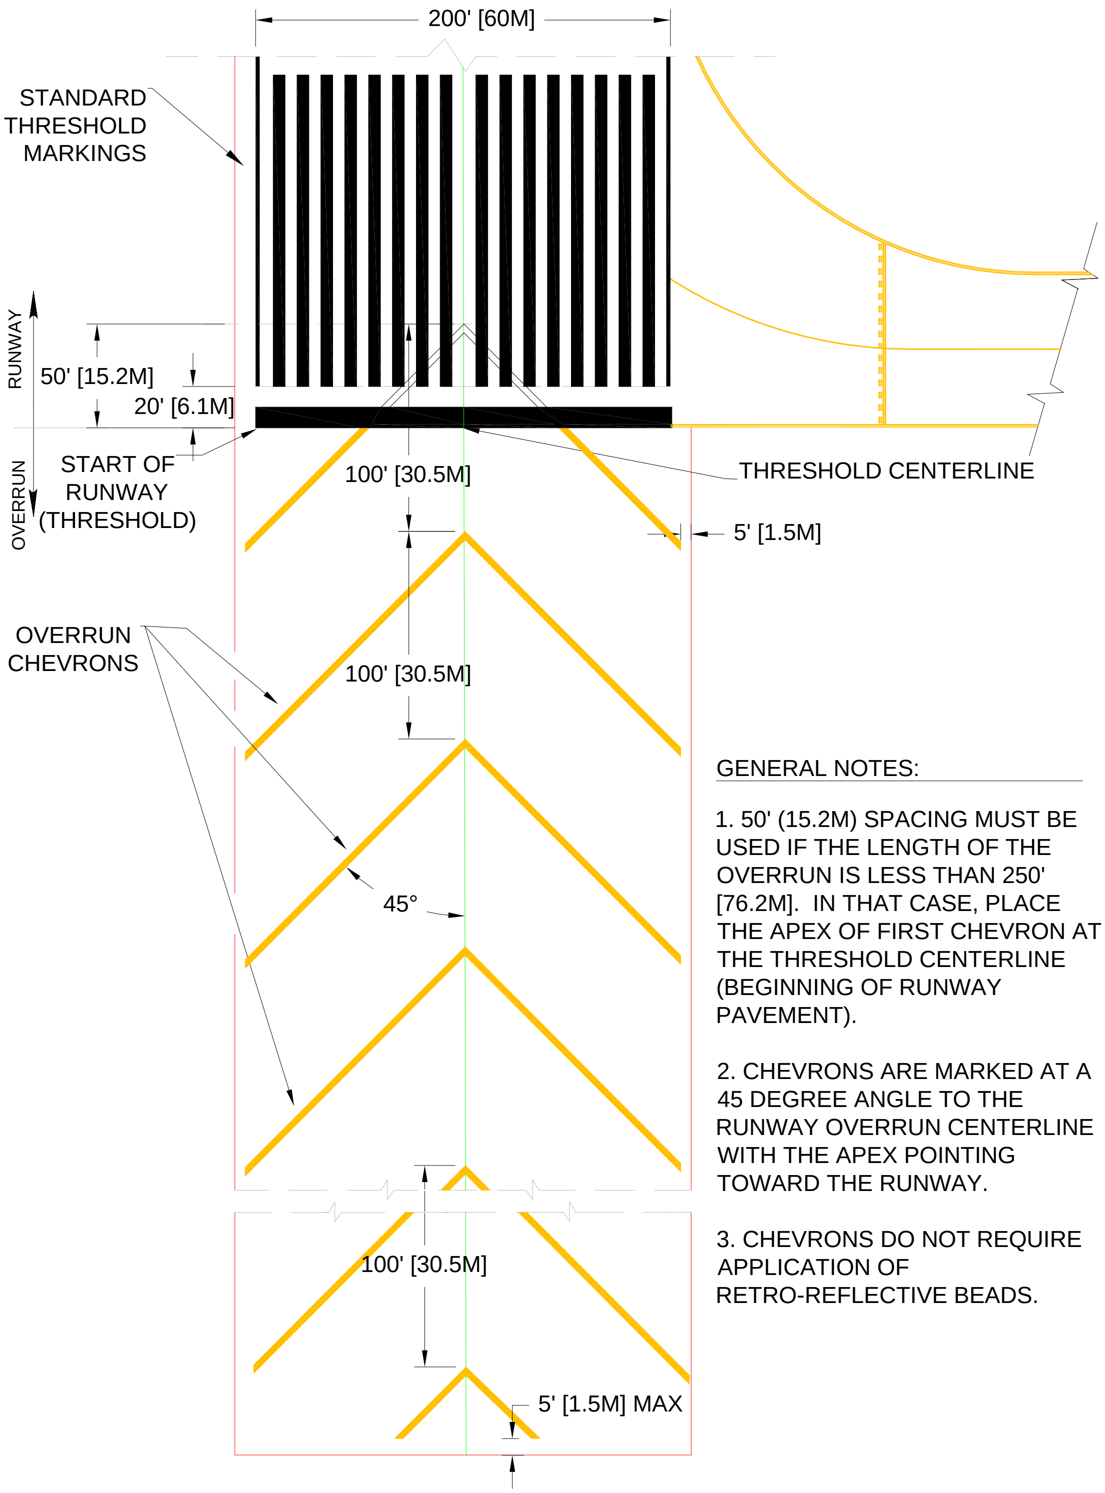
1. ALL LETTERS AND NUMERALS EXCEPT THE NUMBER ELEVEN ARE HORIZONTALLY SPACED 15' [4.6 M] BETWEEN THE NEAR EDGES. THE NUMERALS USED TO FORM "11" ARE SPACED AT 27' [8.2M] BETWEEN INNER EDGES AS SHOWN ABOVE.

2. DIMENSIONS ARE EXPRESSED AS; $\frac{\text{FEET}}{\text{METERS}}$ (E.G. $\frac{60}{18.3}$).

3. WHEN USED ALONE, THE NUMERAL 1 IS PLACED ABOVE A HORIZONTAL BAR TO DIFFERENTIATE IT FROM THE RUNWAY CENTERLINE MARKING.

4. IMPERIAL UNITS OF MEASURE ARE USED AS THE PRIMARY DIMENSIONS IN THIS FIGURE. FOR DESIGNS WHICH USE ROUNDED METRICS FOR DIMENSIONS, CARE MUST BE TAKEN TO ENSURE THE NUMBERS AND LETTERS RETAIN THE INTENDED SHAPE AND PROPORTIONS.

Figure 5-7. Overrun Markings



GENERAL NOTES:

1. 50' (15.2M) SPACING MUST BE USED IF THE LENGTH OF THE OVERRUN IS LESS THAN 250' [76.2M]. IN THAT CASE, PLACE THE APEX OF FIRST CHEVRON AT THE THRESHOLD CENTERLINE (BEGINNING OF RUNWAY PAVEMENT).

2. CHEVRONS ARE MARKED AT A 45 DEGREE ANGLE TO THE RUNWAY OVERRUN CENTERLINE WITH THE APEX POINTING TOWARD THE RUNWAY.

3. CHEVRONS DO NOT REQUIRE APPLICATION OF RETRO-REFLECTIVE BEADS.

5-2.13 Runway Side Stripes.

Retro-reflective white side stripes are marked on precision instrument runways. They are also used optionally on non-precision instrument and VFR runways. Side stripes are not intended to identify the edge of the full-strength pavement on DoD runways; they are intended to enhance the pilot's ability to recognize the runway environment at decision height on landing. If there is a lack of contrast between the full-strength runway pavement and the shoulder pavement, use non-reflective yellow shoulder markings (deceptive surface) on the shoulder pavement. See Figures 5-3 and 5-4.

Note: If there is a significant gap between the inner end of the shoulder markings (deceptive surface) and the runway side stripes (such as occurs when side stripes are spaced at 144-foot [44-meter] separation on a 300-foot [91-meter] -wide runway), also mark double 6-inch (152-millimeter) -wide retro-reflective yellow stripes, separated by a 6-inch (152-millimeter) -wide gap, to enhance delineating the limits of the useable (or full-strength) pavement. Details for these markings are the same as for taxiway or apron edge markings. Place the outer edge of the outermost stripe to coincide with the outermost edge of the useable (or full-strength) pavement and the inner end of the deceptive surface marking. These stripes are curved to follow the outer edge of fillets and terminate at the intersecting taxiway edge or joined to taxiway edge markings, if used.

5-2.13.1 Locating and Layout of Stripes.

The runway side stripe markings consist of one continuous stripe placed on each side of the runway. The side stripes are placed symmetrically about the runway centerline as shown in Figures 5-1 and 5-3. They have a minimum width of 3 feet (0.9 meter) for runways 100 feet (30.5 meters) or more in width and are at least 1.5 feet (0.5 meter) wide for runways less than 100 feet (30.5 meters) wide. The stripes begin 20 feet (6.1 meters) inward from the runway threshold and continue to within 20 feet (6.1 meters) of the runway threshold on the opposite end of the runway. There are exceptions when the threshold is displaced. See paragraph 5-2.14 and Figures 5-4, 5-8, 5-9, and 5-10 for examples.

5-2.13.2 Stripe Separation.

If special missions indicate a need for wider separation on runways 200 or 300 feet (61 meters or 91.4 meters) wide, the side stripes are placed as stated above, except the separation between the inner edges of the stripes is 194 feet (59.1 meters). Separation of side stripes greater than 194 feet (59.1 meters) is not authorized without a non-standard marking waiver.

5-2.14 Displaced Threshold Marking Schemes.

5-2.14.1 Layouts According to Intended Use of the Pavement.

There are four different schemes used to mark the pavement in the displaced area. Select a scheme from those shown in Figures 5-8 through 5-11 that indicates the appropriate and authorized use of the area. Note that for temporarily displaced thresholds, existing markings need not be obliterated. However, Notice to Airmen (NOTAM), Flight Crew Information File (FCIF) memorandum, and any other available methods are used to convey the temporary changes and potential hazards that exist during the construction or maintenance period. See UFC 3-260-01, Appendix B, Section 1, for construction waiver requirements, and Appendix B, Section 14, for a construction phasing plan and safety checklist to be used for such projects.

5-2.14.1.1 Permanently Displaced Threshold Where Displacement Area is Used for Take-Off and/or Landing Ground Roll-Out.

Relocate the longitudinal threshold bars beginning 20 feet (6.1 meters) from the new threshold and place a retro-reflective white transverse stripe to precede them, with the outboard edges on the full-strength runway pavement, or to abut the runway side stripes. Reduce the width and length of the centerline stripes in the displaced threshold area and modify them with retro-reflective white arrowheads leading to the new threshold. Mark retro-reflective white chevrons to point toward the transverse threshold bar at evenly spaced increments across the pavement. Dimensions and layout details are shown in Figure 5-8.

5-2.14.1.2 Permanently Displaced Threshold Where Displacement Area is Used as a Taxiway (Referred to as Relocated Threshold in the Airman's Information Manual [AIM]).

Relocate the longitudinal threshold bars beginning 20 feet (6.1 meters) from the new threshold and place a retro-reflective white transverse threshold bar to precede them, with the outboard edge at the beginning of the runway pavement available for landing. Mark retro-reflective yellow chevrons to point toward the transverse threshold bar at evenly spaced increments across the pavement. Dimensions and layout details are shown in Figure 5-9.

5-2.14.1.3 Permanently Displaced Threshold Where Displacement Area Used as Taxiway and Take-Off and/or Landing Ground Roll.

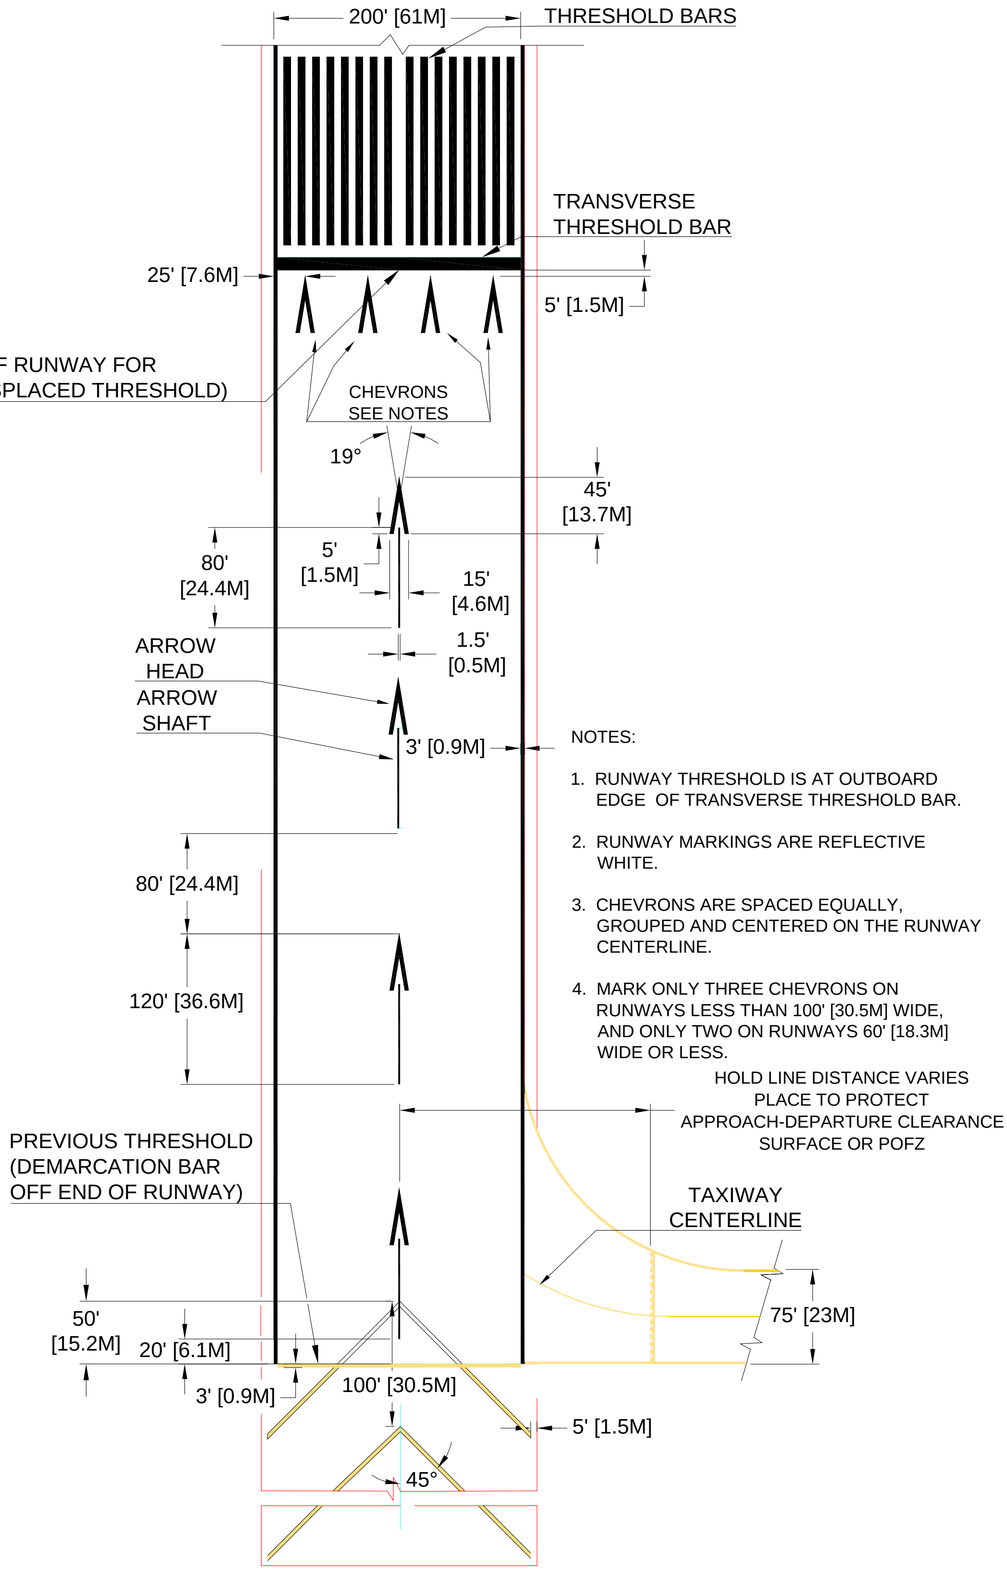
Relocate the longitudinal threshold bars beginning 20 feet (6.1 meters) from the new threshold and place a retro-reflective white transverse threshold bar to precede them, with the outboard edge at the beginning of the runway pavement. Mark retro-reflective white chevrons to point toward the transverse threshold bar at evenly spaced increments across the pavement. Modify runway centerline stripes in the displacement area used for takeoff with retro-reflective white arrowheads. Mark a retroreflective yellow demarcation bar across the full width of the pavement at the end of the aligned taxiway, delineating the point where the takeoff roll begins. Dimensions and layout details are shown in Figure 5-10.

5-2.14.1.4 Temporarily Displaced Thresholds.

For temporarily displaced thresholds, place a retroreflective white transverse stripe that extends from side stripe to side stripe (or edge to edge of pavement if side stripes are not used) at the new threshold. Modify the centerlines within the displacement with arrowheads and mark chevrons across the runway width pointing to the transverse bar.

Use retroreflective white for arrowheads and chevrons if the area is used for takeoff or roll-out, or retroreflective yellow if the area is planned only for taxiing operations. It is not necessary to reposition the standard threshold markings, modify the width and length of centerline stripes, or obliterate other existing markings within the displaced area; however, NOTAM, FCIF memorandum, and any other available methods are used to convey the temporary changes and potential hazards to pilots. Dimensions and layout details are shown in Figure 5-11.

Figure 5-8 Permanently Displaced Threshold Where Preceding Pavement is Used as Runway (Take-Off or Landing)



NOTES:

1. RUNWAY THRESHOLD IS AT OUTBOARD EDGE OF TRANSVERSE THRESHOLD BAR.
2. RUNWAY MARKINGS ARE REFLECTIVE WHITE.
3. CHEVRONS ARE SPACED EQUALLY, GROUPED AND CENTERED ON THE RUNWAY CENTERLINE.
4. MARK ONLY THREE CHEVRONS ON RUNWAYS LESS THAN 100' [30.5M] WIDE, AND ONLY TWO ON RUNWAYS 60' [18.3M] WIDE OR LESS.

Figure 5-9. Permanently Displaced Threshold Where Preceding Pavement is Used as a Taxiway

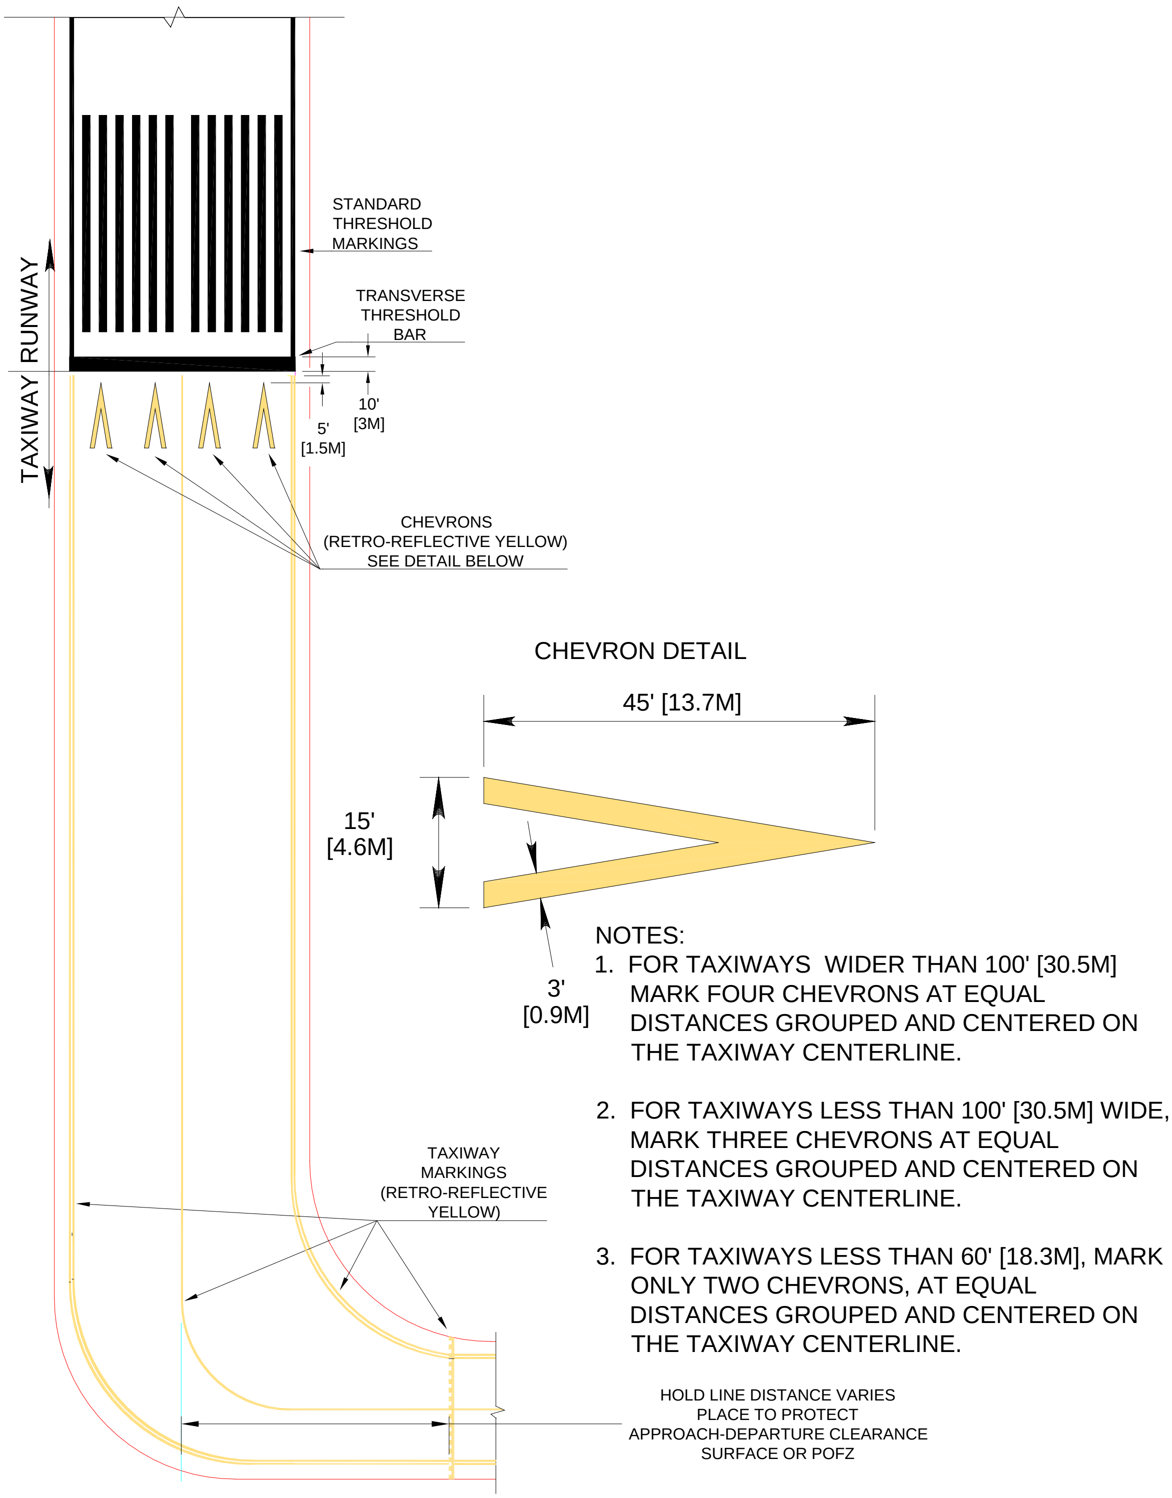


Figure 5-10. Permanently Displaced Threshold Where Displacement Area is Used as a Taxiway and for Take-Off and/or Landing Ground Roll

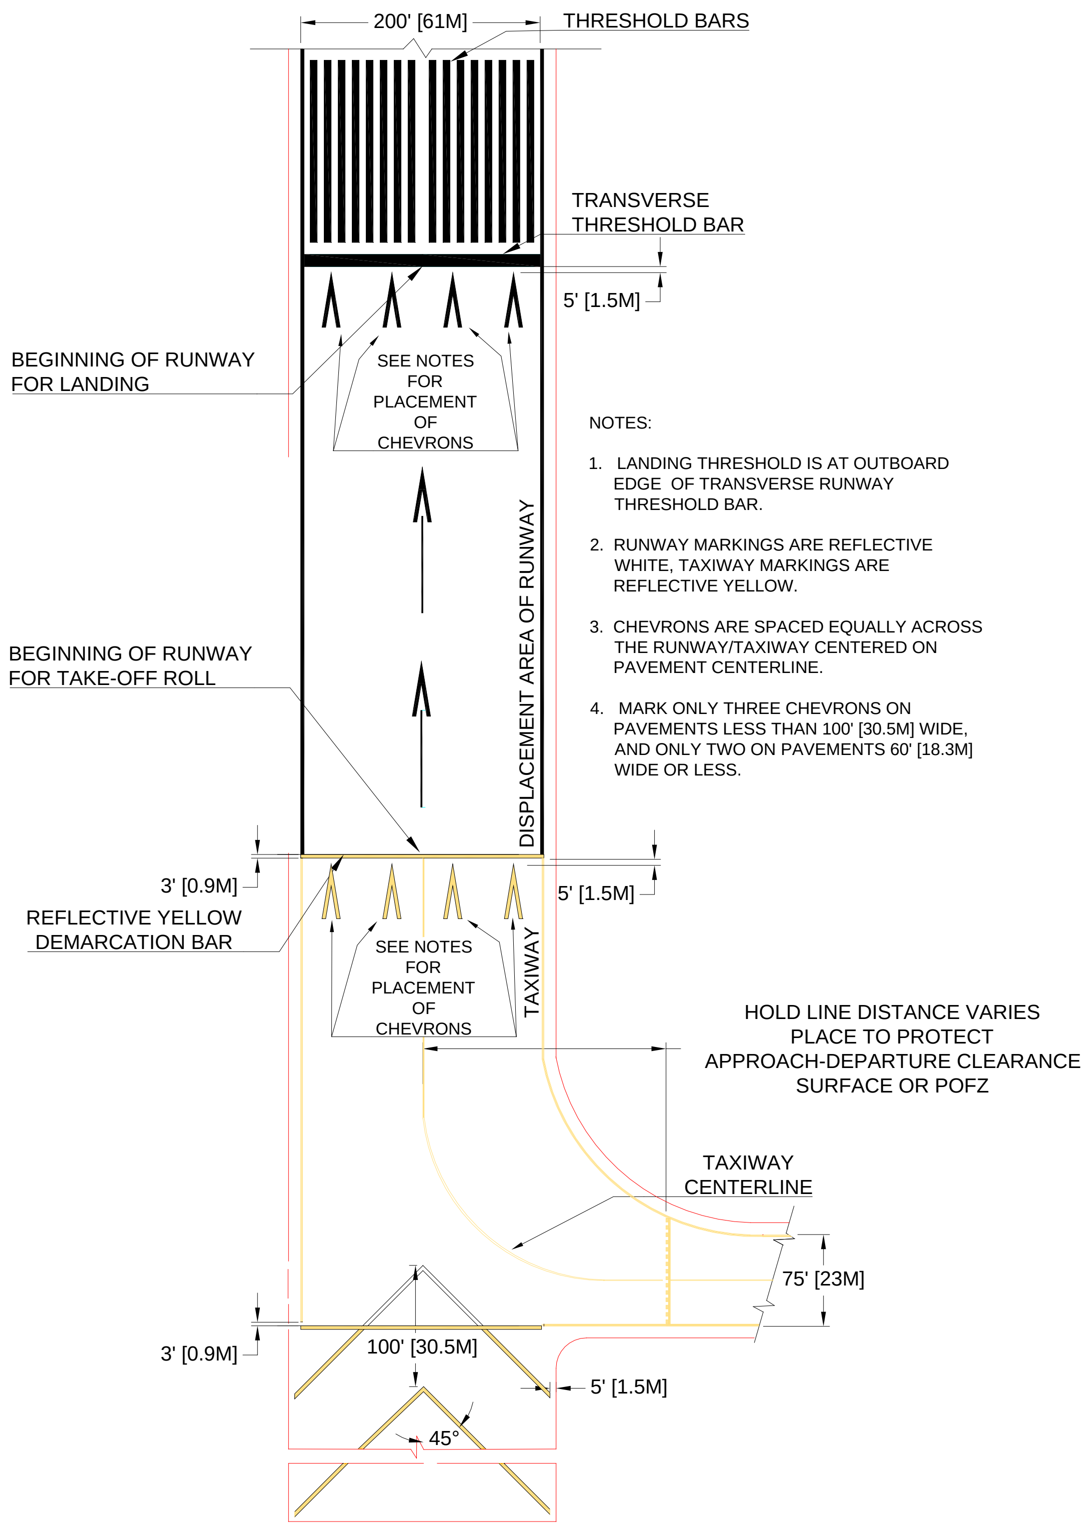

Figure 5-11. Temporarily Displaced Threshold

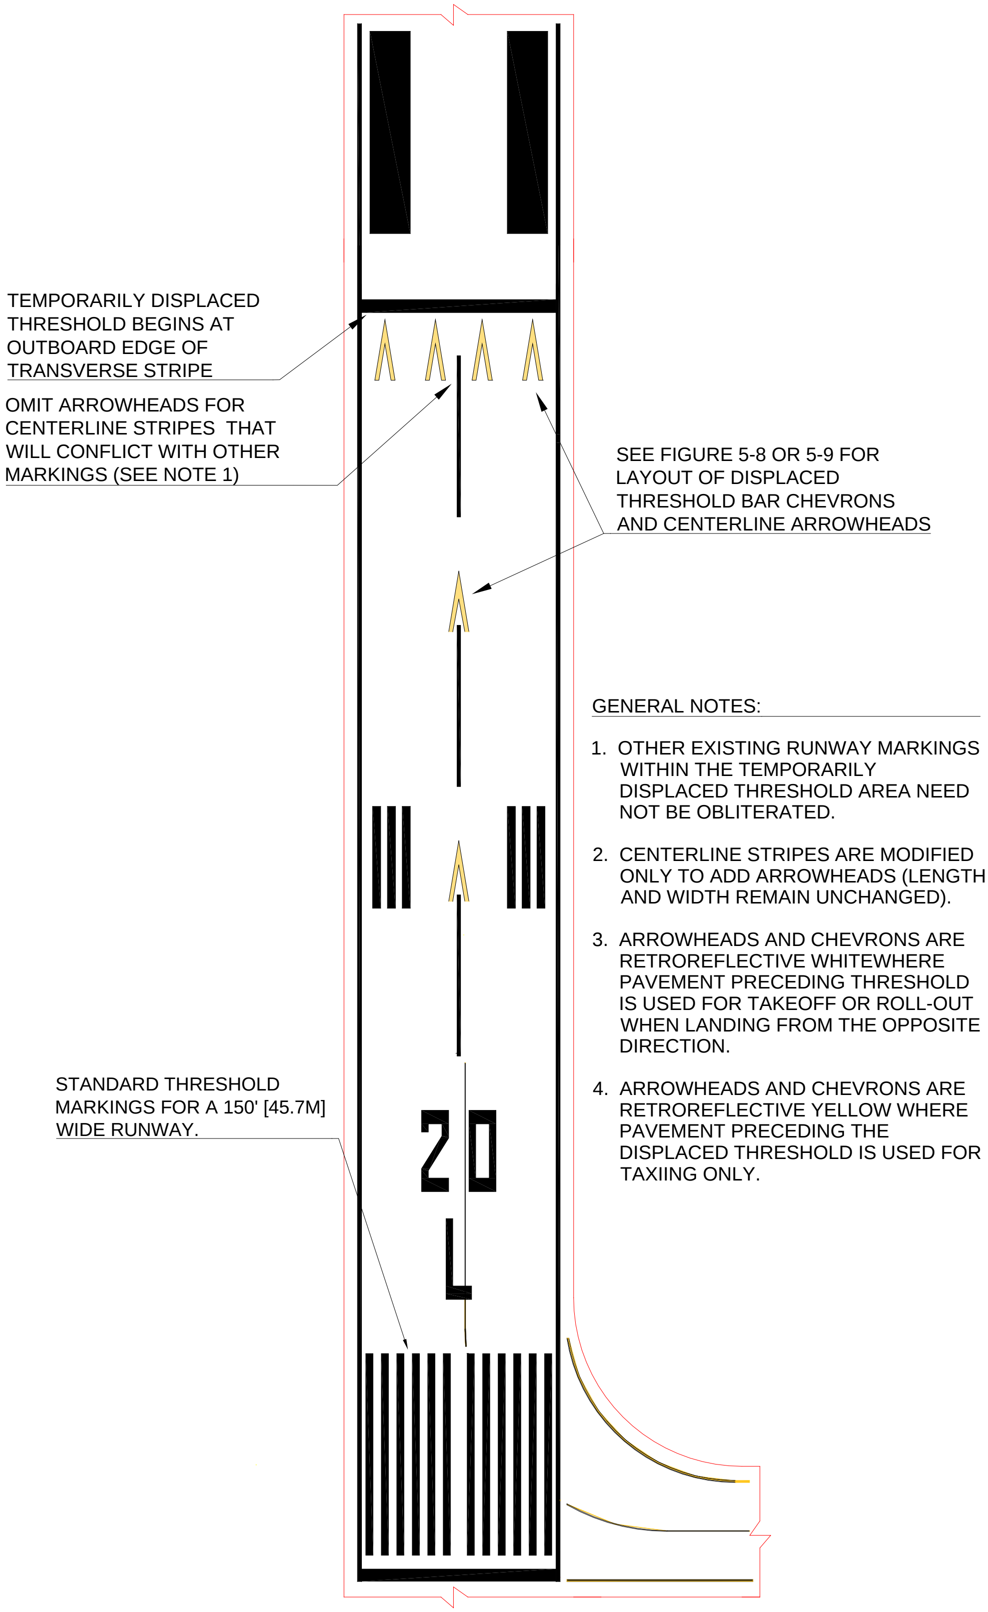


GENERAL NOTES:

1. OTHER EXISTING RUNWAY MARKINGS WITHIN THE TEMPORARILY DISPLACED THRESHOLD AREA NEED NOT BE OBLITERATED.
2. CENTERLINE STRIPES ARE MODIFIED ONLY TO ADD ARROWHEADS (LENGTH AND WIDTH REMAIN UNCHANGED).
3. ARROWHEADS AND CHEVRONS ARE RETROREFLECTIVE WHITEWHERE PAVEMENT PRECEDING THRESHOLD IS USED FOR TAKEOFF OR ROLL-OUT WHEN LANDING FROM THE OPPOSITE DIRECTION.
4. ARROWHEADS AND CHEVRONS ARE RETROREFLECTIVE YELLOW WHERE PAVEMENT PRECEDING THE DISPLACED THRESHOLD IS USED FOR TAXIING ONLY.

5-2.15 Touchdown Zone and Fixed Distance Markings.

5-2.15.1 Touchdown Zone (TDZ) Markings.

TDZ markings consist of pairs of longitudinal stripes placed symmetrically about the centerline. A group of three stripes are provided in the first two pairs of TDZ markings, two stripes in the next two groups of pairs, and single stripes in the last two pairs. Omit any pair of markings that fall within 1,000 feet (304.8 meters) of the runway midpoint. The lateral distance between each pair of longitudinal stripes measured at their inner edges is a constant 72 feet (21.9 meters). The layout and dimensions are shown in Figure 5-4.

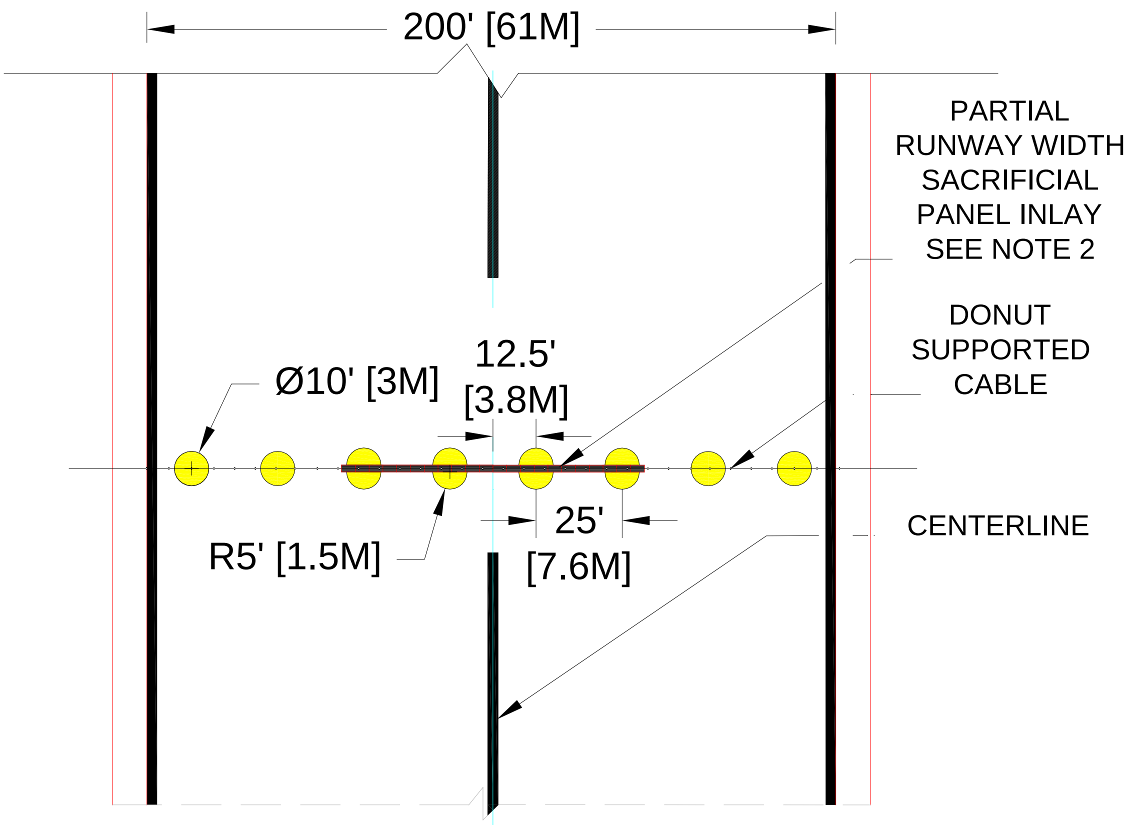
5-2.15.2 Fixed Distance (Aiming Point) Markings.

Provide aiming point markings on runways that are 150 feet (45.7 meters) or more wide and at least 4,000 feet (1,219.2 meters) long. Substitute them in place of the second pair of touchdown zone markings. The layout plan and dimensions are shown in Figure 5-4.

5-2.15.3 Aircraft Arresting System (AAS) Warning Markings.

Mark AAS locations on the runway with a series of discs placed beneath and centered on the pendant. Where TDZ and disc markings coincide, the TDZ marking is interrupted at that location for a minimum distance of 1 foot (0.3 meter) from the edge of the disc marking. If the designation and disc markings coincide, shift the designation marking longitudinally to eliminate the conflict. The layout plan and dimensions for these markings are shown in Figure 5-12. Do not use these markings in overruns.

Figure 5-12. Aircraft Arresting System (AAS) Warning Markings



NOTES

1. SIX WARNING MARKINGS ARE USED FOR 150' [46.7M] WIDE RUNWAYS, EIGHT ARE USED ON RUNWAYS 200' [61M] WIDE OR WIDER.

2. WHEN POLYETHYLENE PANELS ARE INSTALLED BENEATH PENDANTS, MARK 5' [1.5M] RADIUS SEMI-CIRCLES ON EITHER SIDE OF POLYETHYLENE PANEL INLAYS. PLACE THEM AT THE SAME SPACING ACROSS THE RUNWAY AS WHEN NO PANELS ARE USED.

This Page Intentionally Left Blank

CHAPTER 6 TAXIWAY AND APRON MARKINGS

6-1 GENERAL INFORMATION.

Unless otherwise indicated, most taxiway, apron, and taxilane markings for both fixed and rotary-wing facilities are marked in retro-reflective yellow. All markings of any color on light-colored pavement are optionally highlighted by marking a black, non-reflectorized 6-inch (152-millimeter) border (see paragraph 3-1.5).

6-2 TAXIWAY AND TAXILANE CENTERLINE STRIPE.

Mark the centerline of all taxiways, guidelines on runways, and taxilanes on aprons as well as parking positions and pads, with a single continuous 6-inch (152-millimeter) -wide retro-reflective yellow stripe. The width is optionally increased to 12 inches (305 millimeters) when necessary; however, make the line width uniform (either one width or the other) wherever used over the entire airfield. Exceptions to this provision apply for parking positions and inside hangars.

6-2.1 Directional Changes.

All directional changes are accomplished with smooth, single radius curves. Position nose wheel guidelines to maintain a clearance of at least 10 feet (3 meters) between the aircraft's outermost main gear and the edge of the full-strength pavement when the cockpit is maintained over the nose wheel guideline through the turn. Also ensure adequate wingtip clearance is provided for the most demanding aircraft that uses the taxi route. On runways, the curve is tangent to a line parallel with and 3 feet (0.9 meter) from the near side of the runway centerline marking. The straight segment extends 200 feet (61 meters) beyond the point of tangency. See Figure 6-1 for these and other typical layout schemes.

6-2.2 Taxiway and Taxilane Turn Radii.

6-2.2.1 General Intersection Geometry.

On hammerheads, aprons, and pads, and at runway/taxiway and taxiway/taxiway intersections, the radius for the curves are greater than the minimum turning radius for the assigned mission aircraft and are positioned to maintain a clearance of at least 10 feet (3 meters) between the outermost main gear of a C-5 and the edge of the full-strength pavement. See USACE Transportation Systems Center Report 13-2 for aircraft turning diagrams. The recommended radius for 90-degree runway/taxiway intersections is 150 feet (45.7 meters). The recommended radius for 90-degree taxiway/taxiway intersections is 125 feet (38.1 meters). Other radii are allowed, depending on local requirements. In all cases, ensure these radii accommodate the necessary wingtip clearance distance as well as the pavement structure (clearance between outer main gear and edge of pavement) for the most demanding aircraft that uses the intersection before marking nose wheel guidelines.

6-2.2.2 Aprons for Cargo Aircraft.

Typical taxilane turning radii for cargo aircraft aprons are provided in Table 6.1 and Figure 6-2. Use these to determine the appropriate turning radii for cargo aircraft. For aircraft not shown in Table 6.1, compute the wing tip clearance and main gear distance from the appropriate aircraft characteristics found in the Facility Requirements Document (FRD) for the Mission Design Series (MDS) aircraft, or the aircraft turning diagrams found in USACE Transportation Systems Center Report 13-2. Use UFC 3-260-01, Table 6.1, “Cargo Aircraft Apron Layout Dimensions,” or Table 6.2, “Rotary Wing Aprons,” for minimum wingtip clearances. When marking an apron for a specific aircraft with features less stringent than for a C-5 or 747-8, coordinate with the airfield management and flight safety functions to ensure procedures are published to require aircraft wing-walkers be used for any aircraft that requires greater distances than those provided for safe clearance to obstacles. Publish this information in the Airfield Operating Instruction (AOI) at locations that require, have, or utilize an AOI.

6-3 TAXIWAY, APRON, AND TAXILANE EDGE STRIPES.

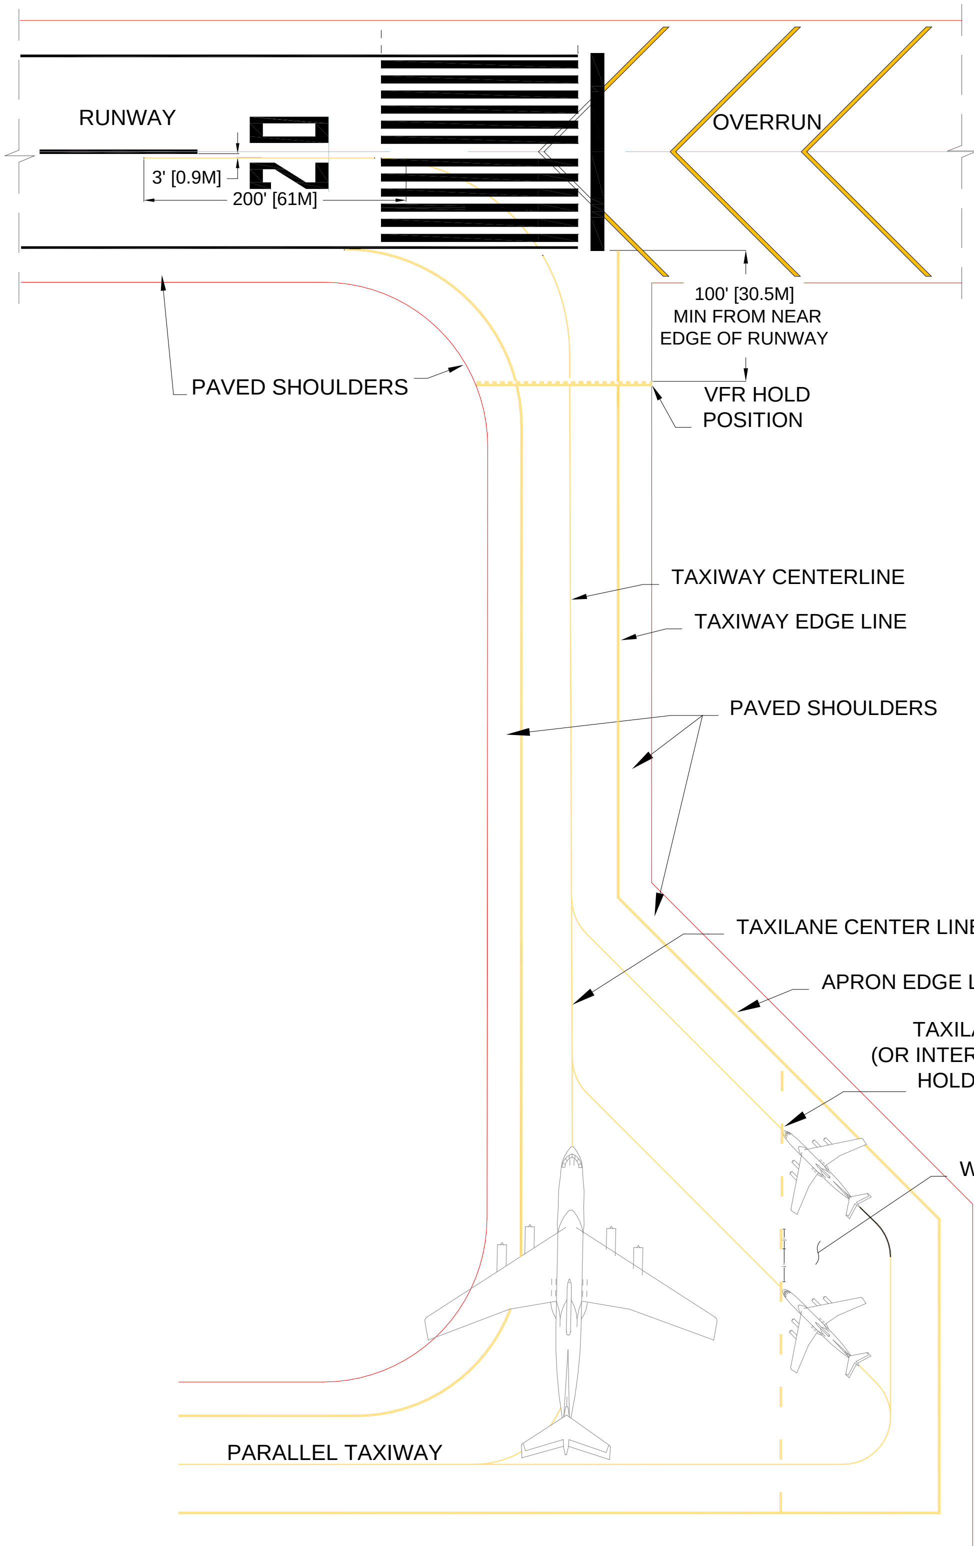
6-3.1 Taxiway and Apron Edge Stripes.

When there is little contrast between the full-strength taxiway or apron boundary and the adjacent paved shoulder or other paved area, mark the edge of the usable pavement with two continuous 6-inch (152-millimeter) -wide retro-reflective yellow stripes separated by a 6-inch (152-millimeter) -wide gap. This marking is used to delineate the usable limits of the taxiway or apron from other pavements or surfaces not intended for routine use by aircraft. It is never used in areas where aircraft are required to cross the designated boundary when operated by a pilot or qualified maintainer (towing aircraft across these markings is accepted if the adjacent area is designated and/or marked as a towway). No portion of the marking is placed on non-load-bearing pavements. Use the tangents for the taxiway centerline stripe on curves; in areas where this is not practical, form a uniform arc to establish the usable area on the full-strength pavement. Figure 6-1 shows typical taxiway/apron edge lines; Figure 6-3 provides the width of the stripes and the space between them. Edge stripes are optionally highlighted with black borders on light-colored pavement (see paragraph 3-1.5).

6-3.2 Taxilane Edge Stripes.

This marking is used to define the limits of a designated taxi route where the surrounding pavement is intended for use by aircraft. Aircraft movement across the designated boundary is permitted either by direction of air traffic control (ATC), a marshaller, or at the pilot's discretion. This marking consists of two 6-inch (152-millimeter) -wide broken stripes separated by a 6-inch (152-millimeter) -wide gap. The stripes are 15 feet (4.6 meters) long with gaps of 25 feet (7.6 meters). The detail and a typical layout are shown in Figures 6-1 and 6-9. Place the innermost edge of each stripe a distance from the centerline equal to half the wingspan of the most demanding aircraft that uses the taxilane, plus the appropriate wingtip clearance required by UFC 3-260-01, Table 6.1, items 5 or 6.

Figure 6-1. Typical Taxiway and Taxilane Markings



6-4 PARKING STOP BARS.

Parking stop bars are optionally painted at aircraft parking positions to indicate the intended location for the aircraft nose wheel when parked. Stop blocks are painted reflective yellow and are 3 feet (0.9 meter) long and 1 foot (0.3 meter) wide, centered on and oriented perpendicular to the nose wheel guideline. See Table 6-1 and Figure 6-2 for an example for locating these visual aids.

Table 6-1. Cargo Aircraft Apron Layout Dimensions

Aircraft	W	L*	P	I	T	C	R	N
C-5A	222.7' (67.9m)	247.8' (75.5m)	25' (7.6m)	30' (9.1m)	50' (15.2m)	37.5' (11.4m)	90' (27.4m)	34.7' (10.6m)

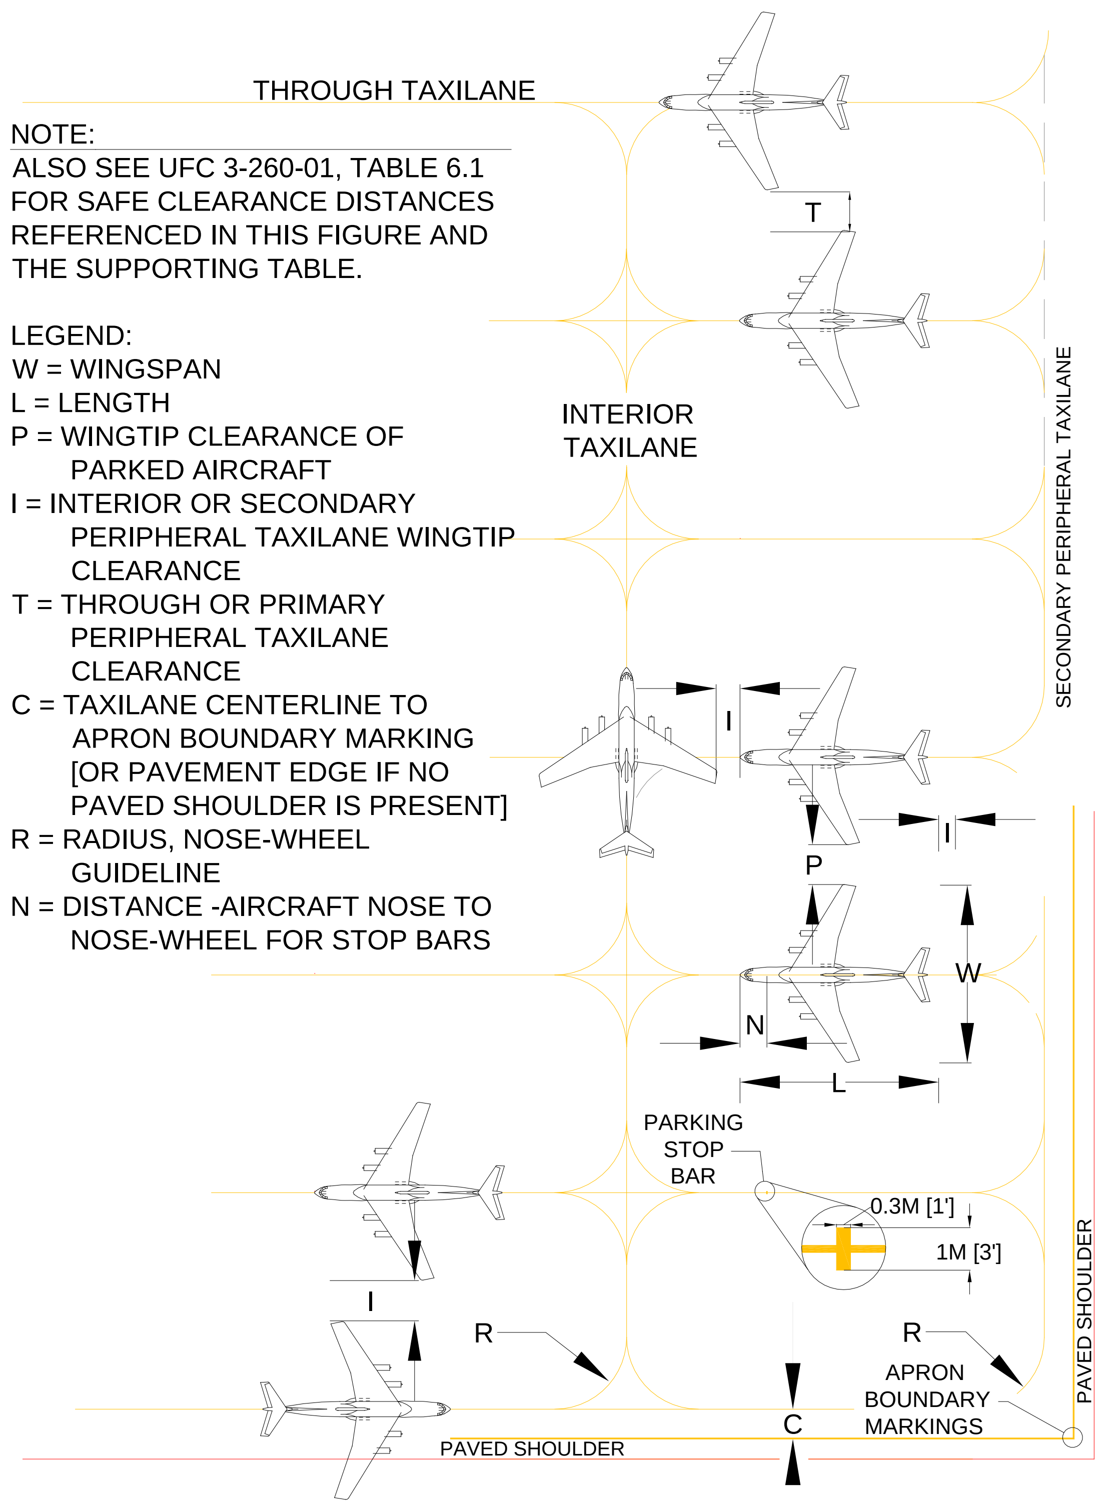
B777-300	200' (61m)	242.3' (73.9m)	20' (6.1m)	30' (9.1m)	50' (15.2m)	37.5' (11.4m)	110' (33.5m)	19.3' (5.9m)

***** Aircraft dimensions provided above do not include appurtenances such as antennas and do not include all model variations due to aircraft modifications.

Figure 6-2. Typical Mass Apron Layout for Cargo Aircraft



6-5 HOLDING POSITIONS.

Holding positions are necessary on all pavements that lead to an active fixed-wing or rotary-wing runway or helipad, and at critical taxiway or taxilane intersections. They designate a boundary intended to protect the runway, helipad, or primary taxiroute from incursions or prevent interference with signals transmitted by electronic navigational aids.

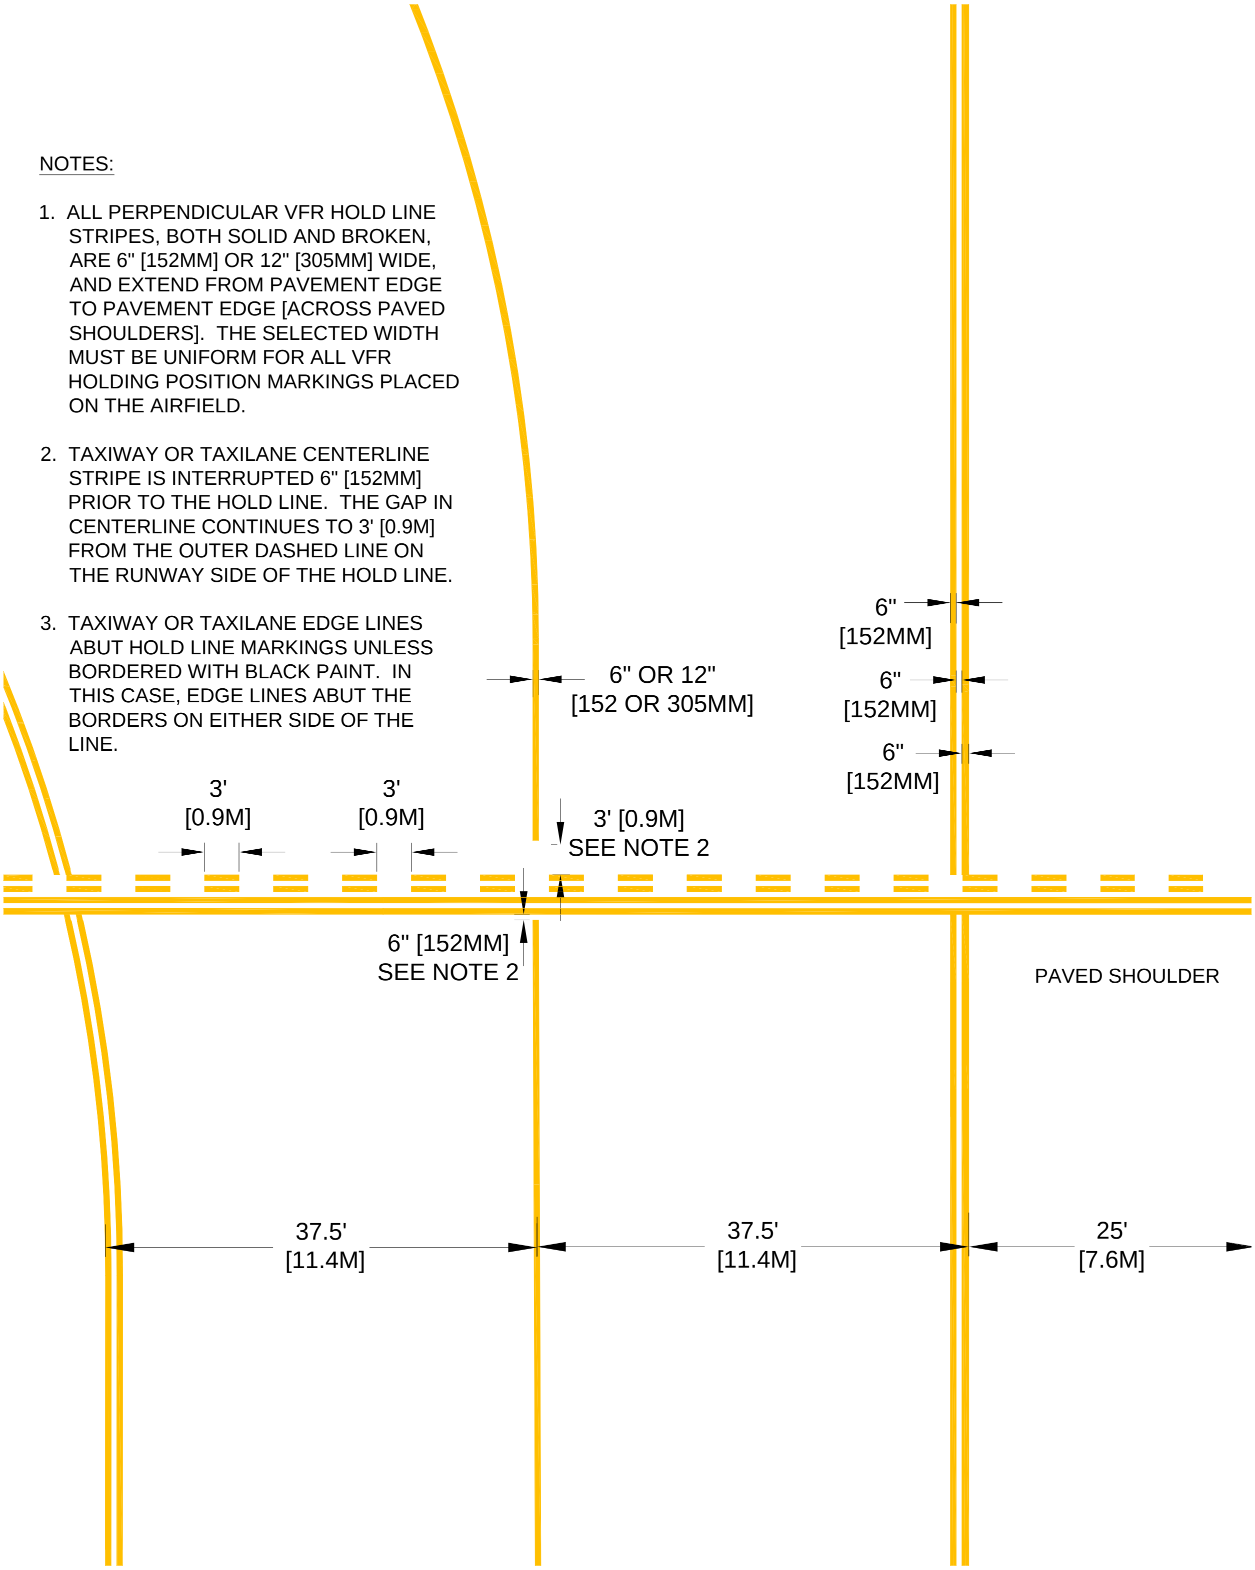
6-5.1 Runway Hold Positions.

There are two patterns for marking runway hold positions: one is used to mark holding positions used for VFR conditions and the other is used to mark holding positions for IFR conditions. Both types are marked in retro-reflective yellow paint and are optionally enhanced with black borders on light-colored pavement. Runways served by precision instrument navigation aids might require an instrument holding position be marked in addition to the VFR holding position. Where practicable, collocate these markings and mark only the VFR holding position. If required, locate the instrument holding position further from the active runway to prevent taxiing or holding aircraft from interfering with signals transmitted to inbound aircraft during IMC and to prevent aircraft and vehicles from violating the precision obstacle free zone (POFZ). This marking is also used to identify the boundary of a microwave landing system (MLS) critical area and to identify the holding position for Category (CAT) II or CAT III operations.

6-5.1.1 VFR Runway Holding Position.

In all cases, a VFR holding position is marked. This holding position is located 100 feet (30.5 meters) to 250 feet (76.2 meters) from the near edge of the runway. The minimum setback from the runway edge is 100 feet (30.5 meters). This distance is measured perpendicular to the long axis of the runway. Measure distances from the runway centerline (divide the published runway width shown in the DoD FLIP by 2 and add the required holding position distance). VFR holding positions are marked from edge to edge of the pavement surface, including paved shoulders. Interrupt taxiway edge lines at the outer edge of the holding position marking, or its black border, if provided. No gap at the edge line interruption is required. Figure 6-3 shows layout and typical positioning for a VFR hold line. Where practicable, setback distances for the VFR runway holding position are increased for instrument runways and where the wingspan of the controlling aircraft is greater than 79 feet (24.1 meters). Suggested setback distances from the runway edge are 175 feet (53.3 meters) for controlling aircraft with wingspans from 79 feet (24.1 meters) up to 171 feet (52.1 meters); and 205 feet (62.5 meters) for controlling aircraft with wingspans greater than 171 feet (52.1 meters). Increase these distances by 1 foot (0.3 meter) for each 100 feet (30.5 meters) of airfield elevation above mean sea level (MSL). Holding positions are placed perpendicular to the runway centerline on taxiways that enter at an angle to the runway; however, do not mark them to allow any portion of the holding aircraft to encroach beyond the minimum established distance.

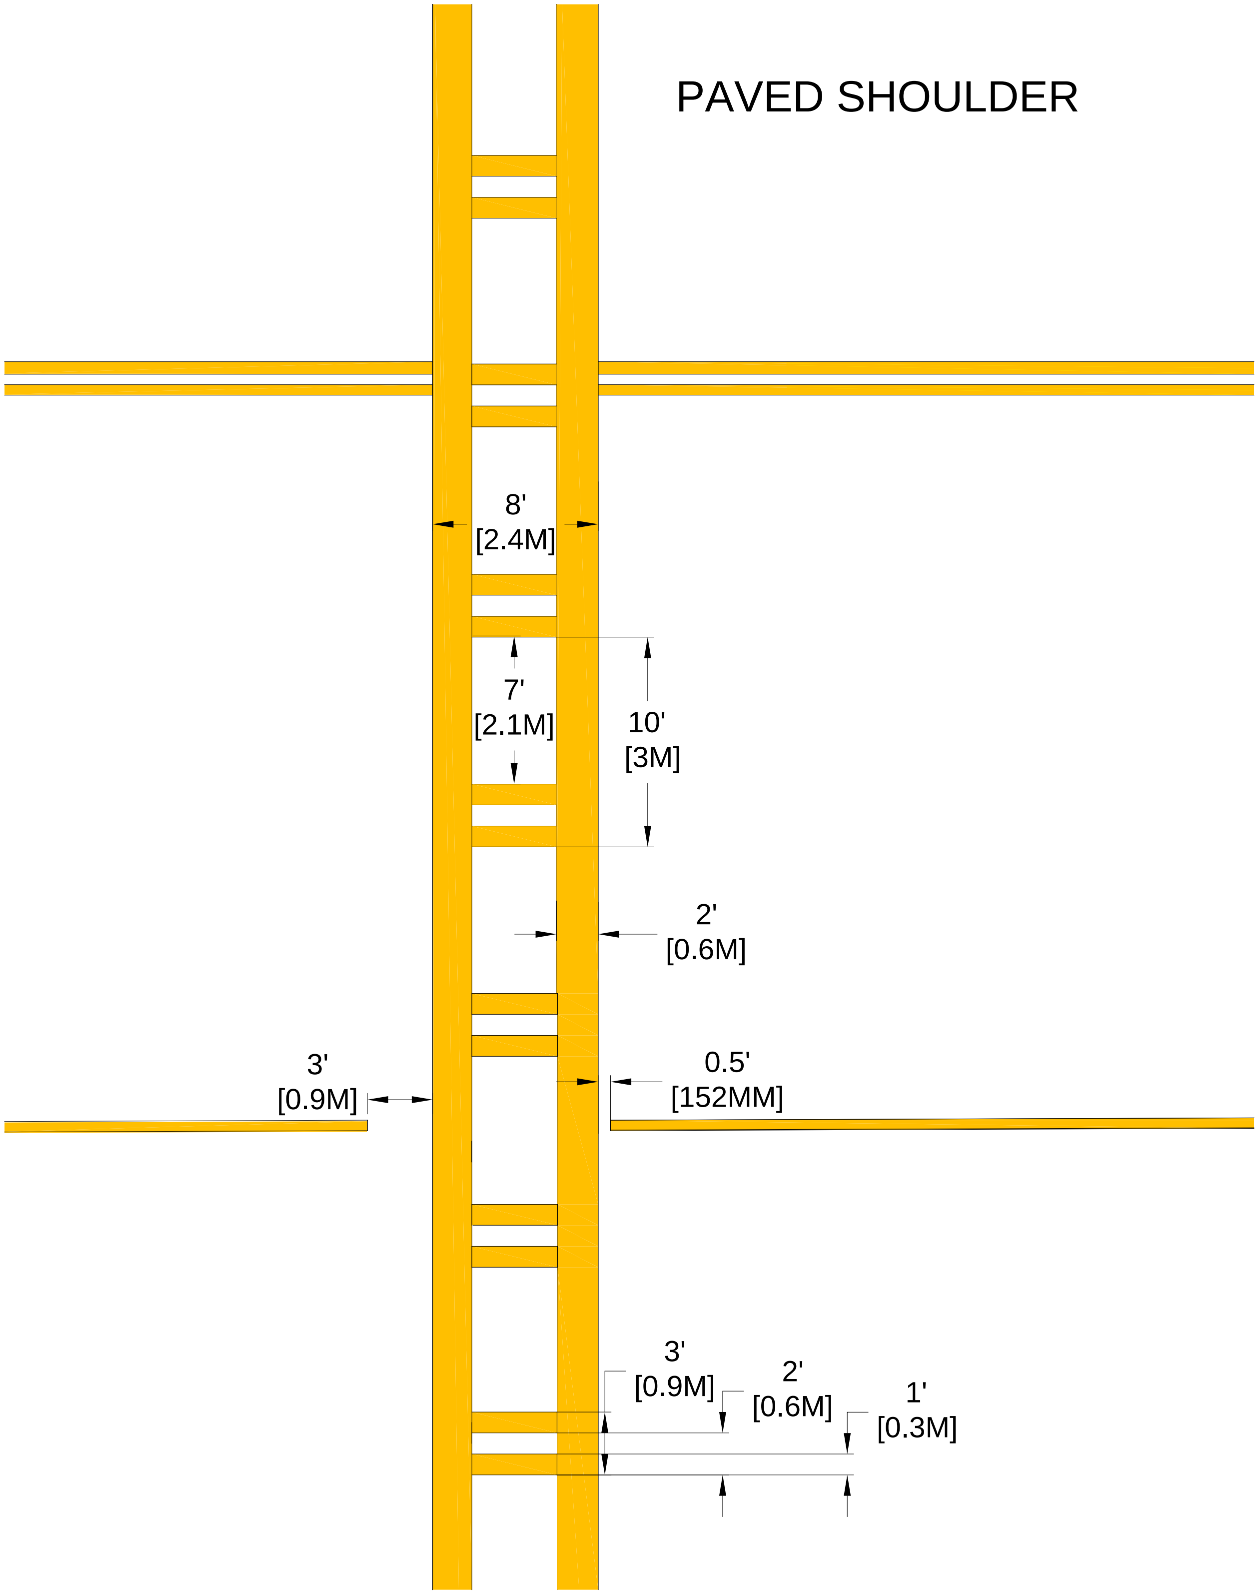
Figure 6-3. VFR Hold Position Markings



6-5.1.2 Instrument Meteorological Conditions (IMC) Holding Position.

The IMC hold position is configured differently from a VFR hold. Locations for the instrument hold line vary, depending on the type and capability of the landing aid. An IMC holding position is only marked when located at a different point along the taxiway (or on a cross-wind runway used for taxi operations or LAHSO). When needed, they are located to prevent interference with electronic navigational aids (NAVAIDs) and provide additional safety during periods of reduced visibility. If an instrument hold line is needed and the taxiway where it needs to be marked also penetrates the POFZ, only one holding position marking is installed to delineate the applicable critical area and the POFZ. The holding position marking is located at the more conservative boundary of the two areas (generally the farthest from the runway). In this instance, the instrument and POFZ holding position markings are not replaced with a VFR runway holding position marking. The airfield manager works with the instrument procedures specialist to designate the applicable critical area and POFZ boundaries, and, as appropriate, determine the holding position location. Figure 6-4 shows the layout for an instrument hold line. Figures 6-5 and 6-6 depict typical positioning for these hold lines. The markings are typically installed perpendicular to the taxiway centerline but might be canted from the perpendicular in unique situations. All holding positions are marked from edge to edge of the pavement surface, including paved shoulders. Interrupt taxiway edge lines at the outermost edges of the holding position marking, or the black borders, if provided. Interrupt centerlines 6 inches (152 millimeters) before the side of the marking where aircraft are to hold and provide a 3-foot (1-meter) gap on the runway side of the marking. No gap at the interruption of edge lines is required. The gap distances cited for the centerline include the black borders, when provided.

Figure 6-4. ILS Hold Position Details



6-5.1.3 Locating IMC Hold Position Markings.

If the height above touchdown (HAT) is 200 feet (61 meters) or greater (ask the airfield manager), mark the instrument holding position at the edge of the glide slope critical area as shown in Figure 6-5. If the HAT is less than 200 feet (61 meters), mark the holding position at the edge of the TDZ critical area or the glide slope critical area, whichever results in a distance farther from the edge of the runway. The glide slope critical area and TDZ critical areas are shown in Figures 6-5 and 6-6. The instrument hold line is placed at least 500 feet (152.4 meters) from the runway centerline when TDZ critical area criteria apply.

Figure 6-5. Locating Instrument Hold Position to Protect Glideslope Critical Area

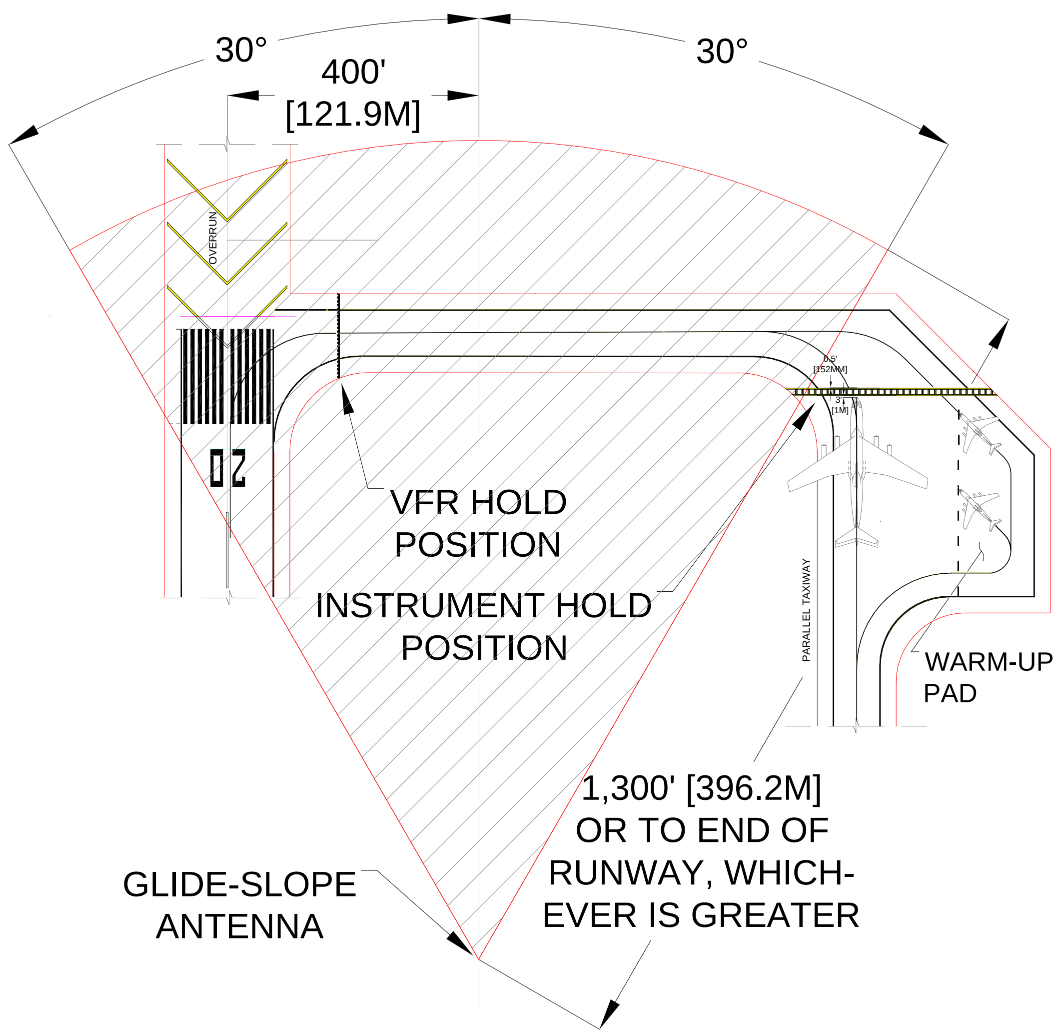


Figure 6-6. Locating Instrument Hold Positions to Protect Touchdown Zone Critical Area

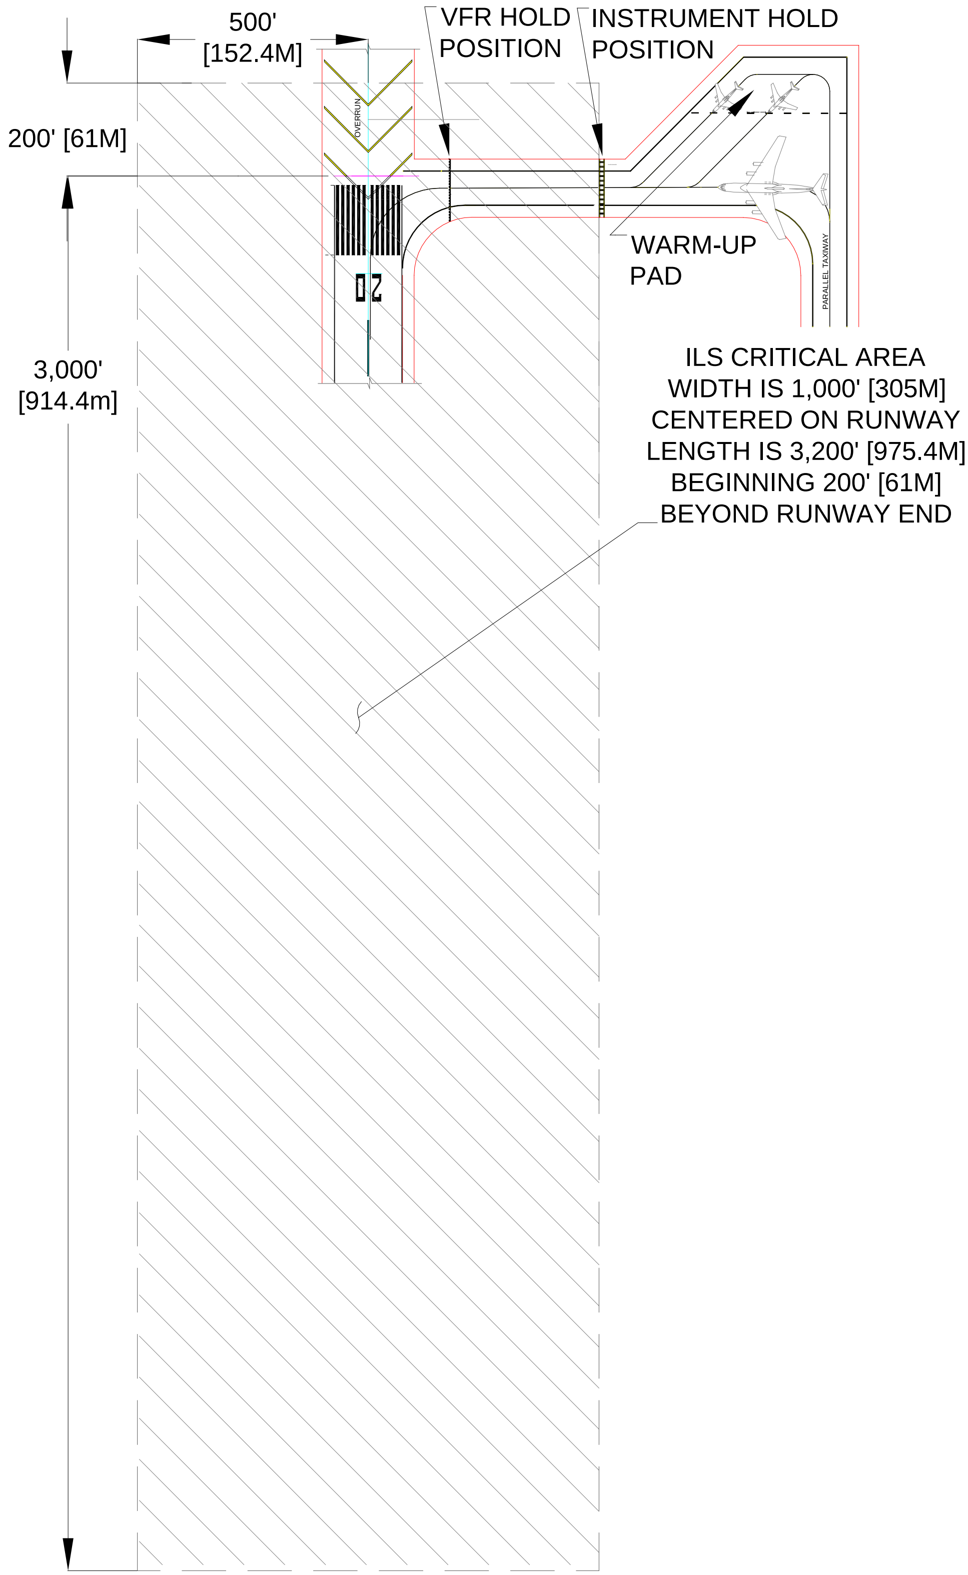


6-5.2 Runway/Runway Holding Position Marking Layout and Placement.

LAHSO for runway/runway intersections require a letter of agreement between the airfield operations authority and the air traffic control tower (ATCT) authority. When a holding position is necessary for such operations, it is marked in one of the patterns described above; however, its location is not less than 280 feet (85.3 meters) from the adjacent runway centerline. This distance is increased by 1 foot (0.3 meter) for each 100 feet (30.5 meters) of airfield elevation above MSL. Such hold lines are located further away to avoid interference with intersecting taxiway clearances and interrupts all other runway markings other than a designation marking. The runway holding position marking extends across the full width of the runway but not onto the runway shoulders or onto any intersecting taxiway fillet.

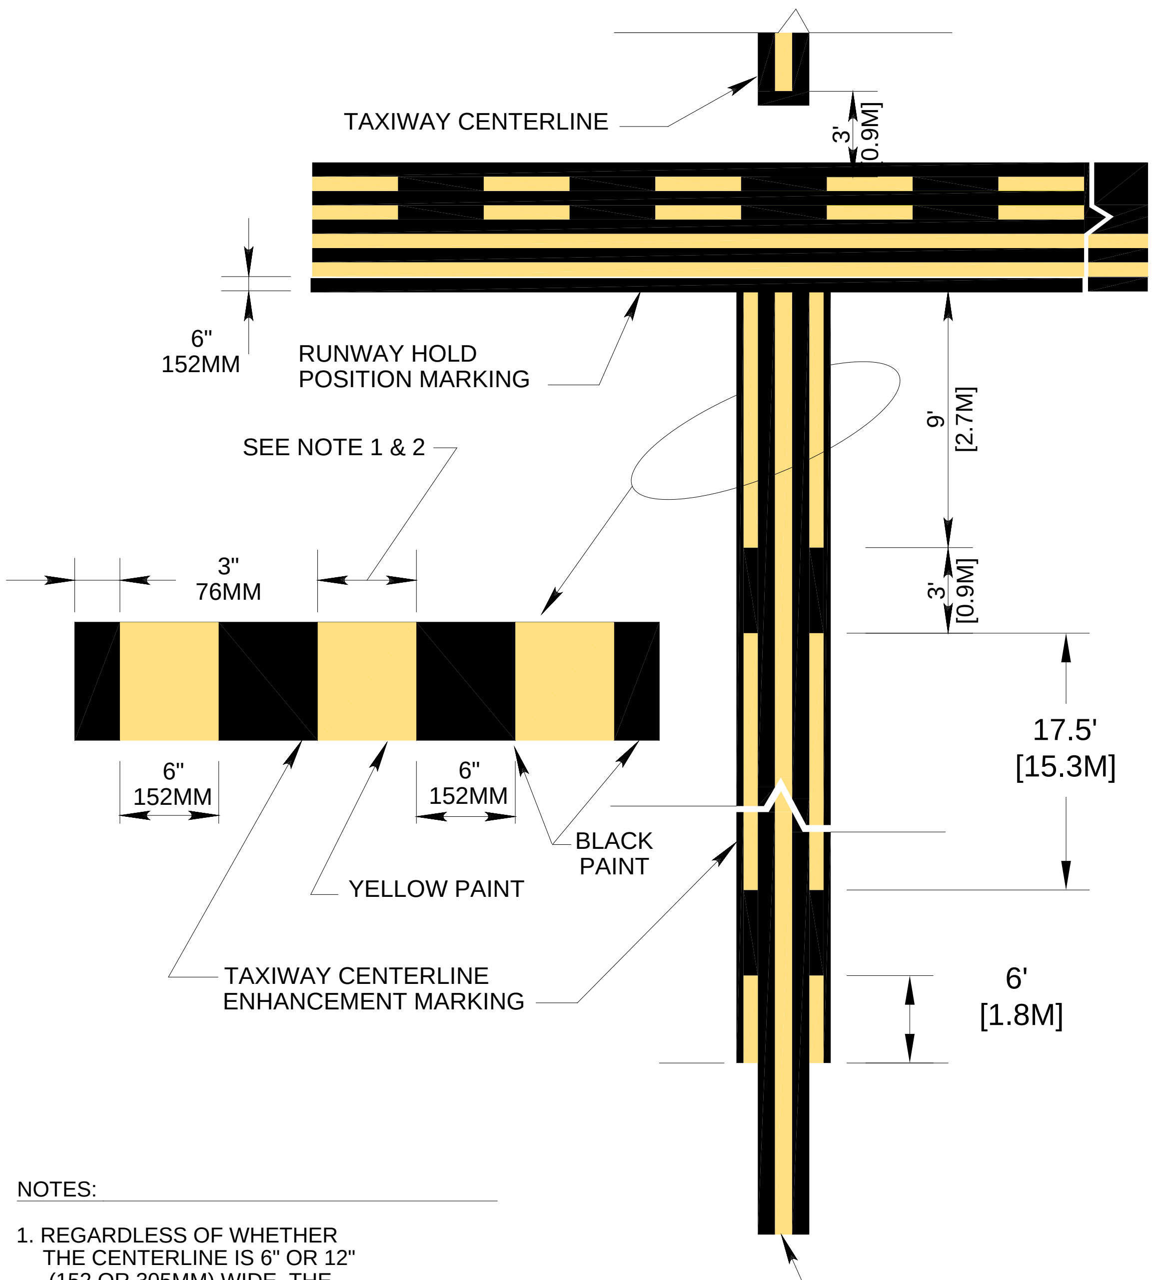
6-5.3 Enhanced Hold Position Marking.

Enhanced markings are intended to be a visual precursor to an approaching runway holding position. These markings are intended to prevent runway incursion and are optionally marked at any runway intersection for any DoD installation but are required at Part 139 (14 CFR Part 139) airports. See Figure 6-7 for details. For additional guidance on marking pavements at civil-owned facilities, see FAA AC 150/5340-1.

6-5.4 Intermediate Hold Position Markings.

Intermediate holding position markings identify the location for aircraft to hold short of an intersecting taxiway, or taxilane on an apron. These permissible markings are placed only where there is an operational need for aircraft to hold short of another taxiway or taxilane intersection. Intermediate holding position markings are retro-reflective yellow and are placed at a distance from the intersecting taxiway or taxilane to provide one-half the wingspan of the most demanding aircraft that uses the taxi path, plus the appropriate wingtip clearance as shown in Table 6-1 of UFC 3-260-01. When placing these markings to protect a taxiway, use the greater wingtip clearance as shown for a through taxilane. The intermediate hold position marking is a 6-inch (152-millimeter) or 12-inch (305-millimeter) -wide dashed line, where the dashes are 3 feet (0.9 meter) long and the gaps are 3 feet (0.9 meter) long; see Figure 6-8 for layout details. Interrupt taxiway or taxilane centerlines and edge lines 6 inches (152 millimeters) before and after the hold position line. Center a dash on the taxipath centerline. If the hold line crosses more than one centerline, center a dash on the path of highest use.

Figure 6-7. Enhanced Hold Position Markings



NOTES:

1. REGARDLESS OF WHETHER THE CENTERLINE IS 6" OR 12" (152 OR 305MM) WIDE, THE DASHED LINES PROVIDED BY THE ENHANCEMENTS WILL ALWAYS BE 6" (152MM)

2. IF TAXIWAY CENTERLINE LIGHTS ARE PRESENT, SHIFT THE TAXIWAY CENTERLINE EITHER RIGHT OR LEFT TO ENSURE THE ENHANCEMENT MARKINGS DO NOT COVER THE LIGHTS.

Figure 6-8. Intermediate Holding Position Marking

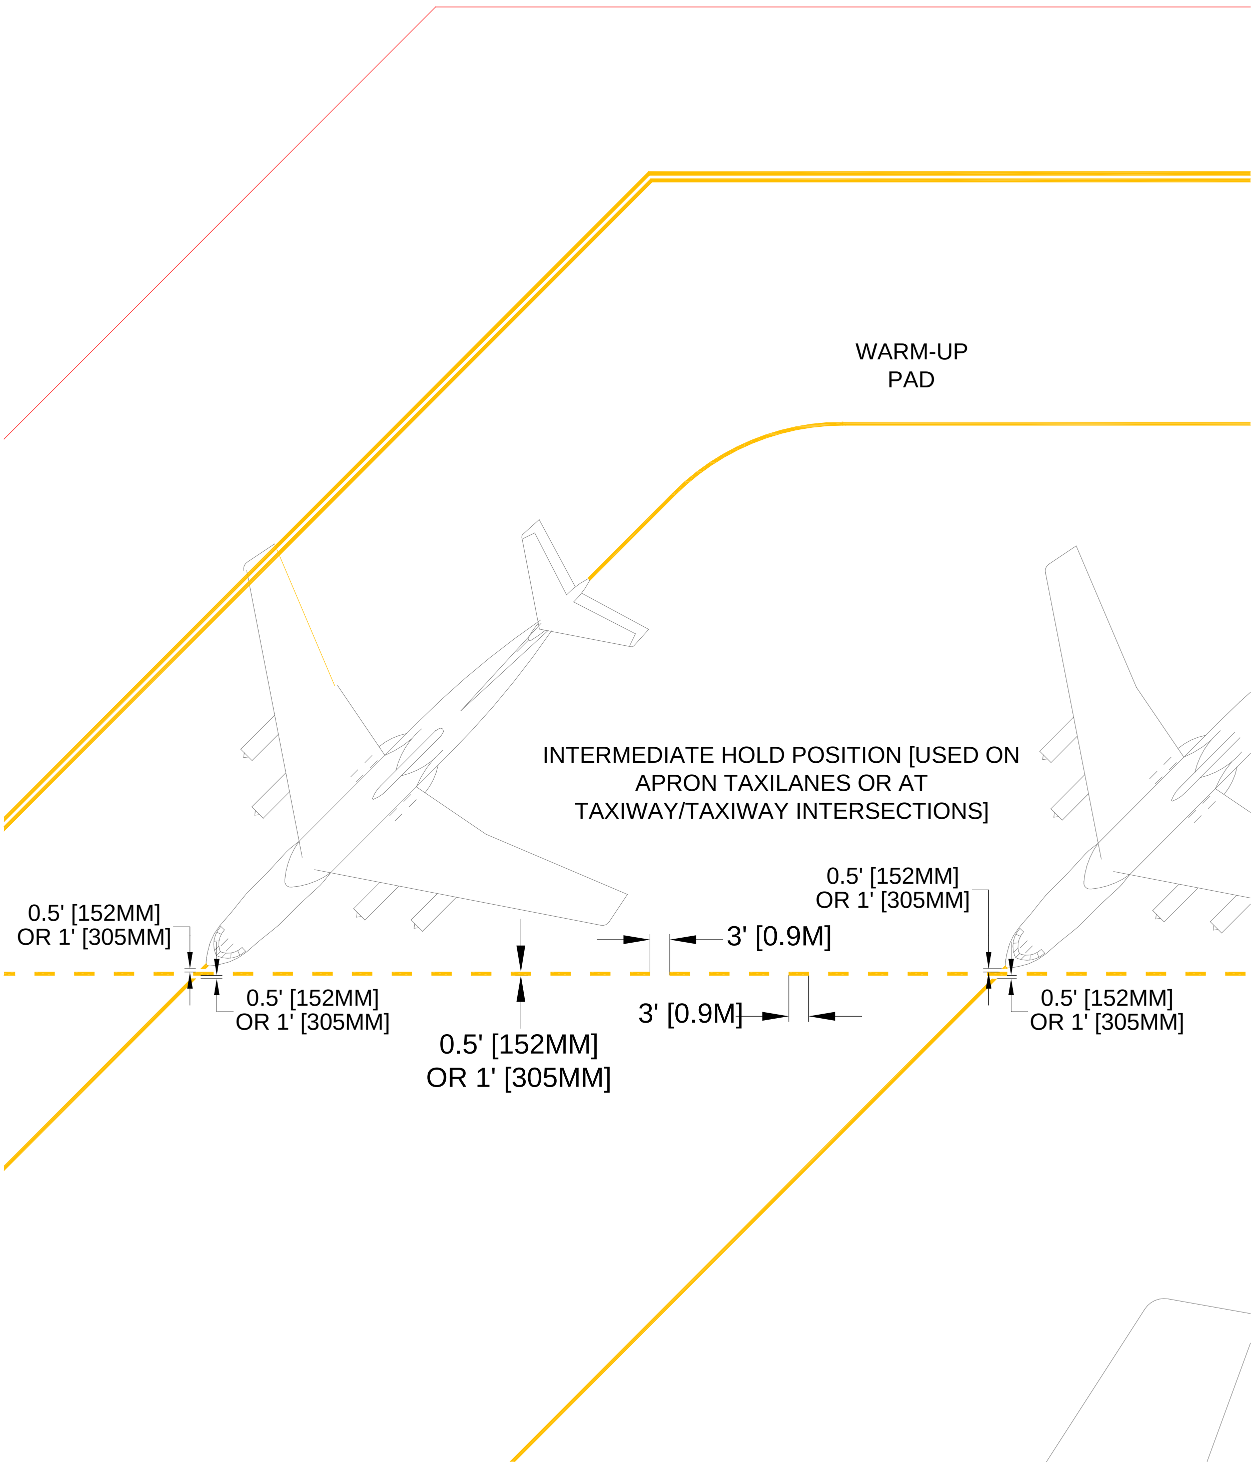


Figure 6-9. Taxilane Edge Stripes

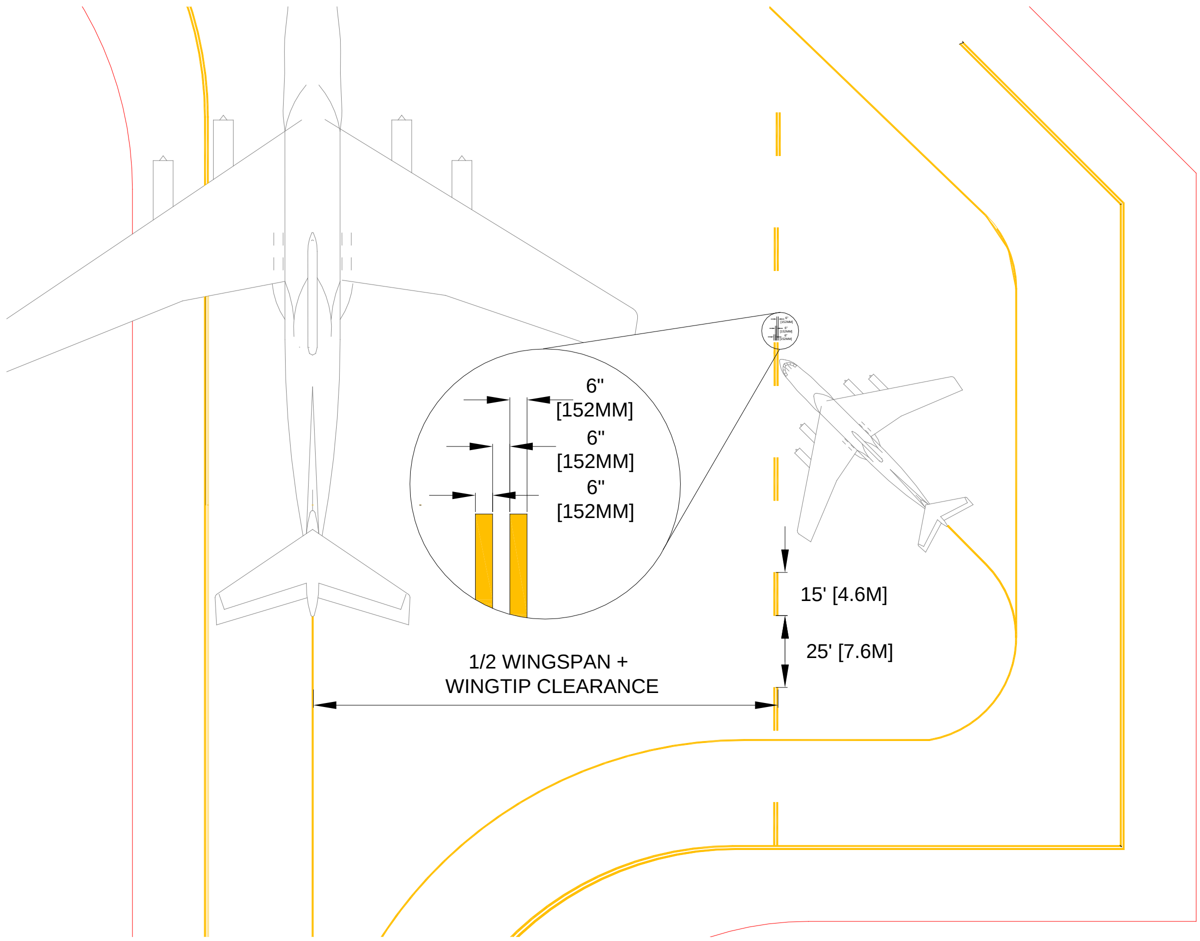


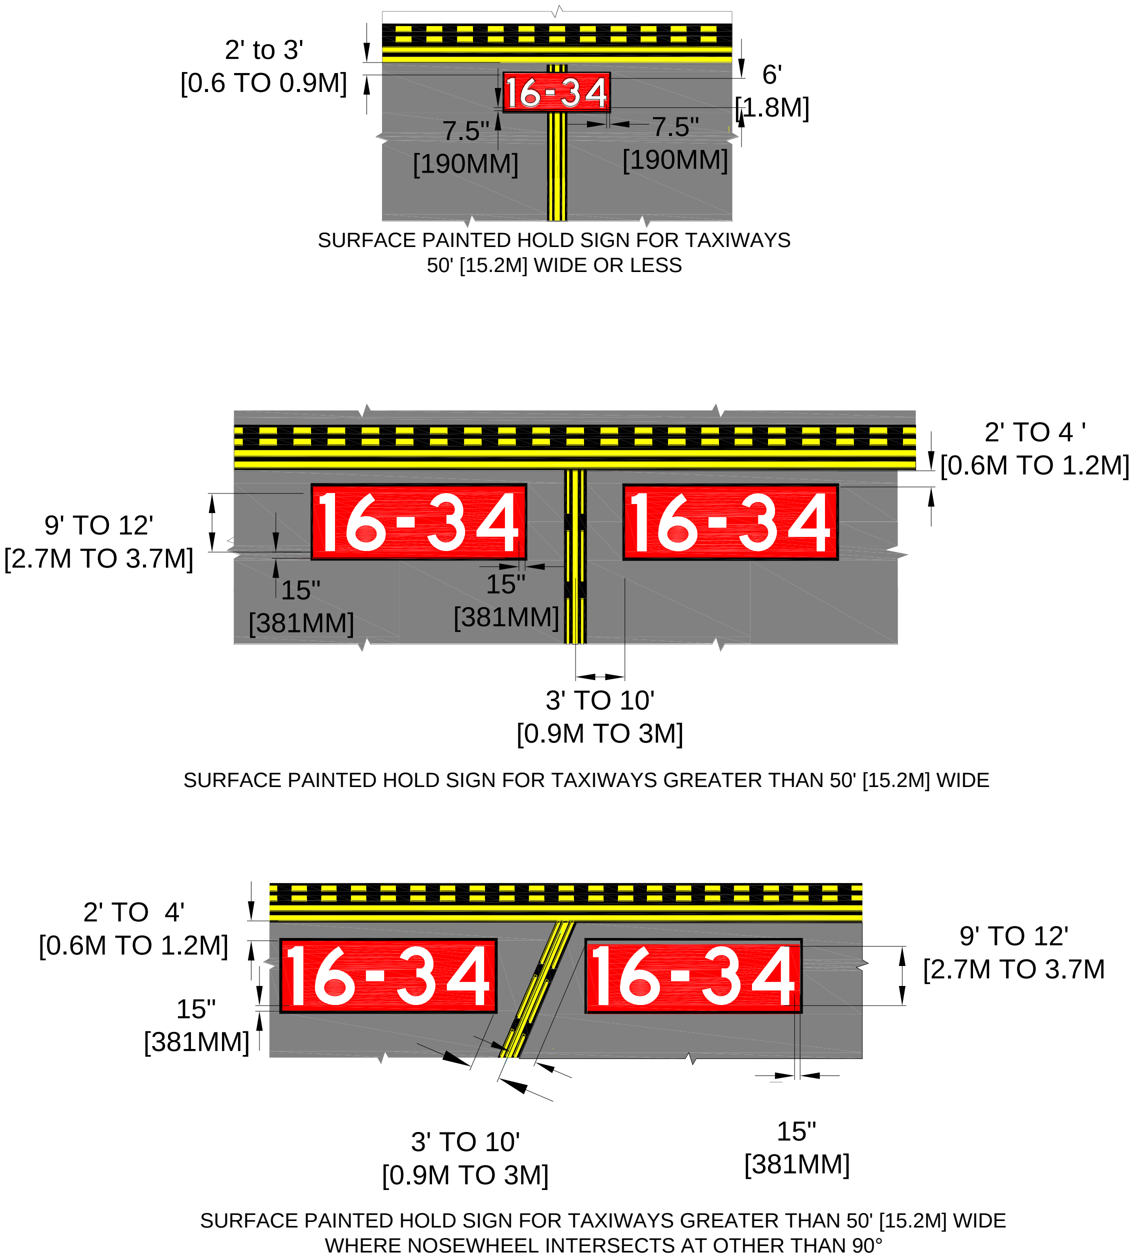
6-5.5 Surface Painted Signs.

Taxiway signs are described in UFC 3-535-01. Where it is desirable to furnish additional guidance at intersections or along taxiways or taxilanes, additional information is provided on the pavement surface. The most common surface-painted sign types are location, direction, and runway hold position signs. Under special circumstances, geographic position marking (GPM) signs are required. GPM signs are used repeatedly along a designated taxi route to serve as indicators of specific locations to allow pilots to confirm their position on the airfield during periods of low visibility. Low-visibility operations are defined as taxiing operations prior to takeoff or after landing that occur when the runway visual range (RVR) is below 1,200 feet (365.8 meters). See FAA AC 120-57 and both UFC 3-535-01 and FAA AC 150/5340-18 for sign requirements. See FAA AC 150/5340-1 for placement, layout, colors, and dimensions. Figures 6-10 through 6-12 show examples of typical runway hold position, location, and direction surface painted signs. The letters and numbers are formed according to the patterns shown in Figures 6-13 through 6-15.

6-5.6 Surface Painted Holding Position Signs.

The surface painted holding position sign provides supplemental visual cues that alert pilots and vehicle drivers of an upcoming holding position location and the associated runway designator(s) as a method to minimize the potential for a runway incursion, and, for certain airport geometries, wrong runway takeoffs. Several configurations of this surface painted sign are allowed to provide maximum flexibility. See Figure 6-10 for three possible layout scenarios. Inscriptions have a height of 12 feet (3.7 meters) where practicable; however, the height is reduced to a minimum height of 9 feet (2.7 meters) when necessary to appropriately fit the marking. Examples of these situations include taxiways with widths narrower than the applicable standard or taxiways that need to display multiple runway designations with directional arrows. In all cases, inscriptions follow inscription criteria shown in Figures 6-13 through 6-15. All other taxiway entrances to the same runway not needing the reduction are to maintain the 12-foot (3.7-meter) height dimension.

Figure 6-10. Surface Painted Runway Hold Position Signs



6-5.7 Surface Painted Taxiway Location Signs.

The surface painted taxiway location sign identifies the taxiway upon which the aircraft is located and is optional when required signage is not available. When necessary, this marking is also used to supplement other signs located along the taxiway system, or where operational experience has indicated that its presence assists flight crews in better ground navigation. These type signs are normally located on the right side of the taxiway centerline in the direction of travel. The edge (excluding the border) of the surface painted taxiway location sign is placed 3 feet (0.9 meter) from the outer edge of the taxiway centerline stripe. When adequate pavement width exists, a surface painted taxiway location sign might be located on the left side of the taxiway centerline if it is co-located with a surface painted holding position sign. In this case, the two surface painted signs mimic the mandatory holding position signs, and the surface painted taxiway location sign is placed to the left of the surface painted holding position sign to be readable in the direction of taxiing toward the runway. The inscription is 12 feet (3.7 meters) in height; however, the height is reduced if necessary to a minimum height of 9 feet (2.7 meters). See Figure 6-11 for an example and detail dimensions. The inscriptions conform in appearance and proportion with the letters, numbers, and symbols in Figures 6-13 through 6-15.

6-5.8 Surface Painted Taxiway Direction Signs.

The surface painted taxiway direction sign is always combined with an arrow to provide directional guidance at an intersection when it is not possible to provide an illuminated taxiway direction sign in accordance with UFC 3-535-01. An exception is where operational experience indicates the addition of a surface painted sign at a troublesome taxiway intersection assists aircrews.

6-5.8.1 The inner edge of surface painted taxiway direction signs (excluding the border, if used) is placed 3 feet (0.9 meter) from the near edge of the taxiway or taxilane nose wheel guideline and is placed on the same side of the nose wheel guideline as the direction the aircraft turns. For example, signs indicating left turns are located on the left side of the line and signs indicating right turns are located on the right side of the line**.**

6-5.8.2 The surface painted taxiway direction sign is not painted on runways, including runways sometimes used as a taxiway, between the runway VFR holding position marking and the runway, nor with surface painted hold position signs**.**

6-5.8.3 For crossing taxiways, a surface painted taxiway direction sign, combined with arrows, indicates the intersecting taxiway designation at the near intersection. In such cases, a single surface painted sign is located on the left side of the taxiway centerline to accommodate the possible directions of travel**.**

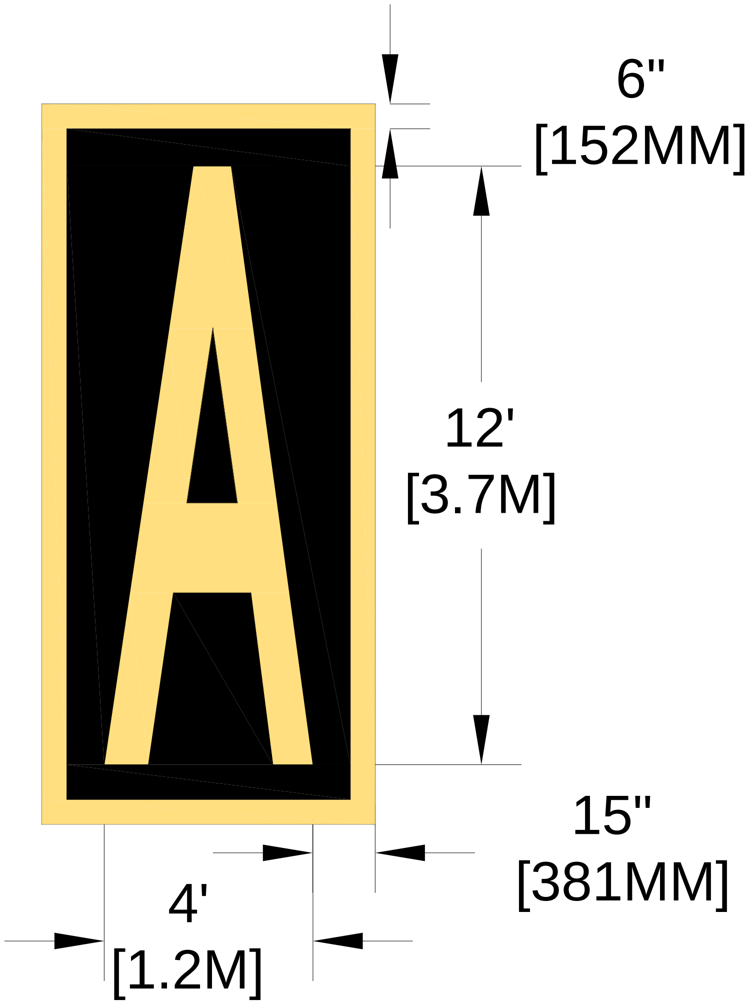
6-5.8.4 Locate these surface painted direction signs a longitudinal distance from crossing taxi routes at the appropriate aircraft wingtip clearance distance for the most demanding aircraft that uses the intersecting taxi route (taxiway or taxilane). These clearances are provided in UFC 3-260-01, Table 6-1, for fixed wing aircraft, and Table 6-2 for rotary wing aircraft**.**

6-5.8.5 The surface painted taxiway direction sign has a retro-reflective yellow background with a black inscription that includes one or more arrows. See paragraph 3-1.5 for recommended techniques to enhance this marking on light-colored pavements**.**

6-5.8.6 The black inscription is 12 feet (3.7 meters) in height; however, the height is reduced if necessary to a minimum height of 9 feet (2.7 meters). The black inscription is accompanied by an arrow oriented to show the general direction and angle of the turn. The inscriptions and arrows conform in appearance and proportion with the letters, numbers, and symbols in Figures 6-13 through 6-15.

6-5.8.7 The yellow background is rectangular and extends a minimum of 15 inches (381 millimeters) horizontally and vertically beyond the extremities of the black inscription, including the arrow head. A 6-inch (152-millimeter) -wide vertical black stripe separates any two black inscriptions when more than one is included on the same side of the nose wheel guideline**.**

Figure 6-11. Surface Painted Taxiway Location Sign

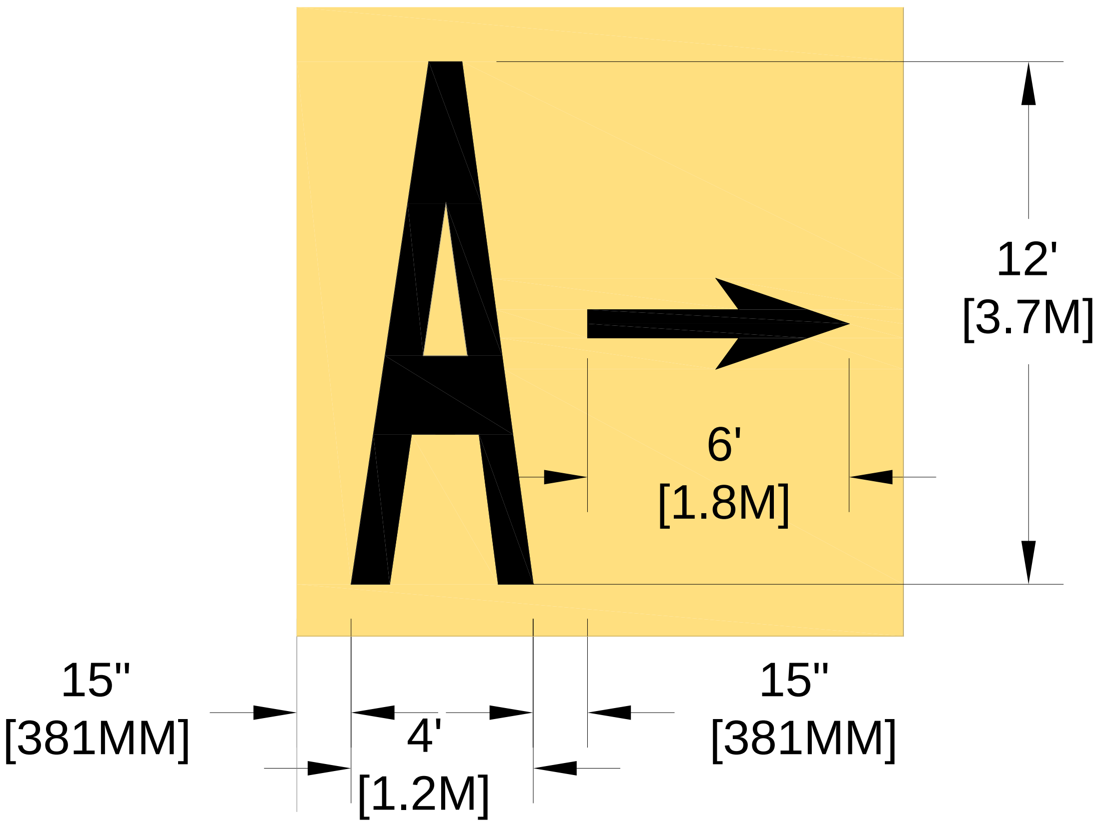


NOTES:

1. CHARACTER HEIGHT, WIDTH, AND LENGTH MAY BE REDUCED PROPORTIONATELY BY A FACTOR OF 0.75 (12' [3.7M] HEIGHT MAY BE REDUCED TO 9' [2.7M] HEIGHT IF STROKE AND CHARACTER WIDTH ARE ALSO REDUCED PROPORTIONATELY).

2. LOCATION SIGNS ARE NOT USED BETWEEN THE VFR HOLD POSITION AND THE RUNWAY, OR ON RUNWAYS USED AS TAXIWAYS.

Figure 6-12. Surface Painted Taxiway Direction Sign

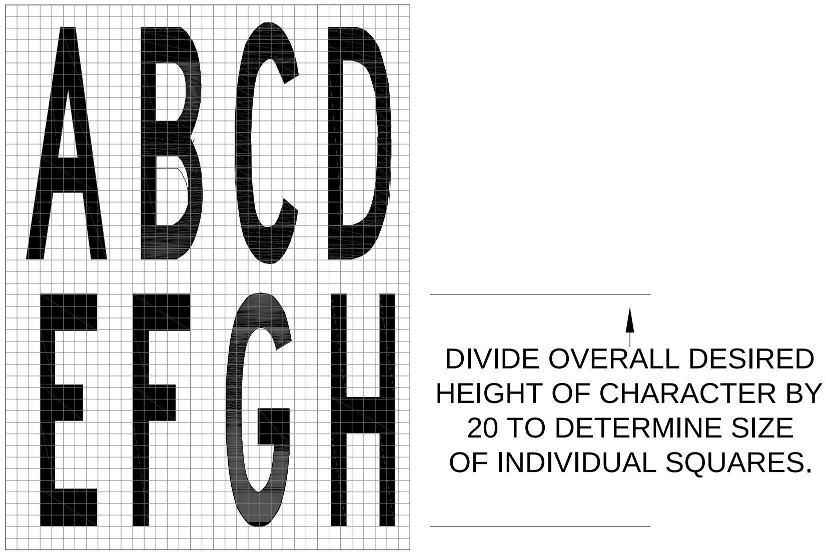


NOTES:

1. CHARACTER AND ARROW HEIGHT, WIDTH, AND LENGTH MAY BE REDUCED PROPORTIONATELY BY A FACTOR OF 0.75 (12' [3.7M] HEIGHT MAY BE REDUCED TO 9' [2.7M] HEIGHT IF STROKE AND CHARACTER WIDTH ARE ALSO REDUCED PROPORTIONATELY).

2. LOCATION SIGNS ARE NOT USED BETWEEN THE VFR HOLD POSITION AND THE RUNWAY, ON RUNWAYS USED AS TAXIWAYS, NOR ARE THEY COLLOCATED WITH SURFACE PAINTED HOLD POSITION SIGNS.

Figure 6-13. Surface Painted Sign Inscription Layout, A through P



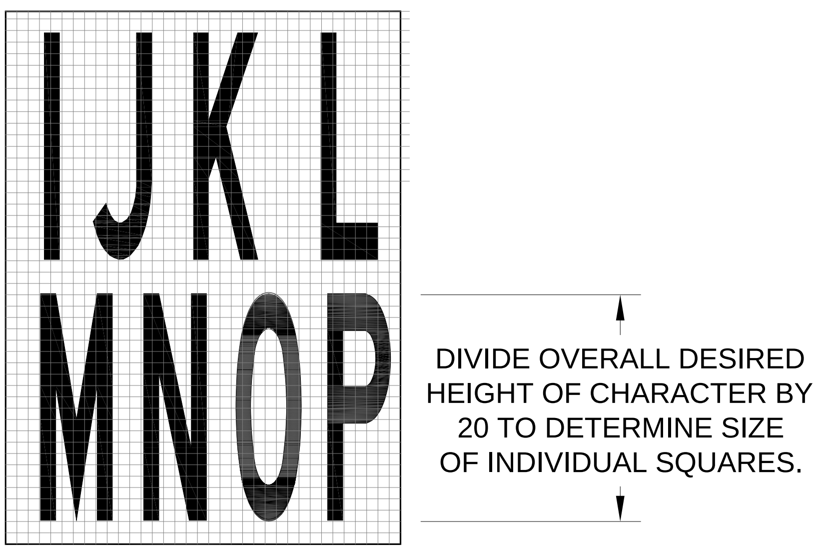


Figure 6-14. Surface Painted Sign Inscription Layout, Q through 6

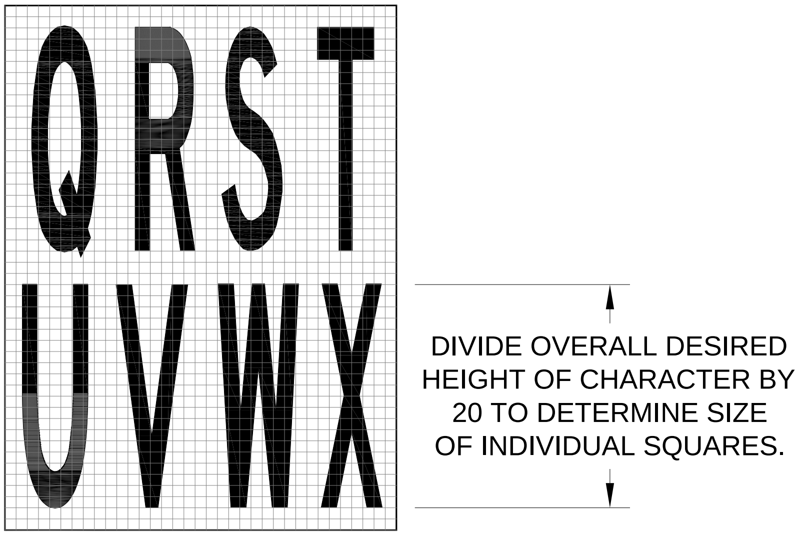

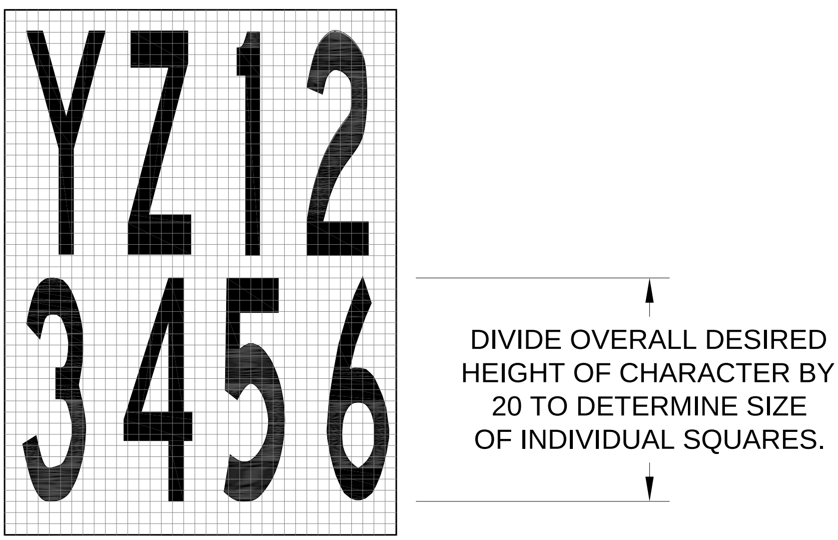

Figure 6-15. Surface Painted Sign Inscription Layout, 7 through 0 and Directional Arrow

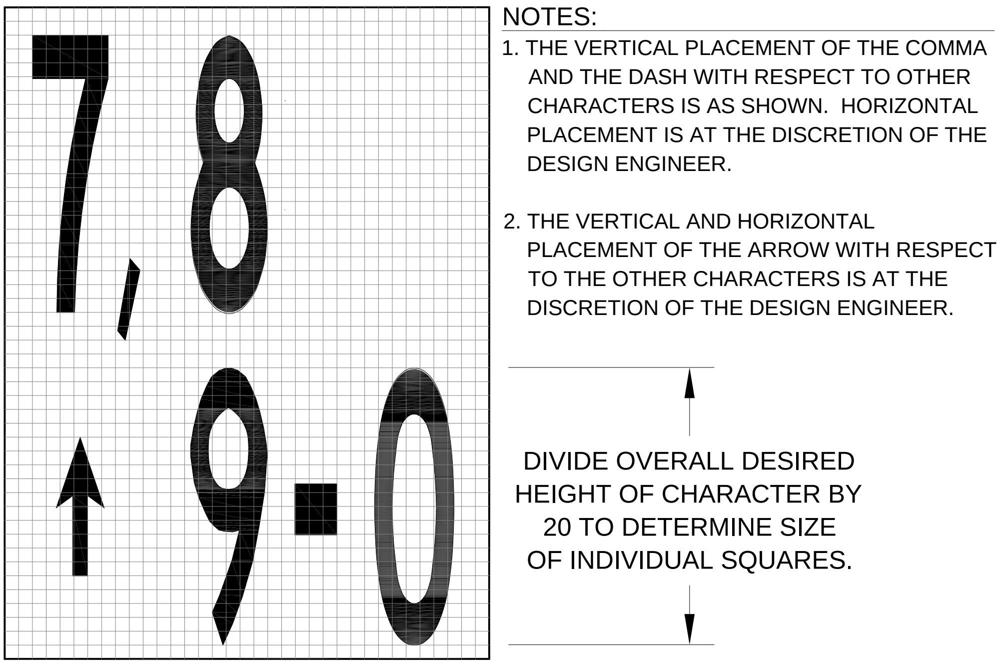
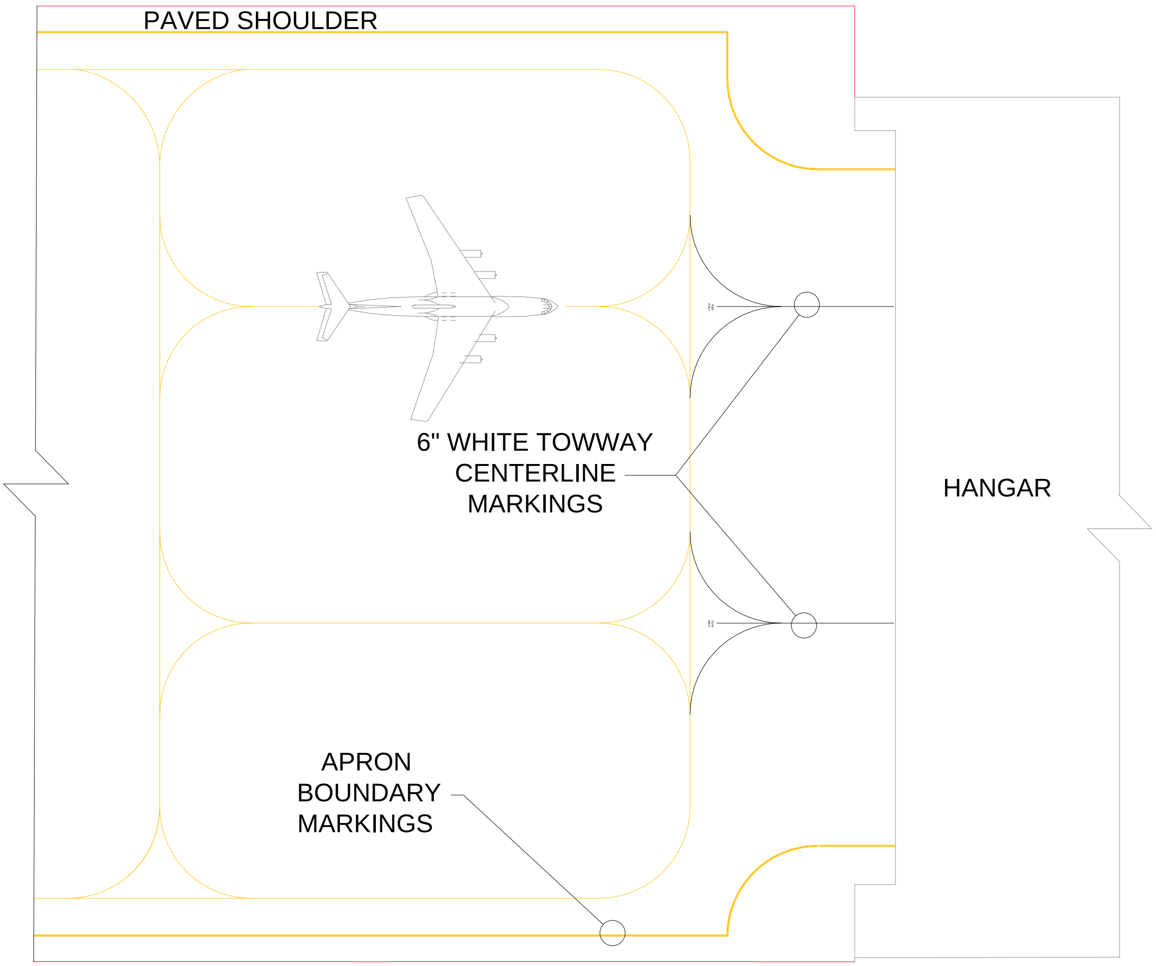


6-5.9 Towway Markings.

For taxilanes where aircraft are to be towed, provide a single, solid, continuous 6-inch (152-millimeter) -wide white painted stripe. A significant gap is provided between the yellow taxilane marking and the white towway lane marking to allow the taxiing pilot to see that the towway is not a continuation of the taxilane. See Figure 6-16.

Figure 6-16 Towway Centerline Marking



NOTES:

1. TOWWAY CENTERLINES ARE 6" [152MM] WIDE WHITE LINES LAID OUT TO MAINTAIN MINIMUM CLEARANCES GIVEN WITHIN CHAPTER 5 OF UFC 3-260-01, *AIRFIELD AND HELIPORT PLANNING AND DESIGN*. USE OF RETROREFLECTIVE BEADS IS ALLOWED WHEN THESE MARKINGS MUST BE USED AT NIGHT.

2. TOWWAY CENTERLINES SHOULD NOT BE MARKED WITHIN THE AIRCRAFT OPERATING AREA OF THE APRON WHERE EXISTING TAXILANE CENTERLINES MAY BE USED FOR TOWING GUIDANCE. IF NECESSARY TO MARK THESE GUIDELINES WITHIN THE APRON BOUNDARIES, MARK THE BEGINNING OF EACH TOWWAY CENTERLINE "TOWWAY OR TOW ONLY" IN MIN 24" [610MM] HIGH LETTERS.

6-5.10 Restricted Area and Restricted Area Entry Control Points (ECP).

USAF AFI 31-101 and U.S. Army Regulation (AR) 190-16 prescribe signage, security force equipment, and security procedures for the protection of aircraft and the areas surrounding them. Borders and signage are necessary to identify these controlled and restricted areas. In cases where it is not practicable to establish a raised physical barrier, it is sometimes permissible to delineate such borders with a retro-reflective red, 6-inch (152-millimeter) -wide painted line surrounding the area, supplemented with ECP markings and warning signs at specific intervals. Spacing between boundary signs is usually 100 feet (30.5 meters); however, there are exceptions for areas with irregular terrain features and for abrupt changes in direction of the boundary, where the maximum distance is reduced. See UFC 3-120-01 for details necessary to mark retro-reflective signs on the pavement. See Figure 6-17 for an example of an ECP and Figure 6-18 for an example of a restricted area warning sign but refer to the specific Service component's security directives for the markings and sign legends required in each situation.

Figure 6-17. Restricted Area Entry Control Points (ECP)

NOTES:

1. ENTRY CONTROL POINT MARKINGS ARE 6" [152MM] WIDE BY 3' [0.9M) LONG RETROREFLECTIVE WHITE BARS SEPARATED BY 6" [152MM] GAPS.

2. THE RESTRICTED AREA BOUNDARY IS A 6" [152MM] WIDE RED BORDER AROUND THE RESTRICTED AREA. SEE AFMAN 31-101, *INTEGRATED DEFENSE.*

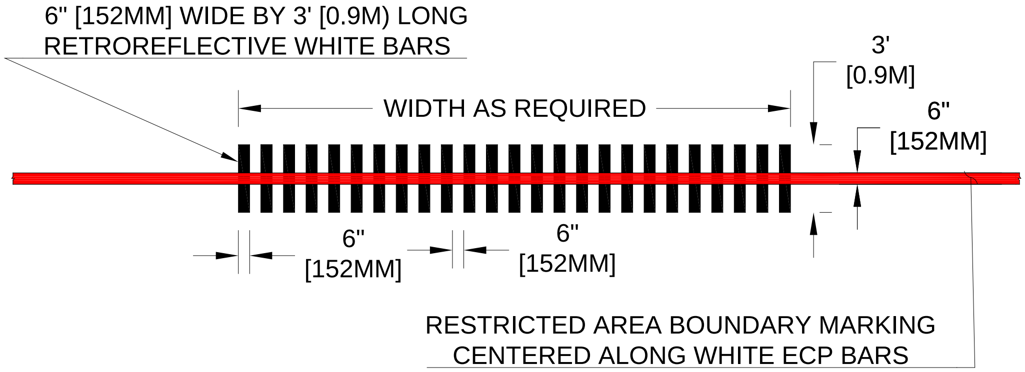


Figure 6-18. Typical Restricted Area Boundary Warning Sign

CHAPTER 7 MARKING PAVEMENTS FOR ROTARY WING OPERATIONS

7-1 GENERAL.

Marking rotary wing facilities conforms to the requirements as set forth below and govern the initial marking and re-marking of serviceable runways, taxiways, landing pads, and other areas designated for rotary wing operations.

7-2 MARKING WITH PAINT OR THERMOPLASTICS.

Do not use thermoplastics to mark rotary-wing helipads, runways, landing lanes, or taxiways due to potential for FOD.

7-3 COLORS AND REFLECTIVITY OF MARKINGS.

Rotary-wing runways, hoverpoints, and pads are marked with retro-reflective white except as noted below. Rotary-wing taxiways, taxi-lane and aprons are marked with retro-reflective yellow except as noted below. Hospital helipads incorporate red in the designator and borders. Rotary-wing shoulders (deceptive surfaces) and overruns are marked in non-reflective yellow durable marking materials except where noted otherwise. For Class A airfields and heliports that are not used strictly for missile security or survival school and are not trafficked by jet aircraft on a daily basis, identification markers, landing pads, and hoverpoints are marked using non-reflective white marking materials. In addition, taxiways, taxilanes, and apron markings on these Class A airfields and heliports are marked using non-reflective yellow durable marking materials except where otherwise noted.

7-4 PAVEMENT CURING TIME AND APPLICATION RATES.

Durable marking materials are applied only after the pavements have been allowed to cure thoroughly. New pavement surfaces are allowed to cure for a minimum of 30 days before application of marking materials. Take care to ensure the pavement surface is dry and clean prior to application of markings. See Chapter 3 for material application rates.

7-4.1 Rigid Pavements.

When painted markings are to be applied to rigid pavements cured with a membrane-type curing compound, the surface to be painted is thoroughly cleaned and the curing compound removed by sandblasting or high-pressure water blasting. Do not allow excessive blasting of the concrete surface when using high water pressure methods. Employ removal methods sufficient only to remove curing compound, old paint, or laitance, and not expose the coarse aggregate in the concrete.

7-4.2 Flexible pavements.

Flexible pavements are allowed to cure as long as practicable before marking to prevent undue softening of the bitumen by the paint or primers, as well as to limit bleeding. The maximum drying-time requirements of the paint specifications are strictly enforced.

7-5 INCREASING VISIBILITY OF MARKINGS.

A hoverpoint is a surface used as a reference or control point for arriving and departing helicopters. Mark hoverpoints with a white circle 30 feet (9.1 meter) in diameter on Class A airfields or heliports except when used for missile security or survival school or on asphalt surfaces where jet aircraft operate. On Class B airfields or Class A airfield/heliports used for missile security or survival school or on asphalt surfaces where jet aircraft operate, mark hoverpoints with a 30-foot (9.1-meter) -outside diameter circle formed with a 12-inch (305-millimeter) -wide white line. When located on a taxiway, the marking is centered on the taxiway centerline. See Figure 7-4.

7-6 HELICOPTER RUNWAY AND LANDING LANE MARKINGS.

Markings on serviceable runways consist of centerline marking, runway azimuth heading numbers, and an “H” letter without a helipad border as shown in Figure 7-1. Helicopter landing lanes are also marked to delineate three equal-length segments to accommodate four equally spaced landing pads, as shown in Figure 7-7.

7-6.1 Rotary-Wing Runway Designator.

The helipad “H” letter is located centered on the runway pavement centerline, 20 feet (6.1 meters) inboard from the beginning of the rotary-wing runway surface. The rotary-wing designator “H” is approximately 30 feet (9.1 meters) in length and 20 feet (6.1 meters) in width. See Figure 7-2 for placement on the runway pavement and Figure 7-3 for dimensions.

7-6.2 Azimuth Runway Designation Marking.

Runway designation is the numeric azimuth heading of the paved strip rounded to the nearest 10-degree increment. Each runway end is designated by number and, where required, by letter to indicate left, right, or center. Numbers and letters assigned are determined from the approach direction and conform to the form and dimensions shown in Figure 7-3.

7-6.2.1 The numeral(s) are retro-reflective white characters consisting of one or two numbers. The number assigned is the whole number nearest one-tenth of the magnetic azimuth of the centerline of the runway, measured clockwise from the magnetic north. Single-digit headings are not preceded by a zero (0). Lateral spacing between the numbers is 10 feet (3 meters), except for the numbers "10" and "11." Spacing between numerals for these runway designations are 7.5 feet (2.3 meters) and 12.5 feet (3.8 meters), respectively.

7-6.2.2 In the case of parallel runways, the retro-reflective white numeric designator and a letter (“L” for left, “C” for center, or “R” for right) are marked to indicate the lateral position of the runway with respect to any others with the same numeric designator on the same airfield.

7-6.2.3 In the case where a letter designation is required, it is placed between rotary-wing designator “H” and the numeric azimuth designator, with a 20-foot (6.1-

meter) gap between each of the characters. See Figure 7-1 for placement on the runway pavement and Figure 7-3 for letter dimensions.

7-6.3 Runway Centerline Marking.

The runway centerline is marked as a solid and continuous reflective white line, 1 foot (0.3 meter) in width. The centerline stripe of each runway terminates 20 feet (6.1 meters) from the runway direction numbers as shown in Figure 7-2.

7-6.4 Runway Side Stripe (Edge) Marking.

When there is little contrast between the runway and the paved shoulder or the surrounding area, the edge of the full-strength pavement is marked with a continuous 12-inch (0.3-meter) -wide stripe. This marking is used to delineate the edge of the runway from other pavements placed to prevent FOD or erosion. Such surfaces are not intended for routine use by aircraft. See Figure 7-1 for an example.

Figure 7-1. Helicopter Runway Markings

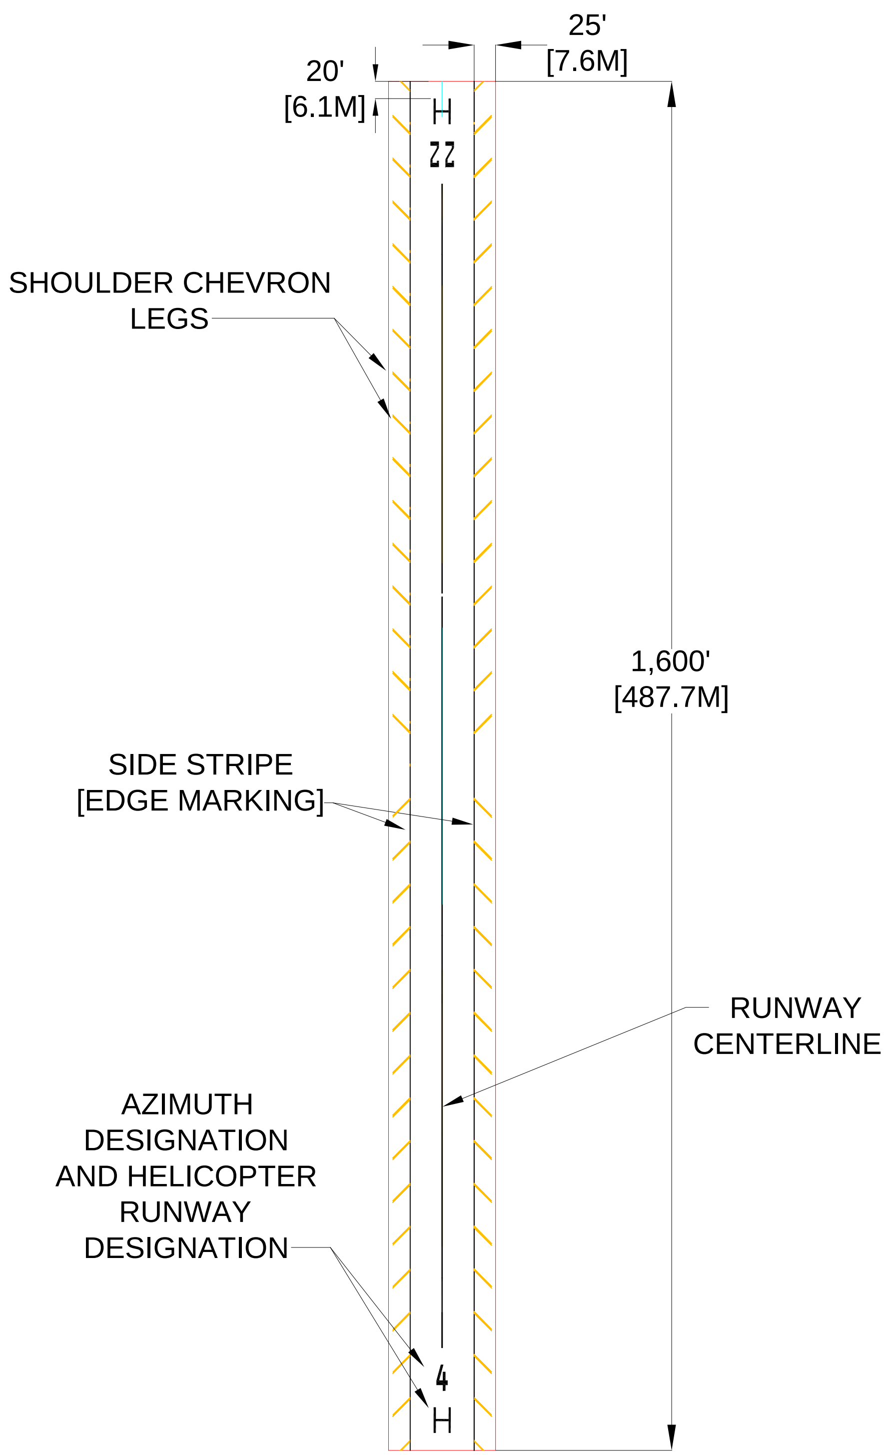

Figure 7-2. Rotary-Wing Designator and Designation Markings

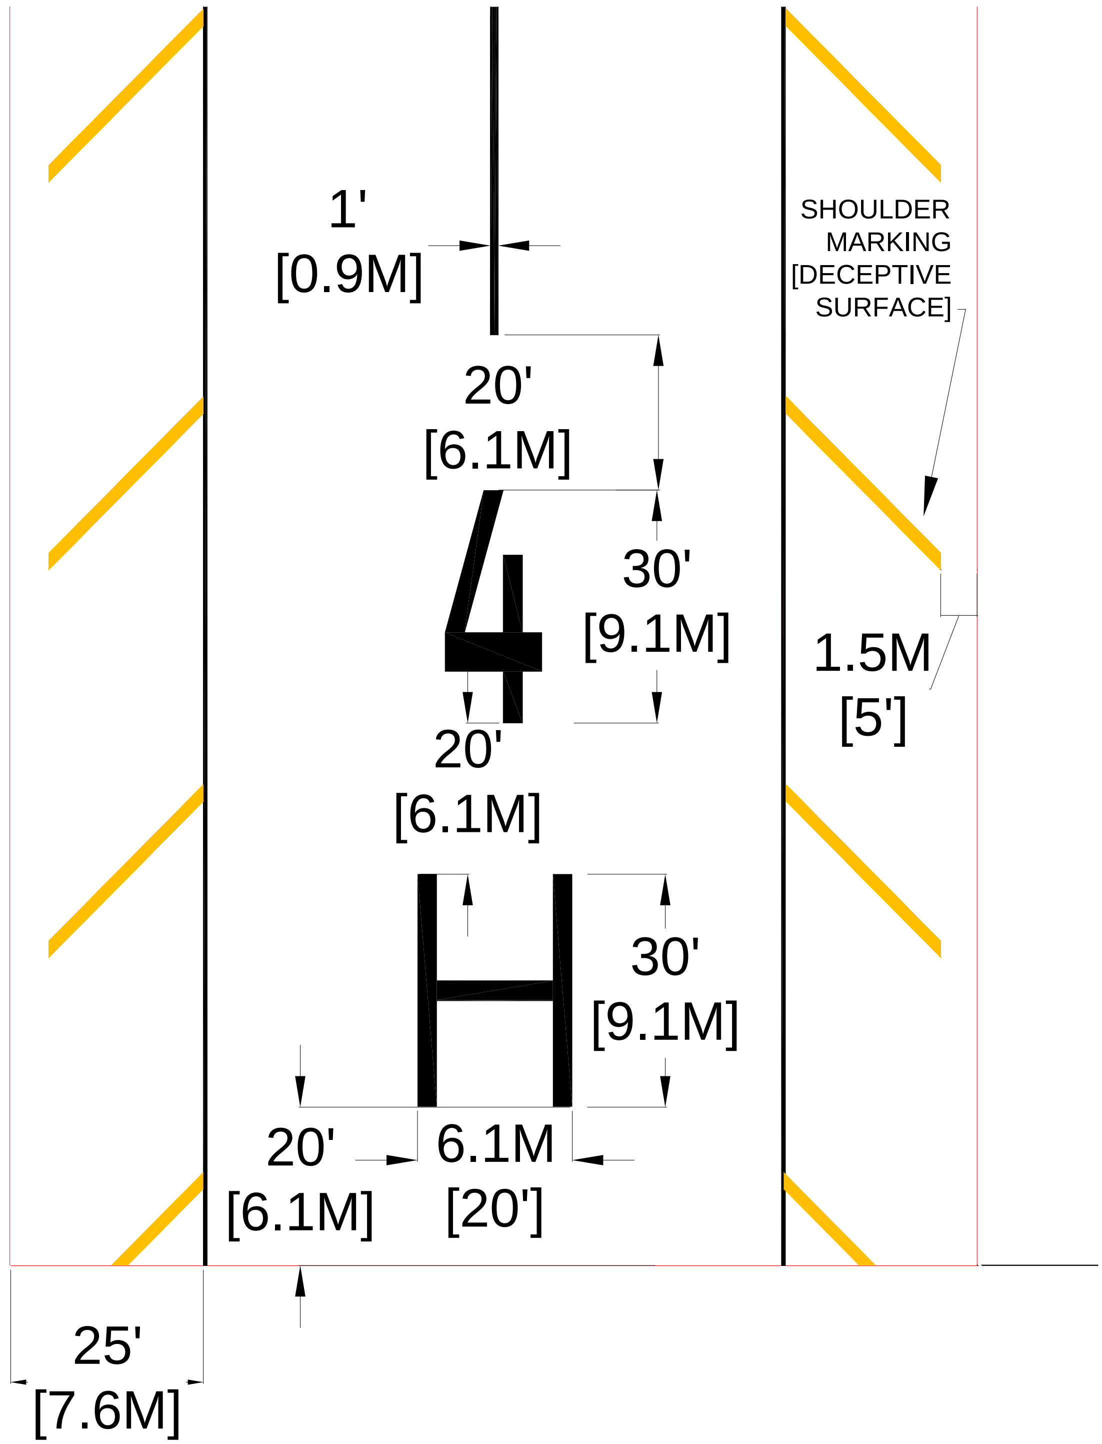

Figure 7-3. Rotary-Wing Runway Designation Numbers and Letters

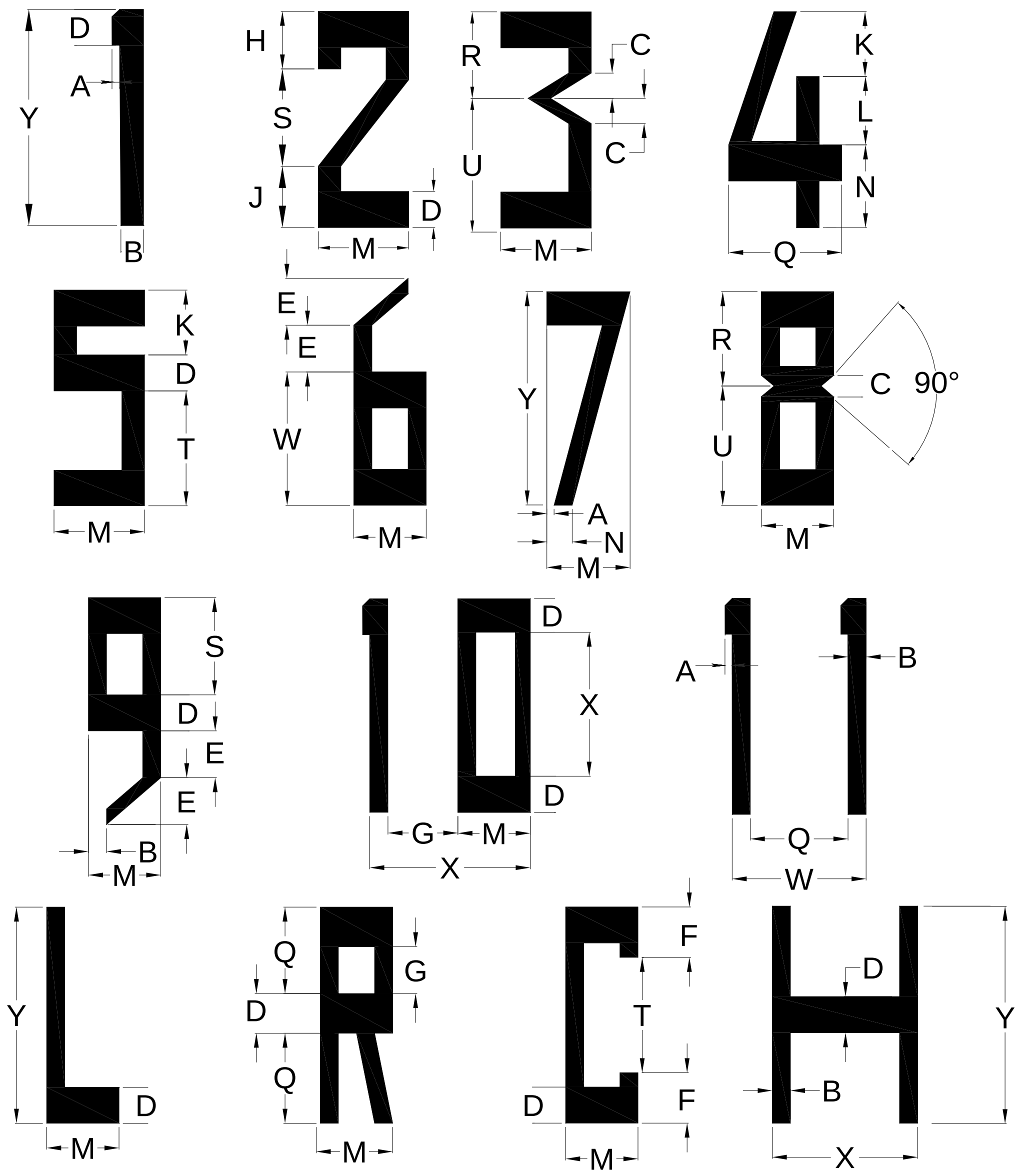

DIMENSION	FEET	METERS	DIMENSION	FEET	METERS	DIMENSION	FEET	METERS

* Not used.

7-7 TAXIWAY MARKINGS.

7-7.1 Centerline Marking.

Marking on serviceable taxiways consists of a centerline stripe and a holding line configured the same as for fixed-wing runways (see Chapter 5). The centerline stripe is a solid retro-reflective yellow line 6 inches (152 millimeters) in width. Where a taxiway and a runway have a common intersection, the centerline marking of the taxiway terminates at a point in line with the inside edge of the runway as shown in Figure 7-4.

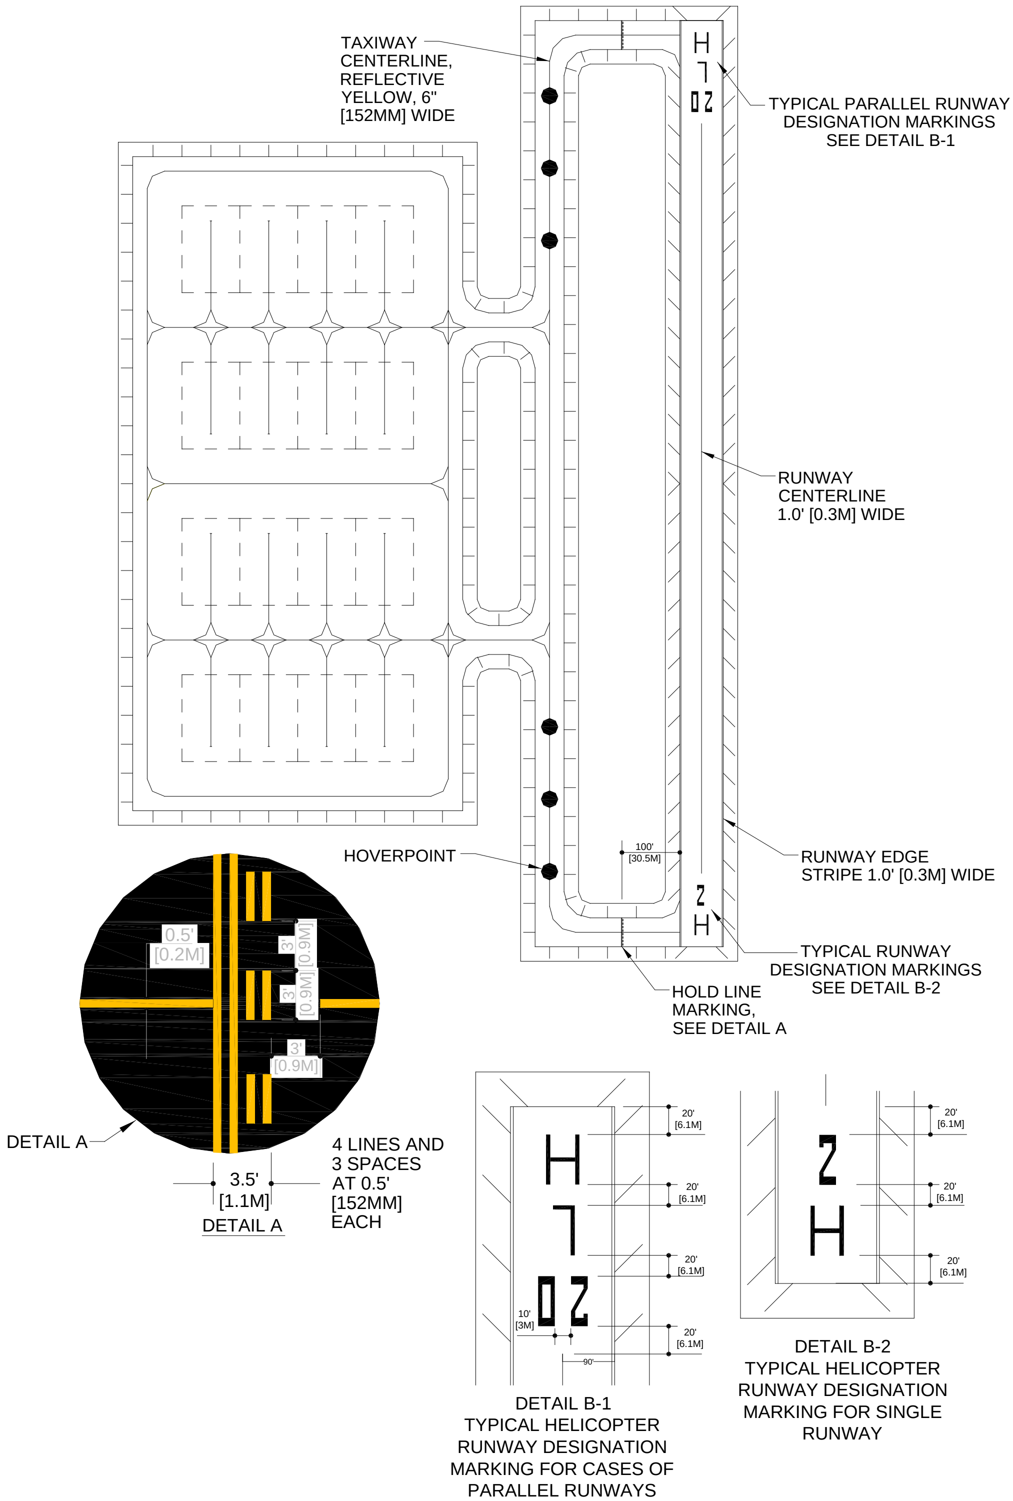
7-7.2 Hold-Line Marking.

Provide hold position markings at appropriate locations to protect against incursions. The hold-line marking for VFR conditions is shown in Detail "A" of Figure 7-4 and is located 100 feet (30.5 meters) from the near edge of the adjacent runway. Also mark an instrument hold marking for runways or helipads provided with IMC landing aids. See paragraph 6-5.1.2 to determine if an instrument hold position is needed, and, if so, where. If any taxiways enter the helipad in the normal direction of approach or departure, place a holding position marking outside the clear zone so there is no potential penetration of the approach departure clearance surface by holding aircraft. See UFC 3-260-01 for applicable dimensions and imaginary surface slopes.

7-8 HOVERPOINTS.

A hoverpoint is a surface used as a reference or control point for arriving and departing helicopters. Mark hoverpoints with a white circle 30 feet (9.1 meter) in diameter on class A airfields or heliports except when used for missile security or survival school or on asphalt surfaces where jet aircraft operate. On Class B airfields or Class A airfield/heliports used for missile security or survival school or on asphalt surfaces where jet aircraft operate, mark hoverpoints with a 30-foot (9.1-meter) -outside diameter circle formed with a 12-inch (305-millimeter) -wide white line. When located on a taxiway, the marking is centered on the taxiway centerline. See Figure 7-4.

Figure 7-4. Heliport Markings



7-9 APRON MARKINGS.

Apron taxi centerlines are a solid yellow line 6 inches (152 millimeters) in width. Rotary wing parking positions are marked with dashed white perimeter lines 6 inches (152 millimeters) in width, and centering guidelines are 6-inch [152-millimeter] -wide solid yellow as shown in Figures 7-12, 7-13, 7-14 and 7-15. Other apron markings such as apron edge markings, deceptive surface (shoulder) markings, and closed or hazardous area markings are as shown in Figure 7-11 and Chapter 8.

7-10 HELIPADS.

Mark a perimeter boundary with a capital "H" in the center to identify a pad intended for helicopter operations. Orient the “H” so it is aligned with the normal direction of approach (appears as an “H” to pilots during their approach to landing). If the facility is intended for single-direction ingress and egress, mark a bar beneath the “H” to show the intended direction of approach/departure. A bar is also placed under the “H” when it is necessary to distinguish the preferred approach direction for bi-directional helipads. The length of the bar is at least equal to the overall width of the “H” and the width equal to Dimension “C” in Figure 7-5. Provide a space between the “H” and the bar equal to half of the bar width. The perimeter boundary marking consists of a broken square marked at the corners and along the edges to delineate the limits of the safe touchdown area. The boundary is sized to accommodate the overall length of the largest helicopter using the facility. Figure 7-5 provides dimensions and layout details.

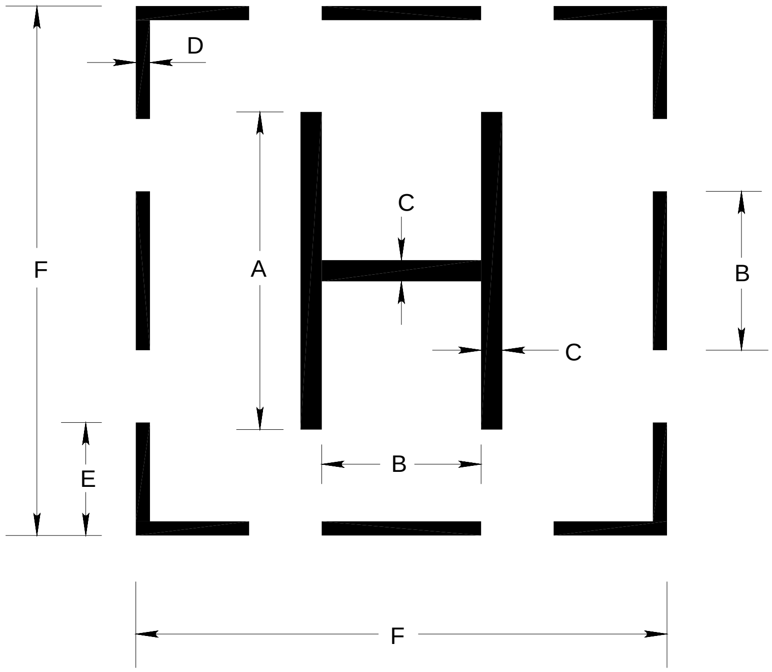
7-10.1 Hospital Helipad Markings.

Medical facility helipads are marked similarly to standard helipads, with the following exceptions: the perimeter border is formed of a solid line and bordered in red, and the letter "H" is marked in red and superimposed on a white cross. Figure 7-6 shows the dimensions and colors for this marking scheme. The cross and pad boundary markings are white and outlined with a 6-inch (152-millimeter) -wide red border to improve contrast. Pad boundary markings are either a solid or segmented line as shown in Figure 7-5.

7-10.2 Elevated Helipad Markings.

The markings are as shown in Figures 7-5 or 7-6, with two information boxes centered in the lower right-hand quadrant of the pad perimeter and oriented to be read in the preferred direction of ingress to the helipad. The boxes provide the maximum allowable helicopter weight expressed in thousands of pounds and the maximum allowable rotor diameter expressed in feet. Details for layout of the elevated helipad are shown in Figures 7-9 and 7-10.

Figure 7-5. Helipad Markings



IDENTIFIER DIMENSIONS

A : 0.6 F (maximum of 20 meters)

B : 0.5 A

HELIPAD SIZE (F)	PATTERN LINE WIDTH (C)	BORDER EDGE WIDTH (D)	CORNER EDGE LENGTH (E)
43.0 - 59 / 13.1 - 18.0	3.0 / 0.9	1.3 / 0.4	5.0 / 1.5
60.0 - 79.0 / 18.3 - 24.1	4.0 / 1.2	2.0 / 0.6	7.0 / 2.13
80.0 - 98.0 / 24.4 - 29.9	5.0 / 1.5	2.0 / 0.6	10 / 3.0
99 OR LARGER / 30.2 OR LARGER	6.5 / 2.0	2.5 / 0.8	11.5 / 3.5

NOTE:

1. DIMENSIONS IN TABLE ARE EXPRESSED AS; $\frac{\text{FEET}}{\text{METERS}}$ e.g. $\frac{3}{10}$
2. ALL COLOR IS NON-REFLECTIVE WHITE FOR U.S.ARMY FACILITIES, BUT RETRO-REFLECTIVE WHITE FOR USAF FACILITIES.

Figure 7-6. Hospital Helipad Markings

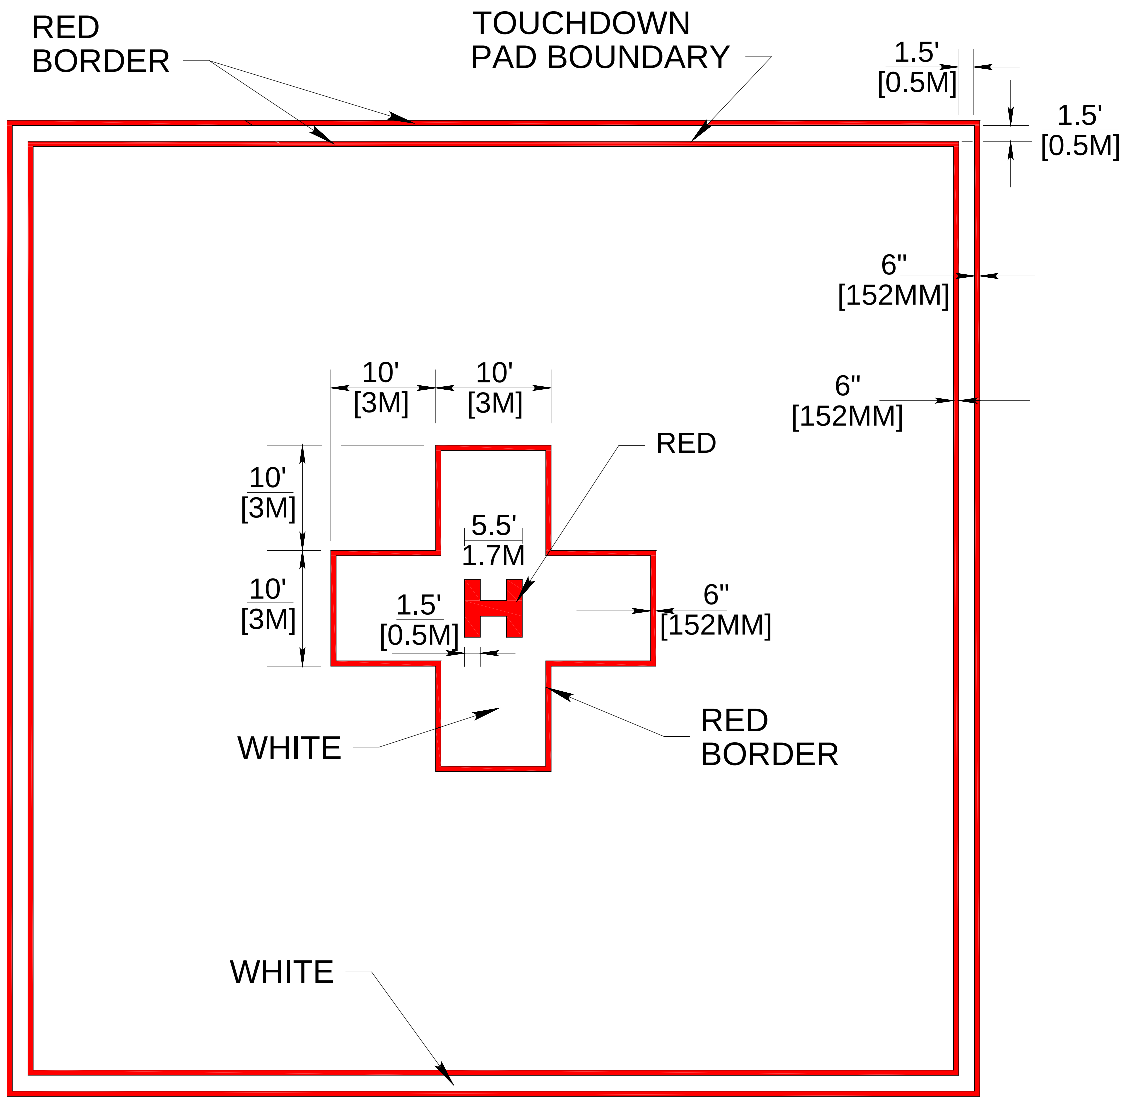


Figure 7-7. Landing Lane Layout

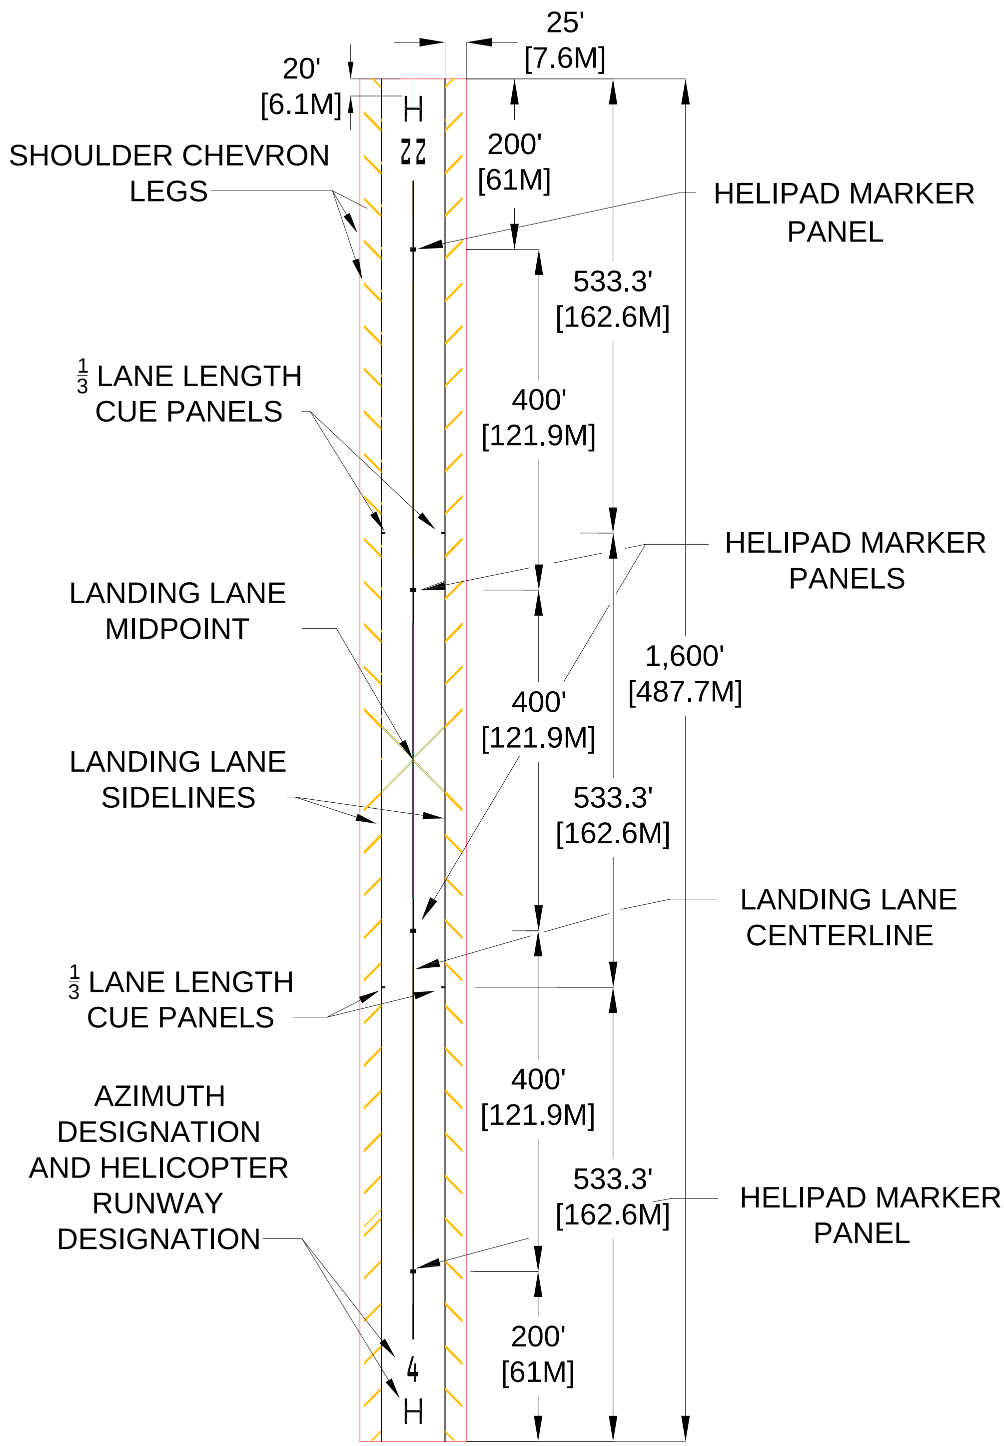

Figure 7-8. Landing Lane Helipad and 1/3rd Length Marker Panels

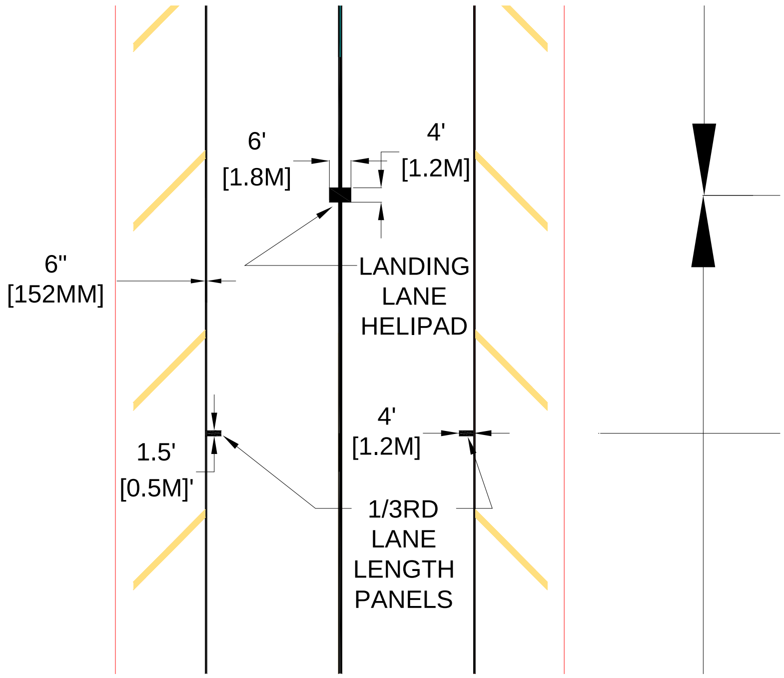

Figure 7-9. Elevated Helipad Example

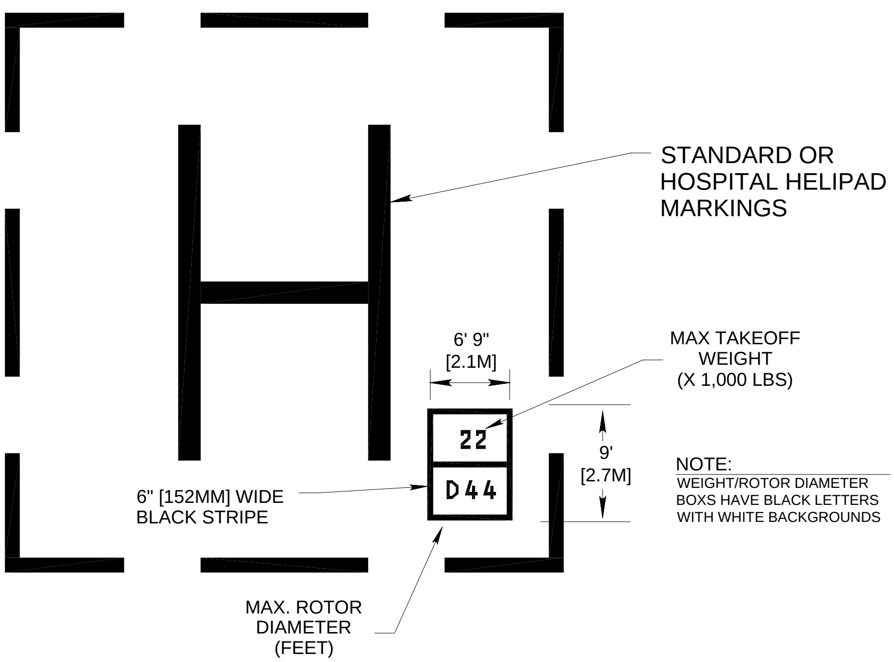

Figure 7-10. Dimensions for Supplemental Elevated Helipad Markings

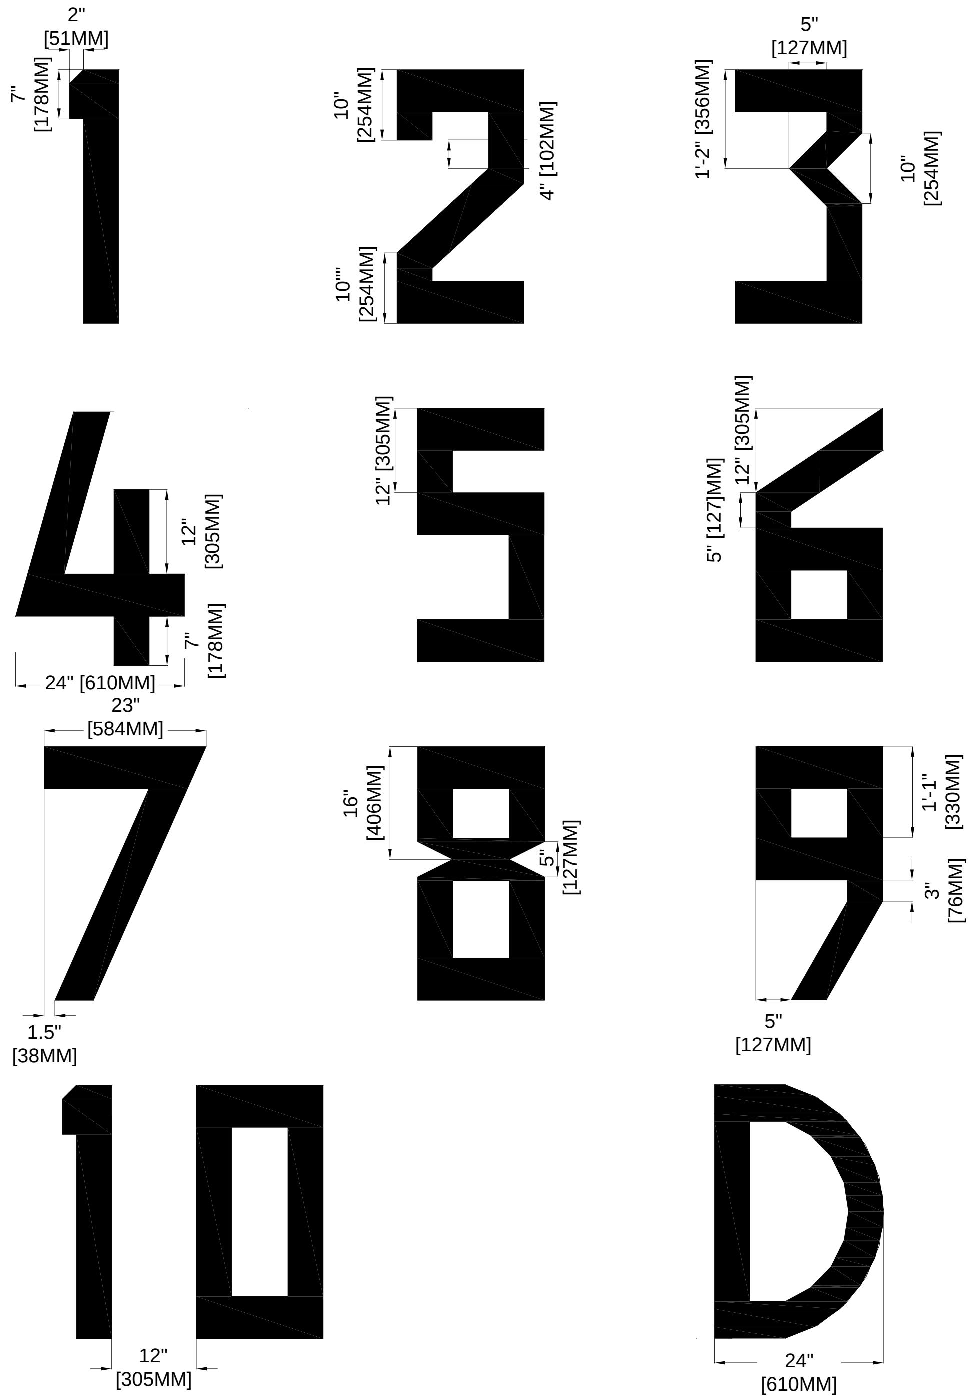


ALL CHARACTERS HAVE THE FOLLOWING CHARACTERISTICS UNLESS SPECIFIED OTHERWISE:

36" [914MM] HEIGHT VERTICAL STROKE OF 5" [127MM]

18" [457MM] WIDTH HORIZONTAL STROKE OF 6" [152MM]

7-10.3 Application.

Rotary wing runway, landing lane, and helipad marking patterns, as appropriate, are used as an identification marker at all heliports, whether at ground level or elevated, and at helicopter takeoff and landing areas. All helicopter landing areas bearing the outdated day marker or nonstandard identification marking are re-marked with the proper identification marking as soon as practicable.

7-10.4 Location.

The appropriate markings are placed in the approximate center of the touchdown area of all helicopter landing pads and on the ends of all helicopter runways and landing lanes.

7-11 OVERRUNS AND SHOULDER MARKINGS.

7-11.1 General.

Overrun and shoulder areas not intended for aircraft traffic are identified with overrun chevrons and shoulder (deceptive surface) markings. These markings consist of lines 18 inches (457 millimeters) wide, marked to within 5 feet (1.5 meters) of the shoulder edge, or for a total length of 25 feet (7.6 meters), whichever is less, in accordance with the requirements below. Configurations complying with these requirements are detailed in Figure 7-11.

7-11.2 Color.

All heliport overrun and shoulder areas are marked with non-reflective yellow paint.

7-11.3 Materials.

Non-reflective paint used in marking or re-marking overrun and shoulder areas consists of any of the materials described in Chapter 3.

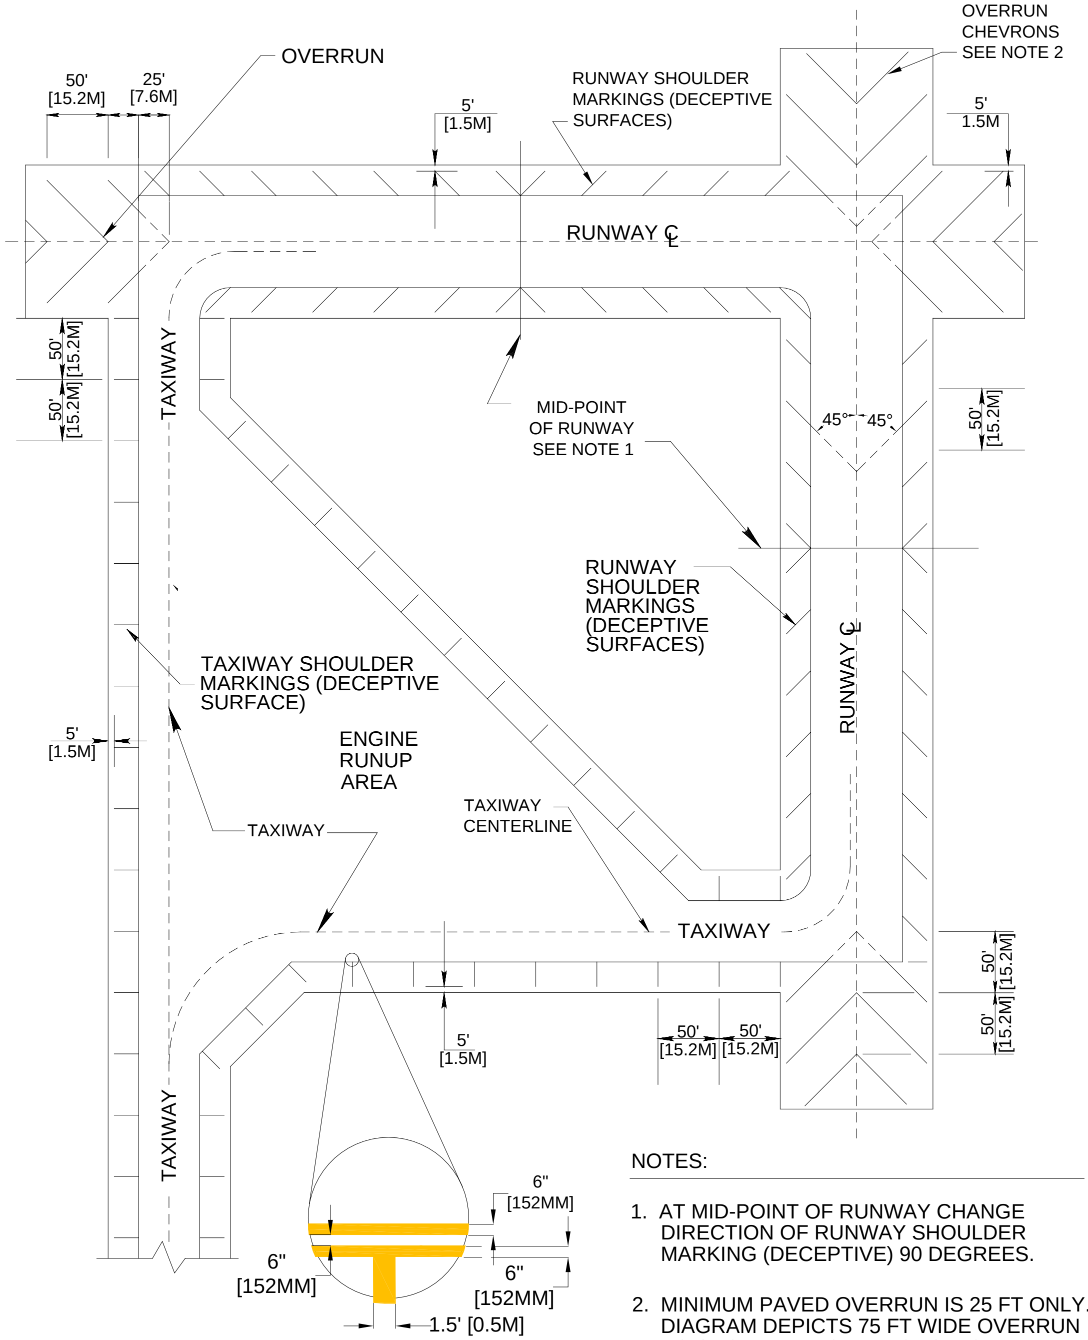
7-11.4 Overrun Areas.

Overrun areas are identified with a chevron marking layout as shown in Figure 7-11. The index point for the layout of the chevron marking is the point of intersection of the runway centerline and the runway threshold line. The apex of the first full chevron on the approach side of the threshold is placed 25 feet (7.6 meters) outward from the index point. Subsequent chevrons are placed on 50-foot (15.2-meter) centers as shown in Figure 7-11. The portion of the partial chevron that overlaps the threshold is not painted on the full-strength pavement. The apex of each chevron is on the centerline, with each leg intersecting at an angle of 45 degrees with the runway centerline, and an unmarked extension of the runway centerline. The chevrons terminate 5 feet (1.5 meters) inside the outer paved edge of the overrun.

7-11.5 Runway Shoulder Areas.

Shoulder areas are not intended for routine aircraft traffic. In cases where the surface does not provide sufficient differing contrast from the surrounding area, they are marked with shoulder (deceptive surface) markings as shown in Figure 7-11. Shoulder markings are a continuation of the chevron legs used in marking overrun areas described above. The chevrons used to form the legs are uniformly laid out from both ends of the runway as shown in Figure 7-11. Shoulder markings terminate at a length of 25 feet (7.6 meters) or at a point 5 feet (1.5 meters) inside the outer edge of the paved shoulder area.

Figure 7-11. Rotary Wing Overruns and Shoulder Markings



NOTES:

1. AT MID-POINT OF RUNWAY CHANGE DIRECTION OF RUNWAY SHOULDER MARKING (DECEPTIVE) 90 DEGREES.

2. MINIMUM PAVED OVERRUN IS 25 FT ONLY. DIAGRAM DEPICTS 75 FT WIDE OVERRUN TO SHOW THAT CHEVRONS WOULD BE REQUIRED AND SPACED 15.2M [50'] BETWEEN CHEVRONS FOR OVERRUNS LARGER THAN THE MINIMUM.

CHAPTER 8 OTHER PAVEMENT MARKINGS

8-1 CLOSED PAVEMENT MARKINGS.

All pavements that are hazardous to aircraft traffic are marked with Xs. Larger ones are used for runways. Smaller Xs, with a slightly different angle where the two legs intersect, are used for taxiways and apron areas. Additional cones, barricades, and lights are used, or sometimes substituted for the Xs, to aid in delineation of substantially hazardous areas, areas that are only hazardous during construction, or some other special project, such as an air show. Refer to Figure 8-1 and Figure 8-2 for dimensions and layout details. The following paragraphs describe the placement of these markings and alternatives for temporarily closed areas.

8-2 PERMANENTLY CLOSED RUNWAYS.

Closed runways are marked to reflect their non-operational status. Ensure markings are visible to aircrew to avoid confusion and prevent mishaps that occur from attempting operations from a pavement of unknown condition or status.

8-2.1 Runway Markings.

For permanently closed runways, obliterate the runway designation markings on both ends of the runway and mark a yellow “X” at each end of the runway and at 1,000-foot (305-meter) intervals along the length, centered on the runway centerline.

8-2.2 Intersections.

For permanently closed runways that intersect an active runway, a solid yellow “X” marking is placed on the closed runway centerline, not more than 50 feet (15.2 meters) from the center of the X to the near paved shoulder edge of the open intersecting runway. See Figure 8-2 for an example.

8-3 PERMANENTLY CLOSED TAXIWAYS OR TAXILANES.

Obliterate the centerline stripe for a minimum of 200 feet (61 meters) from the nearest edge of any serviceable pavement and mark the taxiway or taxilane with an "X" within 25 feet (7.6 meters) of every intersection with any other serviceable pavement (measured from near outer paved shoulder edge of serviceable pavement to the center of the X), and along the taxiway or taxilane centerline at evenly spaced intervals not exceeding 1,000 feet (304.8 meters). Refer to Figure 8-1 for the dimensions of the Xs and Figure 8-2 for a typical layout and placement examples. Additionally, obliterate all extraneous taxiway markings from the adjacent serviceable pavements. For example, remove or hide any line or directional information signs or other markings delineating a route from an active runway to a closed taxiway.

8-4 PERMANENTLY CLOSED APRONS.

When an apron is closed on an active airfield, taxilanes and taxiways leading to the closed area are marked as closed. If the closed apron area adjoins an active apron, supplemental markings are needed to indicate the division between the two areas. The separation is marked with two continuous apron edge stripes as described in Chapter 6 and shown in Figure 6-1. The letter "X," dimensioned as shown in Figure 8-1, is marked 3 feet (0.9 meter) inward toward the closed apron at intervals not exceeding 200 feet (61 meters) on the closed apron sides. Figure 8-3 shows the typical layout for these markings.

8-5 TEMPORARILY CLOSED AIRFIELD PAVEMENTS.

8-5.1 Temporarily Closed Runways.

Place an "X" at both ends of the runway on top of the runway designation number. For temporary purposes, the dimensions of the "X" shown in Figure 8-1 are reduced to allow use of standard 4-foot by 8-foot (1219-millimeter by 2438-millimeter) sheets of plywood. **Note:** Runways closed for periods of five days or less do not need to be marked if a NOTAM is issued to publicize the closure. When temporarily closing a runway, Fabricate the "X" from plywood, canvas, painted picket fence sections, preformed marking tape, or other materials, such as yellow snow fencing. Anchor these materials by any suitable means, such as mechanical screw or wedge-type anchors, or sandbags. Another alternative is using lighted Xs as described in FAA AC 150/5340-1 and FAA AC 150/5345-55.

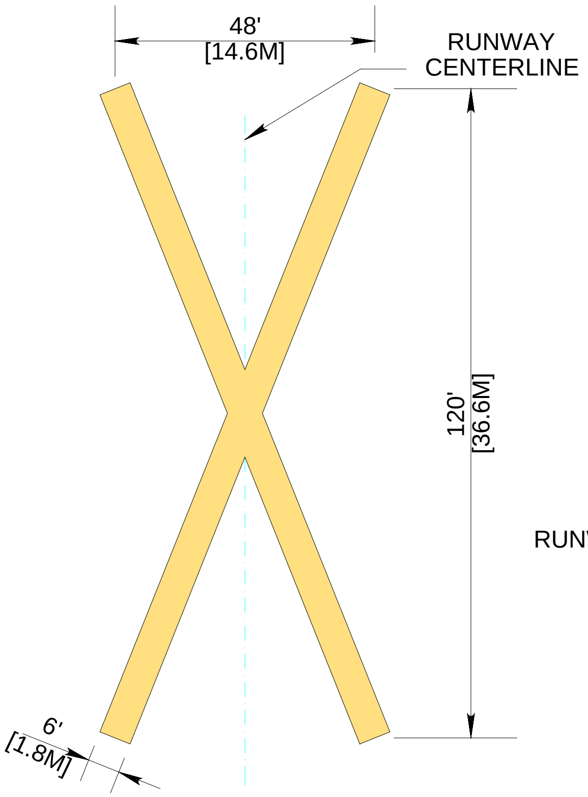
8-5.2 Temporarily Closed Taxiways or Taxilanes.

Ensure an "X" is placed at all access points to the closed pavement. In this case, it is not necessary to obliterate the existing markings. Areas used during periods of reduced visibility or darkness use lighted barricades to ensure the area is adequately marked. If lighted barricades are used to block the access point to the closed pavement, the "X" is omitted. See paragraph 8-6 and Figure 8-4. Use materials described in paragraph 8-5.1 to construct and fasten markers to the pavement.

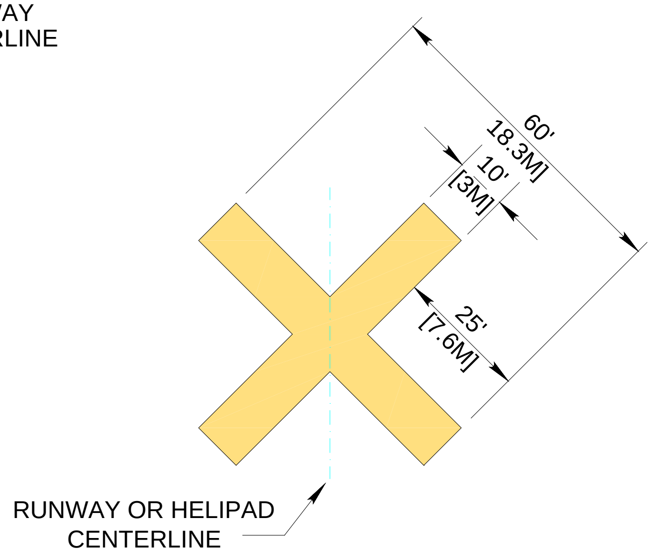
8-5.3 Temporarily Closed Aprons.

When an apron is closed on an active airfield, taxilane and taxiway centerline markings leading to the closed area are removed. However, hazardous areas on aprons caused by construction or other activities of a temporary nature are delineated using barricades or traffic cones equipped with a red light (see Figure 8-4). The lights are optionally steady burning or flashing but ensure they meet the luminance requirements of the FHWA MUTCD for safety zones. Lights are mounted on barricades and spaced at no more than 10-foot (3-meter) intervals. Lights are operated between sunset and sunrise and during periods of low visibility during operations. They are operated by photocell or manually. Solar-powered lights and light-emitting diode (LED) lights are acceptable as long as they meet the above-stated requirements.

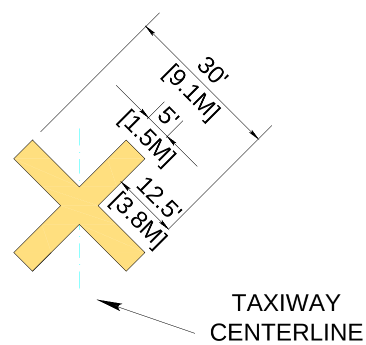
Figure 8-1. Runway, Taxiway, and Apron Area Closure Markings



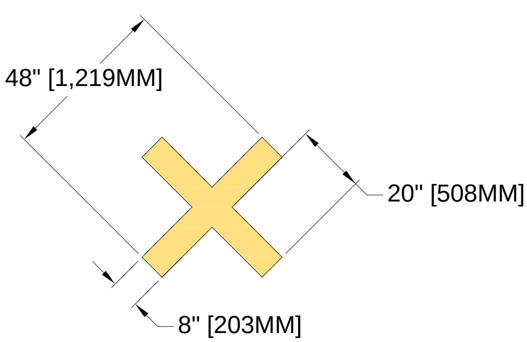
CLOSED RUNWAY
(PREFERRED)



CLOSED ROTARY OR FIXED
WING RUNWAY OR HELIPAD



CLOSED TAXIWAY

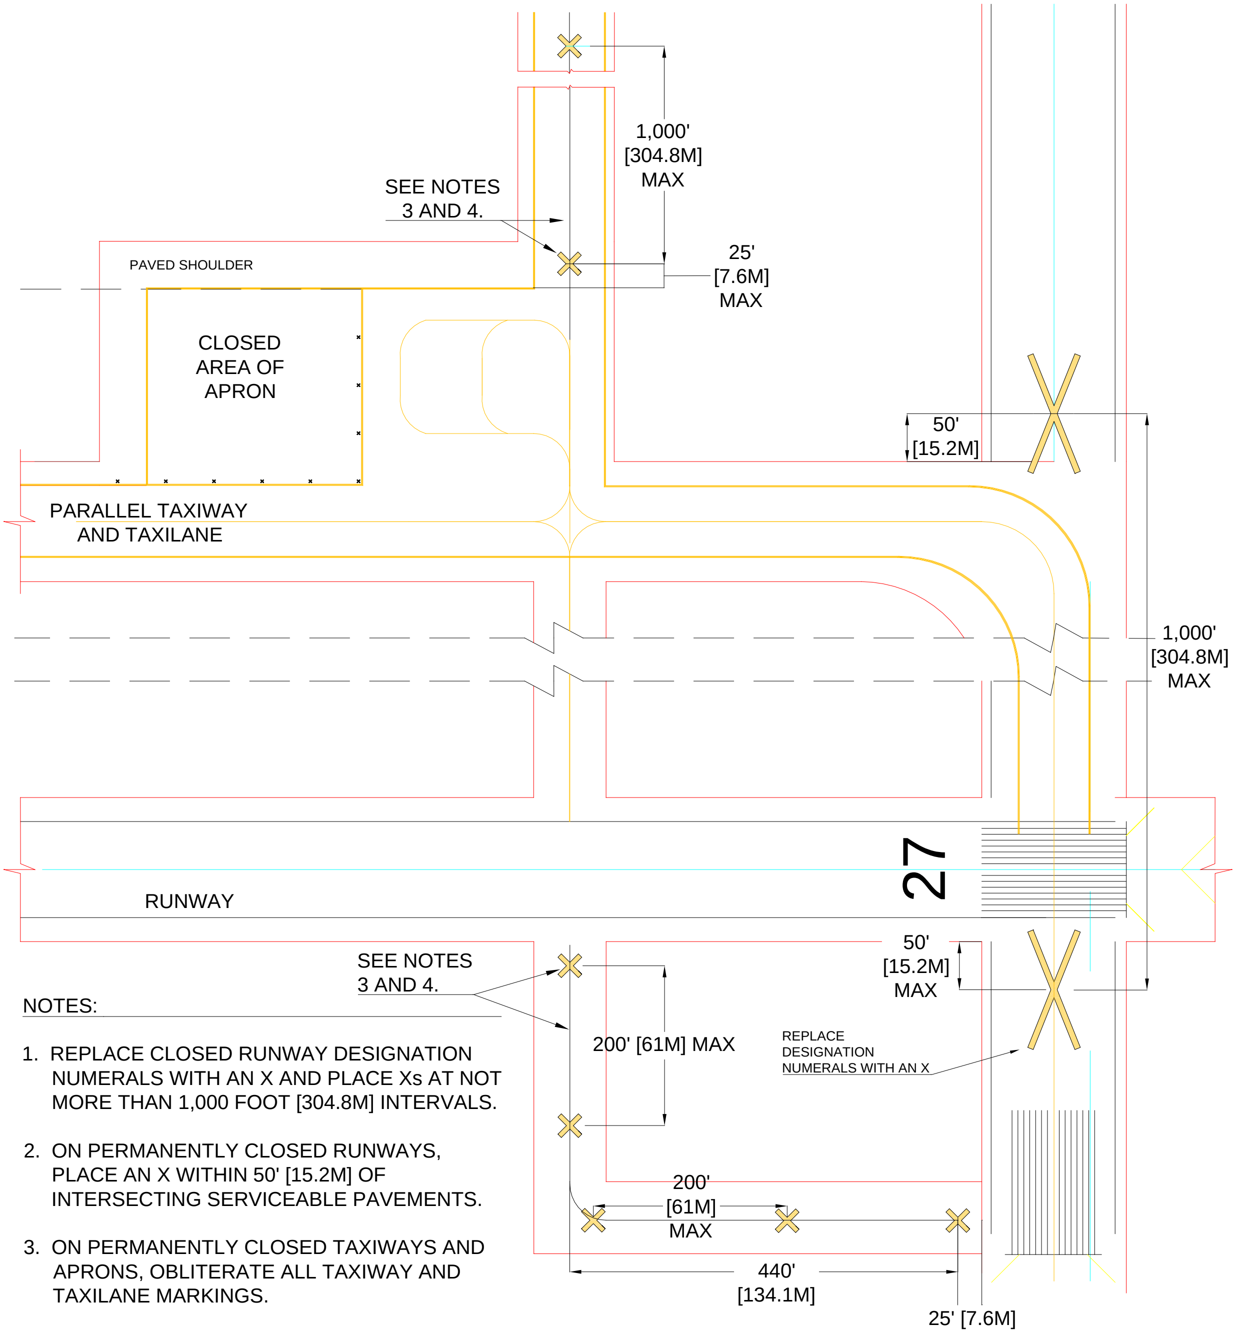


CLOSED APRON BOUNDARY X
(NOT DRAWN TO SCALE)

NOTES:

1. NON-REFLECTIVE YELLOW IS USED FOR CLOSED MARKINGS. REFLECTIVE Xs ARE RECOMMENDED WHEN USED ON AIRFIELDS WHERE OTHER AREAS ARE AVAILABLE FOR NORMAL OPERATIONS.
2. DIMENSIONS ARE SHOWN AS: $\frac{\text{FEET}}{\text{METERS}}$ E.G. $\frac{10}{3}$ EXCEPT WITHIN THE DIAGRAM FOR THE APRON BOUNDARY X.

Figure 8-2. Closed Runway, Taxiway, and Taxilane Pavement Markings



NOTES:

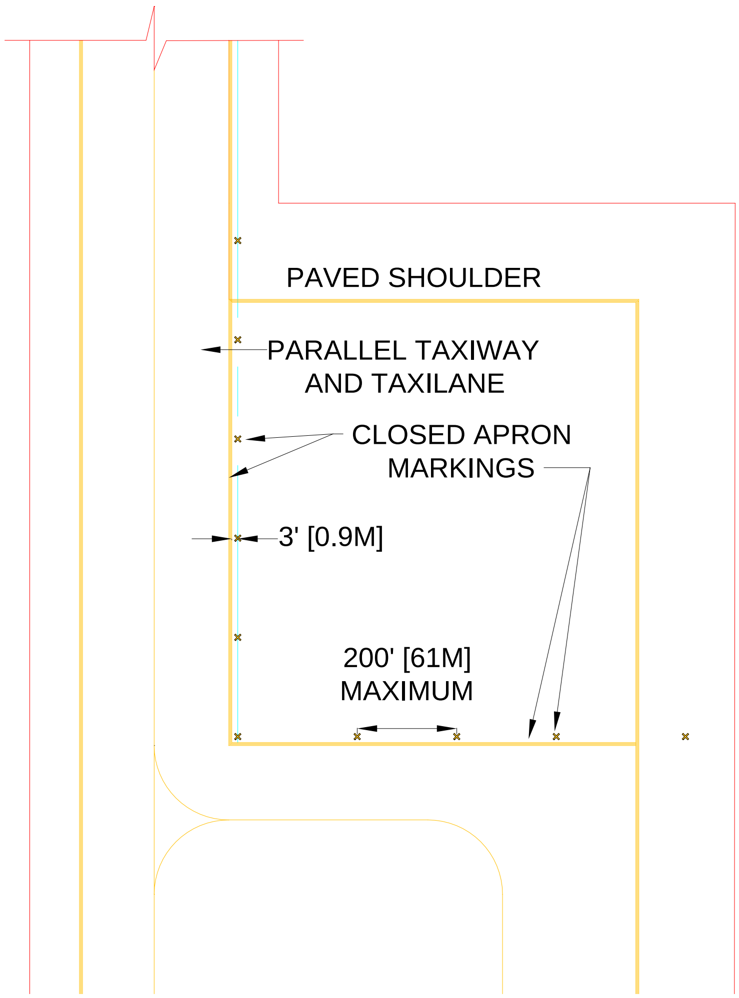
1. REPLACE CLOSED RUNWAY DESIGNATION NUMERALS WITH AN X AND PLACE Xs AT NOT MORE THAN 1,000 FOOT [304.8M] INTERVALS.

2. ON PERMANENTLY CLOSED RUNWAYS, PLACE AN X WITHIN 50' [15.2M] OF INTERSECTING SERVICEABLE PAVEMENTS.

3. ON PERMANENTLY CLOSED TAXIWAYS AND APRONS, OBLITERATE ALL TAXIWAY AND TAXILANE MARKINGS.

4. ON PERMANENTLY CLOSED TAXIWAYS AND APRONS, PLACE AN X WITHIN 25 FEET [7.6M] OF INTERSECTIONS WITH OTHER SERVICEABLE PAVEMENTS AND AT INTERVALS OF NOT MORE THAN 1,000' [304.8M].

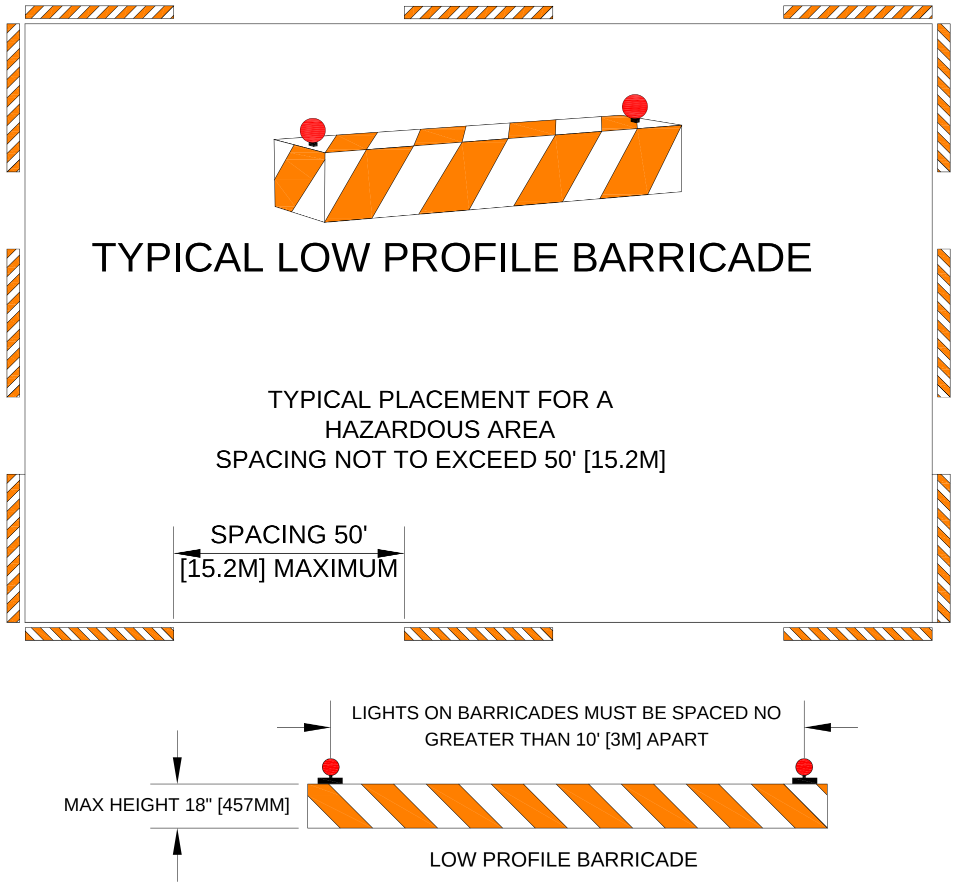
Figure 8-3. Placement of Permanently Closed Apron Pavement Markings



8-6 BARRICADES.

Where pavement markings do not provide adequate definitions of closed or hazardous areas, supplement the markings using retro-reflective orange and white barricades or traffic cones with securely fastened red lights aligned toward aircraft and vehicle ground traffic. All barricades and traffic cones are anchored or weighted to be heavy enough to remain in place during aircraft operations in near proximity. Ensure flashing lights are at least five candelas effective intensity and flash at a rate of from 55 to 160 flashes per minute. Ensure continuous burning lights have an effective intensity of 10 candelas. Low-profile barricades are the preferred method for marking construction areas. Examples are shown in Figure 8-4. Ensure lighted barricades used in close proximity to each other are all of the same type and colors. If flashing lights are used, ensure they have the same flash rates. Place barricades at maximum intervals of 50 feet (15.2 meters) and use dual barricades and lights on each corner and at the ends.

Figure 8-4. Low Profile Barricades



NOTES:

1. BARRICADES MAY NOT EXCEED 18" [457MM} IN HEIGHT(EXCLUSIVE OF SUPPLEMENTARY LIGHTS AND FLAGS) AND SHOULD BE SPACED TO PREVENT BREACH, BUT IN NO CASE GREATER THAN 50' [15.2M] APART. THEY MUST BE OF LOW MASS; EASILY COLLAPSIBLE UPON CONTACT WITH AN AIRCRAFT; AND WEIGHTED OR STURDILY ATTACHED TO THE SURFACE TO PREVENT DISPLACEMENT FROM JET BLAST OR OTHER WIND DISTURBANCE.
2. THE REQUIRED LIGHTS MUST BE RED AND MAY EITHER BE STEADY BURNING OR FLASHING. INTENSITIES AND LUMINANCE MUST BE AT LEAST FIVE CANDELAS EFFECTIVE INTENSITY AND FLASH AT A RATE OF FROM 55 TO 160 FLASHES PER MINUTE.
3. HAZARD LIGHTS MAY NOT BE SPACED GREATER THAN 10' [3M] APART.
4. LIGHTS MUST BE OPERATED BETWEEN SUNSET AND SUNRISE AND DURING PERIODS OF LOW VISIBILITY WHENEVER THE AIRPORT IS OPEN FOR OPERATIONS.
5. BARRICADES MAY BE SUPPLEMENTED WITH ALTERNATING ORANGE AND WHITE FLAGS AT LEAST 20" BY 20" (508MM BY 508MM) SQUARE.

8-7 NON-MOVEMENT AREA BOUNDARY MARKING.

Non-movement area boundary markings are used to delineate the air traffic or ground radio-controlled movement area from the non-controlled movement area. This marking is used only when there is a need specified in the AOI or the letter of agreement between the airport operator and airport traffic control tower since they are sometimes misinterpreted as a holding position marking.

8-7.1 Location.

Locate the non-movement area boundary marking on the boundary between the movement and non-movement area. To avoid confusing this marking with a VFR hold or intermediate hold position, do not place this marking to coincide with the edge of a taxiway.

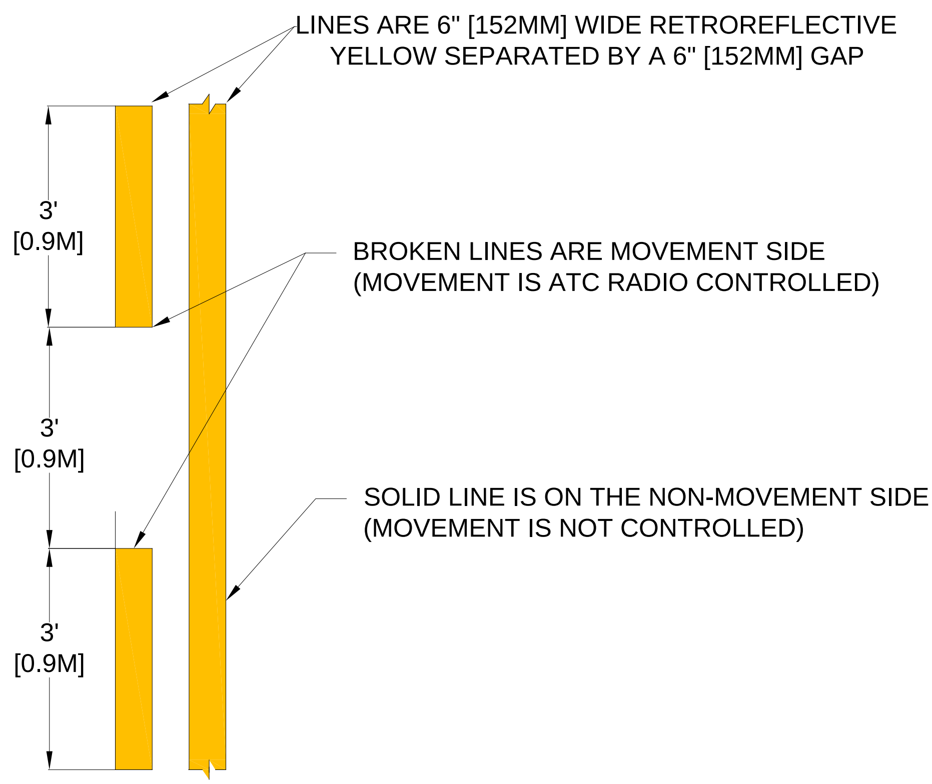
8-7.2 Layout.

The non-movement area boundary marking consists of two retro-reflective yellow lines, one solid and one dashed, as shown in Figure 8-5. The solid yellow line is located on the non-movement (or non-radio controlled) area side; the dashed yellow line is located on the movement (air traffic control/ground control-supervised and radio-controlled) area side. Each line is 6 inches (152 millimeters) in width, with a 6-inch (152-millimeter) gap between the lines. The width of the lines and spaces are optionally doubled to 12 inches (305 millimeters). The dashes are 3 feet (0.9 meter) in length with a 3-foot (0.9-meter) gap between dashes. If a taxiway centerline intersects a non-movement area boundary marking, the taxiway centerline is interrupted 6 inches (152 millimeters) from the solid line (movement area side) and 3 feet (0.9 meter) from the dashed line (non-movement area) side.

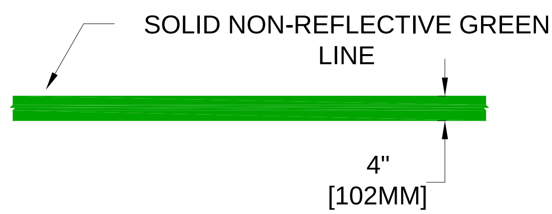
8-8 OBSTRUCTION CLEARANCE LINE.

On Class A airfields, heliports, or aprons servicing only rotary wing aircraft, and where needed, an obstruction clearance line is marked to delineate an apron lateral clearance area as defined by UFC 3-260-01. The line is placed to prevent fixed and mobile objects (e.g., maintenance vehicles, equipment, and storage bins) from being located where they encroach into the required apron lateral clearance distance. The obstruction clearance line consists of a single solid green non-reflective line 4 inches (102 millimeters) wide. The obstruction clearance line is not painted within the usable portion of the apron or on portions of the airfield traversed by aircraft under their own power such as runways, vertical landing pads, helipads, overruns, hoverpoints, taxiways, taxi-lanes, warm-up pads, arm/de-arm pads, hot cargo pads, hot refueling areas, forward arming and refueling pads, compass calibration pads, trim pads, engine run-up or engine check pads; however, it might be painted at or near hangar entrances and exits. See Figure 8-5 for obstruction clearance line details. An obstruction clearance line is not required at installations which ensure the apron lateral clear areas are accessed only by personnel trained on proper placement and movement of equipment, materials, and structures on active airfield pavements and which do not bring or leave such materials, equipment, or structures unattended or without informing the airfield managers and controllers and restricting aircraft movement in the area.

Figure 8-5. Non-Movement Area Boundary and Obstruction Clearance Line Markings



NON-MOVEMENT AREA MARKING



OBSTRUCTION CLEARANCE LINE

8-9 DECEPTIVE SURFACES (SHOULDER MARKINGS).

Shoulders and other areas of airfield pavements that are not intended for aircraft traffic but have the appearance of operational pavement are marked as deceptive surfaces. Use deceptive surface markings when the paved shoulder width exceeds the standard dimension given in UFC 3-260-01 or if experience shows there is a lack of definition between the full-strength pavement and shoulders. **Note:** If there is a significant gap between the deceptive surface markings and the runway side stripe (such as occurs when side stripes are spaced at a 144-foot [43.9-meter] separation on a 300-foot [91.4-meter] -wide runway), double 6-inch (152-millimeter) -wide yellow stripes separated by a 6-inch (152-millimeter) -wide gap are optionally added to the inner ends of the deceptive surface markings to longitudinally delineate the limit of the load-bearing pavement. Place the outer edge of the outermost stripe to coincide with the outer edge of the full-strength pavement and the inner end of the deceptive surface marking. These stripes are curved to follow the outer radius of fillets and terminated at the intersecting taxiway edge, or joined to taxiway edge markings, where used.

8-10 RUNWAY SHOULDERS.

Mark deceptive surfaces on the edges of runways with diagonal stripes as shown in Figure 8-6. The stripes are uniformly laid out from each end of the runway to the midpoint, reversing direction at the midpoint. Begin the measurement for spacing at the initial overrun chevron apex. Stripes are located so the inner edge of the marking is coincident with the edge of the full-strength pavement and the stripe extends to within 5 feet (1.5 meters) of the outer pavement edge or for a length of 25 feet (7.6 meters), whichever results in the shorter length line.

8-11 TAXIWAY AND APRON SHOULDERS.

Mark deceptive surfaces on the edges of taxiways and aprons with perpendicular stripes as shown in Figure 8-7. These markings consist of a series of 3-foot (0.9-meter) -wide stripes positioned perpendicular to the edge markings. On curves, a stripe is placed at each point of tangency and intermediate stripes are spaced uniformly up to 30 feet (9.1 meters) apart. Stripes are placed so the inner edge of the marking is coincident with the edge of the full-strength pavement.

8-12 VEHICULAR ACCESS MARKING.

Mark vehicular access routes according to the FHWA MUTCD. Additionally, ensure all vehicular access roads leading to a movement area or taxiway/taxilane are marked with a white "stop" bar. See paragraph 4.5.

8-13 INERTIAL NAVIGATION SYSTEM (INS) CHECKPOINT MARKINGS.

INS checkpoint markings are provided to allow data input or calibration of the aircraft INS. Contrasting colors are used for the border, numerals, and letters. A record of actual coordinates is normally maintained by base operations flight data, transient alert, and maintenance control. Figure 8-8 shows a typical layout scheme. Suggested locations are nose wheel parking spots on aprons and ramps; engine run-up areas adjacent to runway ends; hammerheads; or taxiway and apron holding positions. **Note:** For Air Force installations, survey support for NAVAIDs and INS checkpoints are coordinated with base and MAJCOM mapping, charting, and geodesy offices, according to AFI 14-205.

8-14 GROUND RECEIVER CHECKPOINT MARKINGS.

Identify instrument navigation checkpoint markings such as VHF omni range (VOR) and tactical air navigation (TACAN) markings as shown in Figure 8-8. Where directional alignment of the aircraft is required, paint a 6-inch (152-millimeter) -wide line through the center of the circle that extends outside the circle aligned toward the transmitter. Terminate the line with an arrowhead. Black or white paint is used to contrast this marking, as required. If the checkpoint marking conflicts with a taxiway centerline, interrupt the taxiway centerline 3 feet (0.9 meter) on either side of the checkpoint marking. A supplemental sign is required for the checkpoint marking; see UFC 3-535-01 for size, lettering, and placement. **Note:** For Air Force installations, survey support for NAVAIDs and INS points are coordinated with base and MAJCOM mapping, charting, and geodesy offices, according to AFI 14-205.

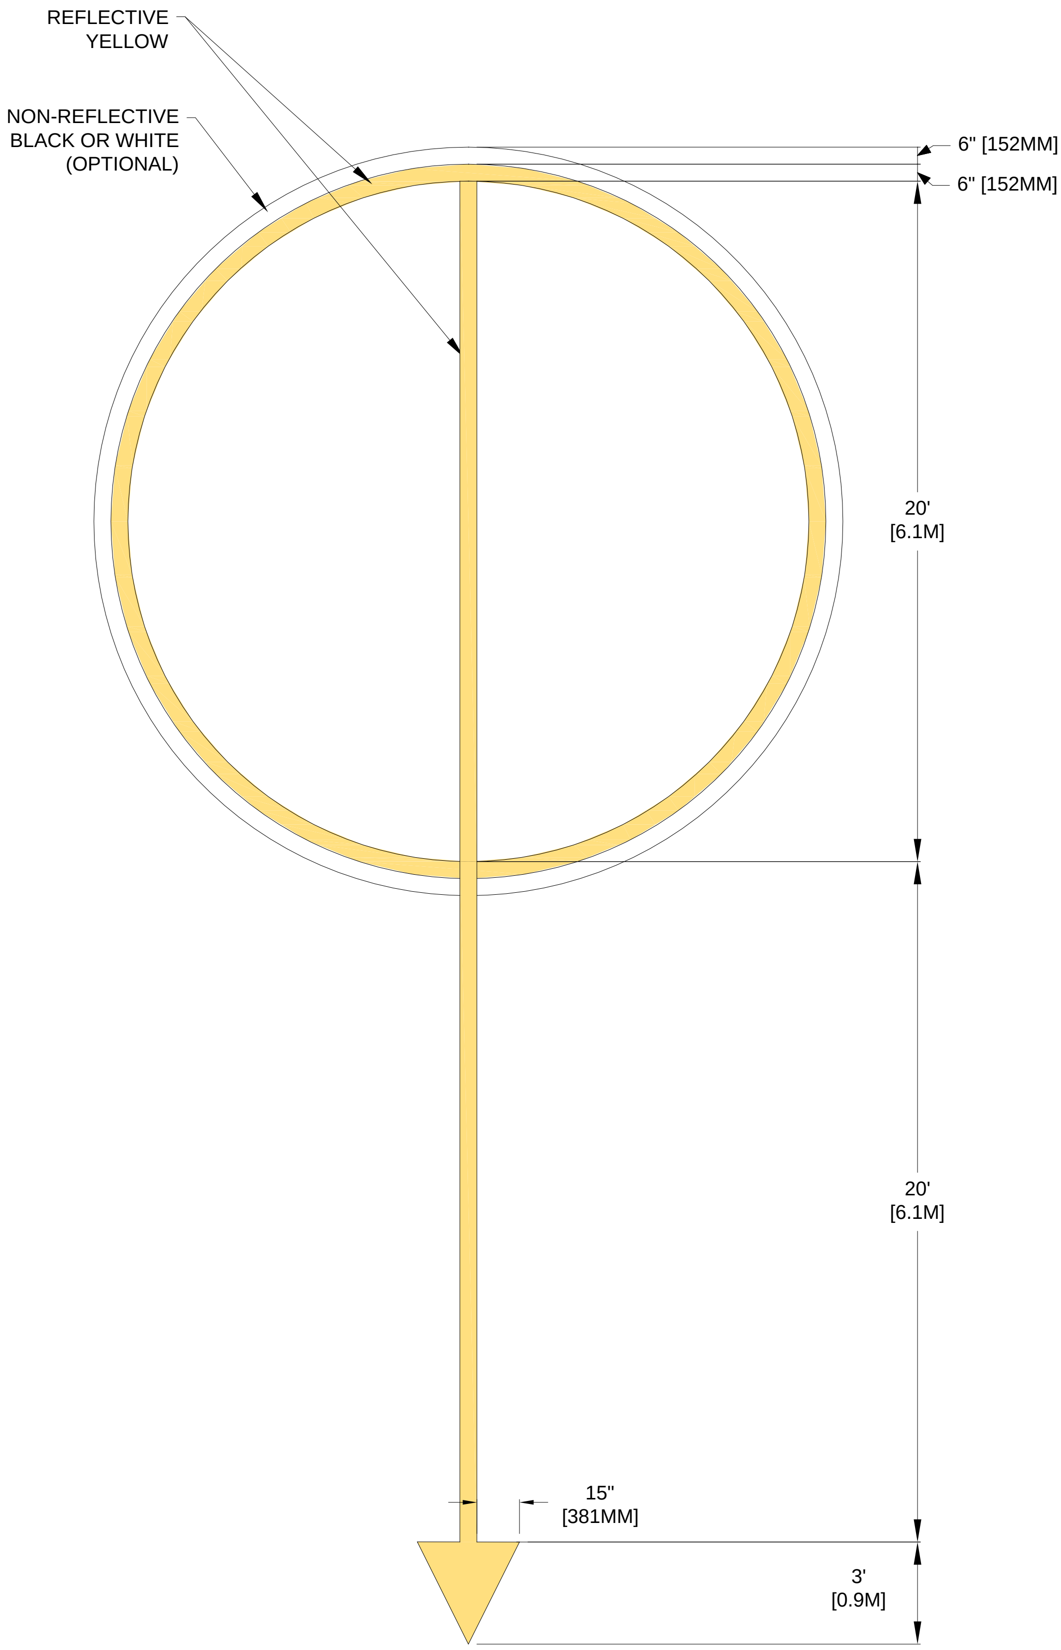
MULTIPLY BY 25.4 TO CONVERT INCHES TO MILLIMETERS

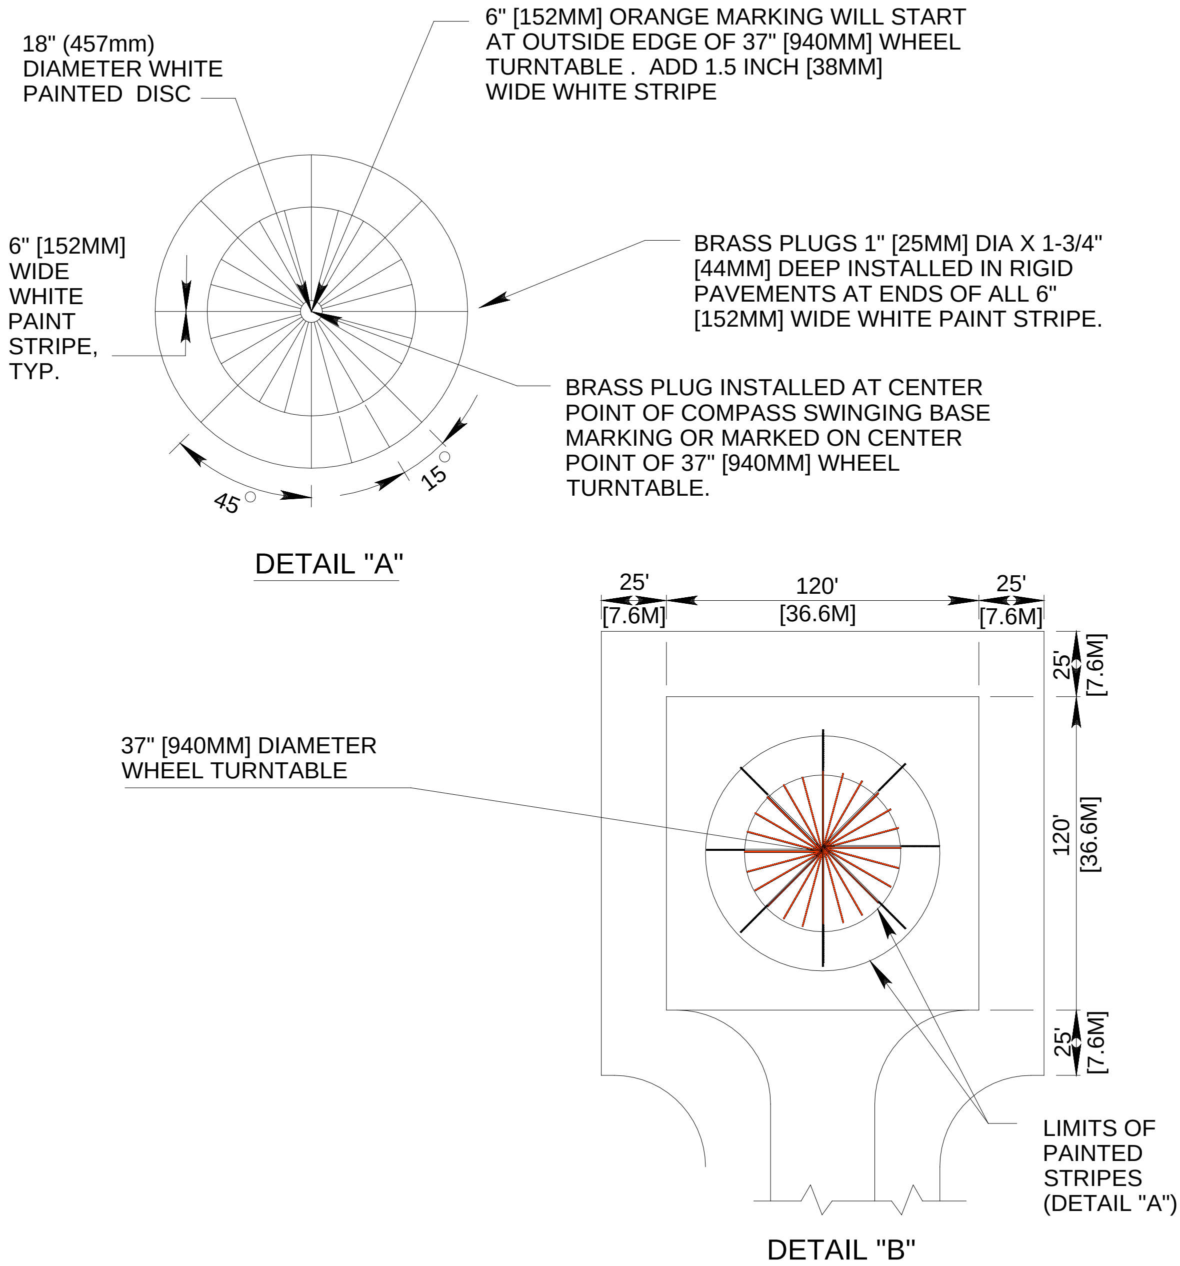
Figure 8-9. Ground Receiver Checkpoint (Directional)



8-15 COMPASS CALIBRATION PAD (CCP) MARKINGS.

Compass swinging bases are established in accordance with UFC 3-260-01, Chapter 6 and Appendix B10. Mark CCPs in accordance with the applicable aircraft maintenance Technical Order (T.O.), considering primarily the most demanding aircraft that are serviced on the apron. If aircraft are serviced which do not require a specific marking within the T.O., optionally use either the more restrictive criteria provided in UFC 3-260-01 and described below or the general guidelines for compass calibration pads in FAA AC 150/5300-13 for Class B airfields; otherwise, use the criteria described below. Swinging bases for aligning aircraft for the precise calibration of all types of air navigation equipment are marked as shown in Figures 8-10 and 8-11. The stripes are set at magnetic directions from the corresponding true compass rose control point at every 15 degrees (15°). A 6-inch (152-millimeter) -wide orange stripe is painted for each of the 24 compass rose control points. These stripes begin at the center of the pad and extend outward for a minimum length of 25 feet (7.6 meters). Border each stripe with a 1.5-inch (38-millimeter) -wide white stripe. At a distance of 27 feet (8.2 meters) from the center of the pad, identify the azimuth of each stripe as measured from magnetic north with 24-inch (610-millimeter) -high by 15-inch (381-millimeter) -wide orange block numerals (Figure 8-11). All azimuth numbers contain three numerals (e.g., 045). The stroke of each numeral is a minimum of 3.5 inches (89 millimeters) wide. Each azimuth number is painted on a solid white background formed from a rectangle 26 inches (660 millimeters) high by 51 inches (1,295 millimeters) wide.

Figure 8-10. Compass Calibration Pad Markings

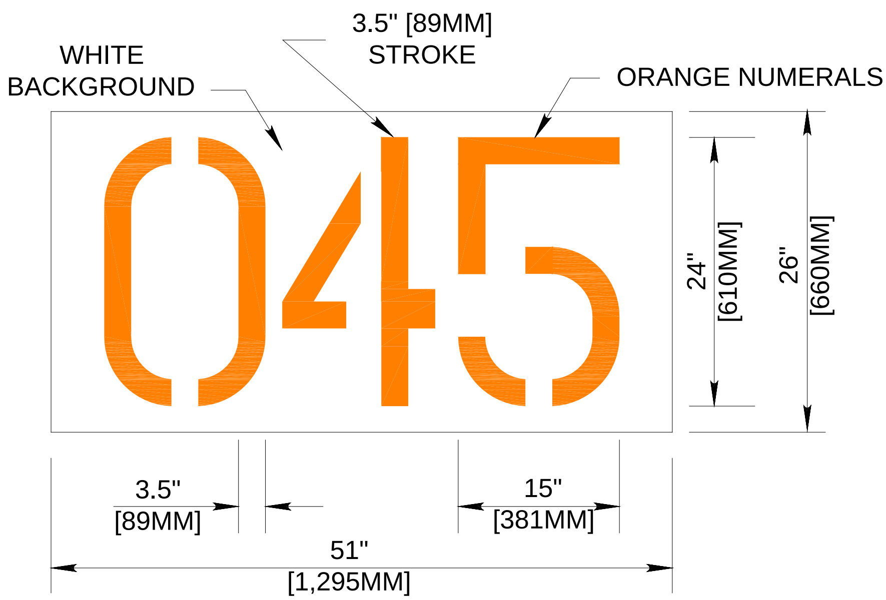


NOTES:

1. UNITS ARE EXPRESSED AS $\frac{\text{FEET}}{\text{METERS}}$ (e.g. $\frac{10}{3}$).

2. SEE UFC 3-260-01 FOR SURVEY REQUIREMENTS AND UFC 3-260-02 FOR PAVEMENT AND SUBGRADE DESIGN REQUIREMENTS.

Figure 8-11. Compass Calibration Pad Numerals



8-16 T-6 PROPELLER HAZARD PAVEMENT MARKINGS.

In an effort to reduce the hazard caused by T-6 propellers, T-6 parking positions are marked in accordance with Figure 8-12.

8-17 F-16 ENGINE INLET DANGER AREA PAVEMENT MARKINGS.

In an effort to reduce the hazard caused by F-16 engine inlet suction, F-16 parking positions are optionally marked in accordance with Figure 8-13; however, aircraft maintenance personnel determine whether the radius is established at 15 feet (4.6 meters) for idle thrust or 25 feet (7.6 meters) for mil-thrust.

8-18 HYDRANT FUEL PIT LID MARKING.

If needed to alert pilots, vehicle operators, or maintenance personnel, hydrant fuel pit covers and/or adjacent pavement is optionally marked as shown in Figure 8-14. In areas where snow is not a factor, these pits do not necessarily require markings of this type.

8-19 STATIC GROUND MARKINGS.

See UFC 3-575-01, *Lightning and Static Electricity Protection Systems,* and Army Techniques Publication (ATP) 4-43, *Petroleum Supply Operations*, for static grounding, testing, and marking requirements.

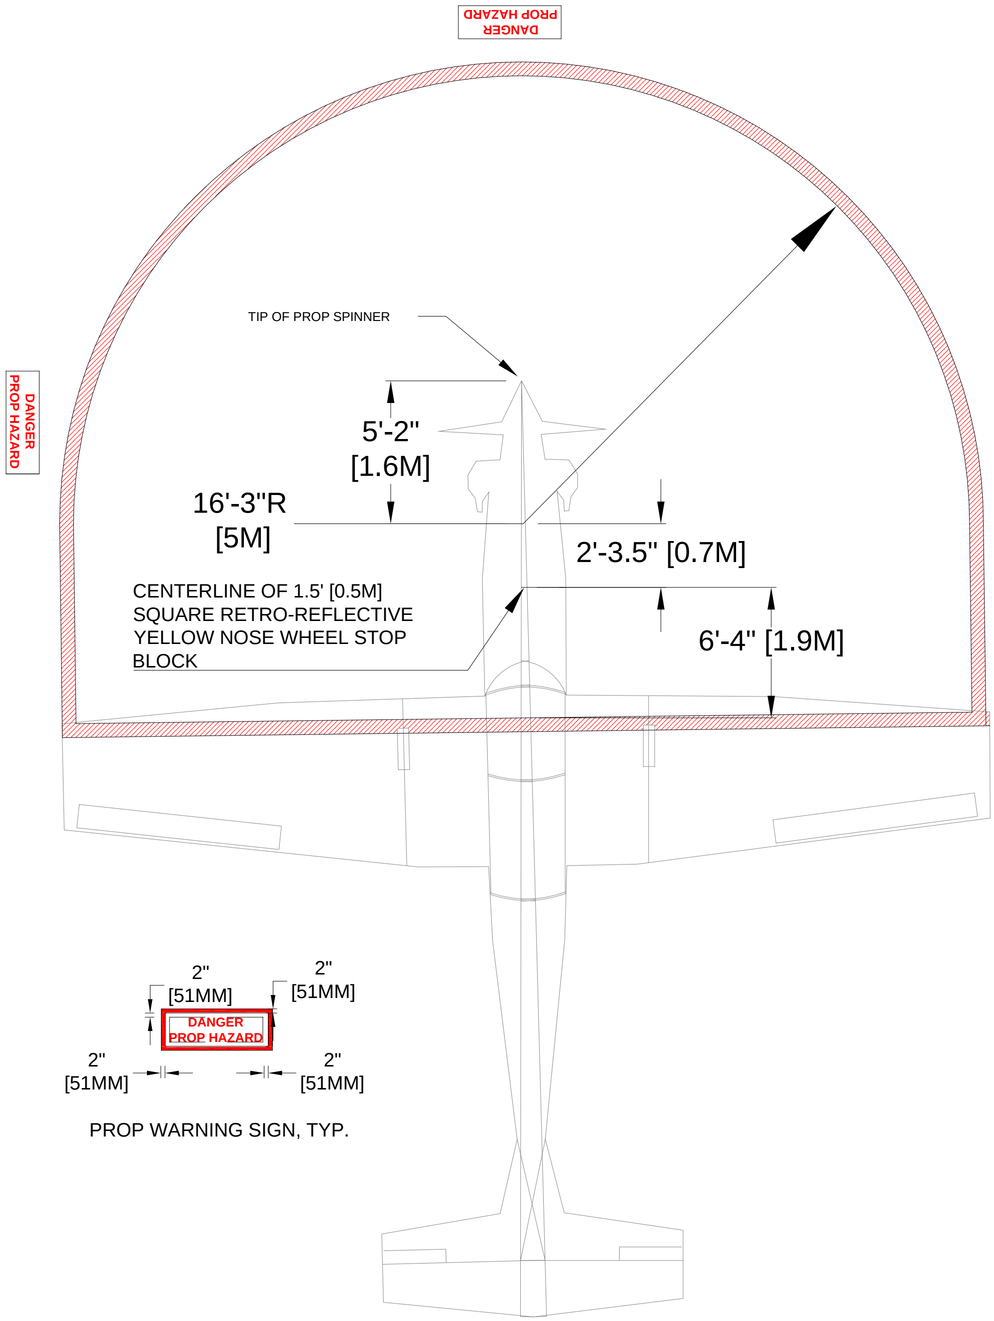
8-20 C-12 PROP HAZARD WARNING MARKING.

In an effort to reduce the hazard caused by C-12 propellers and exhaust, C-12 parking positions are marked in accordance with Figure 8-15.

8-21 EXPEDIENT AIRFIELD MARKINGS.

There are two VFR types of expedient airfields: the landing zone (LZ) (formerly called shortfields or assault landing zones) and the minimum operating strip (MOS). They are rapidly developed to support operations due to an urgent need but support different types of operations. LZs are developed to support airlift operations for C-130 and C-17 aircraft and the MOS is developed for base recovery after an attack to allow the launch and recovery of fighter aircraft. The schemes for marking an MOS are described in T.O. 35E2-6-1, *Minimum Airfield Operating Surface Marking System*. The schemes for marking an LZ are provided in TM 3-34.48-2, *Theater of Operations: Roads, Airfields, and Heliports – Airfield and Heliport Design*, Volume II.

Figure 8-12. T-6 Propeller Hazard Area Pavement Markings



NOTES:

1. WARNING SIGNS WILL BE 4" [102MM] HIGH RED LETTERS ON A WHITE BACKGROUND THAT EXTENDS AT LEAST 2' [51MM] BEYOND THE EXTREMITIES OF THE LETTERS. PLACEMENT SHALL BE AT MINIMUM, AS SHOWN ABOVE.

2. PROP WARNING ARC AND OTHER BOUNDARIES WILL BE A 6" [152MM] CONTINUOUS RED LINE WITH RETRO-REFLECTIVE BEADS EMBEDDED. AN ANTI-SKID MATERIAL SHOULD ALSO BE INCORPORATED ACCORDING TO THE MANUFACTURERS RECOMMENDATIONS.

3. PAINT AND GLASS BEADS SHALL BE IN ACCORDANCE WITH STANDARDS PROVIDED IN CHAPTER 3 OF THIS MANUAL.

Figure 8-13. F-16 Engine Inlet Danger Area Pavement Markings for Idle Thrust

APPENDIX B BEST PRACTICES

B-1 PAVEMENT MARKING.

B-1.1 DEVELOPMENT SPONSORSHIP.

The FAA funded, and the American Concrete Pavement Association (ACPA), in cooperation with the Innovative Pavement Research Foundation (IPRF), executed Project 05-1, *Develop and Publish a Best Marking Practices Handbook*. The products were delivered in September 2008 and are available for download: http://www.iprf.org/products/main.html

B-1.2 CONTENTS.

The manual is composed of the following products:

- Airfield Marking Handbook (pdf format)
- PowerPoint Presentation
- Instructional video (The instructional video requires the DivX codec, which is downloadable from the same website.)

Note: Printed copies of this report are available at no cost; however, a nominal shipping and handling fee applies.

B-1.3 EXCEPTIONS.

The practices, methods, and recommended materials provided within the report do not necessarily comply with the mandatory policies established within this UFC or individually by the Services. In cases where there are conflicts, this UFC, as well as Service, MAJCOM, and MACOM-specific policies, govern.

B-2 PREVIOUS AIRFIELD MARKING PATTERN STANDARDS.

B-2.1 PATTERN SIZES AND LAYOUTS.

Previous pavement marking standards called for smaller and differently spaced marking schemes from those standardized by the FAA or ICAO. This UFC attempts to standardize marking standards and practices across DoD in an effort to enable uniform recognition of surface painted markings and better promote aviation safety, regardless of the geographic location of the airfield.

When to Implement New Marking Patterns/Layouts.

Due to the potentially significant budgetary impact caused by arbitrary implementation of new standards, continue marking current patterns until renovation of the pavement (reconstruction or overlay) or at least 50 percent of the individual pavement feature (e.g., a runway, a taxiway system, or individual aprons and taxilanes). This allows a phased approach to replacing obsolete patterns or marking schemes.

Exceptions to Civil Standards on DoD-Owned Facilities.

Note that not all FAA-promulgated size requirements and enhancements have been made mandatory requirements in this UFC. This is because military missions, needs, and funding constraints are different from those of civil operational interests. Where FAA or ICAO standards differ from those within this UFC, these standards govern unless waivered by the appropriate authority.

B-2.2 PREVIOUS STANDARDS.

Obsolete USAF Standards.

B-3 METRICATION OF DIMENSIONS.

B-3.1 METRIC VALUES TO USE.

The technologies addressed in this UFC when developed were based on the inch-pound system used in the United States. Because DoD operates in many foreign countries, and because it is beneficial and necessary to use SI units when developing and constructing projects in those theaters, rational conversions are shown here for cases where NATO or ICAO standards are not called out. In an effort to maintain compliance with both U.S. civil standards and international civil aviation standards, imperial and metric dimensions are provided where practicable within the text. The following table was developed to reduce crowding of dimensions and improve clarity and readability in some of the figures within the document. If necessary, use these values to validate the values provided in the figures.

Table B-1 Inches to Millimeters

Inch-Pound Dimension (Inches)	SI Dimension (Millimeters)
2.00 inches	51 millimeters
3.00 inches	76 millimeters
3.50 inches	89 millimeters
4.00 inches	102 millimeters
5.00 inches	127 millimeters
6.00 inches	152 millimeters
7.00 inches	178 millimeters
7.50 inches	191 millimeters
8.00 inches	203 millimeters
10.00 inches	254 millimeters
12.00 inches	305 millimeters
13.00 inches	330 millimeters
14.00 inches	356 millimeters
15.00 inches	381 millimeters
16.00 inches	406 millimeters
18.00 inches	457 millimeters
20.00 inches	508 millimeters
23.00 inches	584 millimeters
24.00 inches	610 millimeters
26.00 inches	660 millimeters
36.00 inches	914 millimeters
37.00 inches	940 millimeters
48.00 inches	1219 millimeters
51.00 inches	1,295 millimeters

Table B-2 Feet to Meters

Inch-Pound Dimension (Feet) [Nominal Tolerance Dimension]	Metric Used (rounded to nearest tenth of meter)
0.5 foot	0.2 meter
1 foot	0.3 meter
1.3 feet	0.4 meter
1.5 feet	0.5 meter
2 feet	0.6 meter
2.29 feet	0.7 meter
2.5 feet	0.8 meter
3 feet	0.9 meter
3.5 feet	1.1 meters
4 feet	1.2 meters
4.5 feet	1.4 meters
5 feet	1.5 meters
5.17 feet	1.6 meters
5.5 feet	1.7 meters
5.75 feet	1.75 meters
6 feet	1.8 meters
6.33 feet	1.9 meters
6.5 feet	1.98 meters
6.6 feet	2.0 meters
6.75 feet	2.1 meters
7 feet	2.13 meters
7.5 feet	2.3 meters
8 feet	2.4 meters
8.4 feet	2.56 meters
8.5 feet	2.6 meters
9 feet	2.7 meters
9.5 feet	2.9 meters
10 feet	3 meters
11 feet	3.4 meters
11.5 feet	3.5 meters
12 feet	3.7 meters
12.5 feet	3.8 meters
13 feet	3.96 meters
13.2 feet	4.0 meters
13.5 feet	4.1 meters
14 feet	4.3 meters
15 feet	4.6 meters

Inch-Pound Dimension (Feet) [Nominal Tolerance Dimension]	Metric Used (rounded to nearest tenth of meter)
16 feet	4.9 meters
16.25 feet	5.0 meters
17 feet	5.2 meters
17.5 feet	5.3 meters
18 feet	5.5 meters
18.5 feet	5.6 meters
19 feet	5.8 meters
20 feet	6.1 meters
20.66 feet	6.3 meters
22 feet	6.7 meters
24 feet	7.3 meters
24.5 feet	7.5 meters
25 feet	7.6 meters
26 feet	7.9 meters
27 feet	8.2 meters
28 feet	8.5 meters
30 feet	9.1 meters
30.8 feet	9.4 meters

C-2 TERMS

Precision Approach Runway Category I—A runway served by an instrument landing system (ILS), microwave landing system (MLS), or precision approach radar (PAR) and visual aids intended for operations down to 60 meters (200 feet) decision height, and down to a runway visual range (RVR) on the order of 720 meters (2,400 feet).

Precision Approach Runway Category II—A runway served by ILS or MLS and visual aids intended for operations down to 30 meters (100 feet) decision height and down to an RVR on the order of 360 meters (1,200 feet).

Precision Approach Runway Category III—A runway served by ILS or MLS (no decision height being applicable) and:

> **Category IIIa:** By visual aids intended for operations down to an RVR on the order of 210 meters (700 feet).
>
> **Category IIIb:** By visual aids intended for operations down to an RVR on the order of 45 meters (150 feet).
>
> **Category IIIc:** Intended for operations without reliance on external visual reference. (The RVR is 0).

Entry Control Point—A marked location on the periphery of a controlled and restricted area for accessing and exiting the designated area.

Index of Refraction—The ratio of the speed of radiation (as light) in one medium (as a vacuum) to that in another medium—also called *refractive index*.

Taxilane—Designated path marked through parking, maintenance, or hangar aprons, or on the perimeter of such aprons, to permit the safe ground movement of aircraft operating under their own power.

Taxitrak—A specially prepared or designated path, on an airfield other than mass parking areas, on which aircraft move under their own power to and from taxiways to dispersed platforms.

Taxiway—A specially prepared or designated path, on an airfield or heliport other than apron areas, on which aircraft move under their own power to and from landing, service, and parking areas.

Towway—Paved surface over which an aircraft is towed.

Record of Changes (changes are indicated by **1**\ ... /**1**/)

Change No.	**Date**	**Location**

This FC supersedes ETL 02-16, *Design, Construction, Maintenance, and Evaluation of the Pegasus Glacial Ice Runway for Heavy Wheeled Aircraft Operations*, dated Oct 2002; and ETL 07-12, *Design, Construction, Maintenance, and Evaluation of the McMurdo Sound (Antarctica) Sea Ice Runway*, dated Sep 2007.

FOREWORD

Facilities Criteria (FC) provide functional requirements (i.e., defined by users and operational needs of a particular facility type) for specific DoD Component(s), and are intended for use with unified technical requirements published in DoD Unified Facilities Criteria (UFC). FC are applicable only to the DoD Component(s) indicated in the title, and do not represent unified DoD requirements. Differences in functional requirements between DoD Components may exist due to differences in policies and operational needs.

All construction outside of the United States is also governed by Status of Forces Agreements (SOFA), Host Nation Funded Construction Agreements (HNFA), and in some instances, Bilateral Infrastructure Agreements (BIA.) Therefore, the acquisition team must ensure compliance with the most stringent of the UFC (replace w/ FC), the SOFA, the HNFA, and the BIA, as applicable.

Because FC are coordinated with unified DoD technical requirements, they form an element of the DoD UFC system applicable to specific facility types. The UFC system is prescribed by MIL-STD 3007 and provides planning, design, construction, sustainment, restoration, and modernization criteria, and applicable to the Military Departments, Defense Agencies, and the DoD Field Activities. The UFC System also includes technical requirements and functional requirements for specific facility types, both published as UFC documents and FC documents.

FC are living documents and will be periodically reviewed, updated, and made available to users as part of the Services' responsibility for providing criteria for military construction. Headquarters, U.S. Army Corps of Engineers (HQUSACE), Naval Facilities Engineering Command (NAVFAC), and the Air Force Civil Engineer Center (AFCEC) are responsible for administration of the UFC system. Defense agencies should contact the preparing service for document interpretation and improvements. Technical content is the responsibility of the cognizant DoD working group. Recommended changes with supporting rationale should be sent to the respective service proponent office by the following electronic form: Criteria Change Request. The form is also accessible from the Internet site listed below.

FC are effective upon issuance and are distributed only in electronic media from the following source:

- Whole Building Design Guide web site http://dod.wbdg.org/.

Refer to UFC 1-200-01, *General Building Requirements*, for implementation of new issuances on projects.

AUTHORIZED BY:

JOE SCIABICA, SES
Director
Air Force Civil Engineer Center

FACILITIES CRITERIA (FC)
NEW SUMMARY SHEET

Document: FC 3-260-06F, *Design, Construction, Maintenance, and Evaluation of Snow and Ice Airfields in Antarctica*

Superseding:

- ETL 02-16, *Design, Construction, Maintenance, and Evaluation of the Pegasus Glacial Ice Runway for Heavy Wheeled Aircraft Operations*, and ETL 07-12, *Design, Construction, Maintenance, and Evaluation of the McMurdo Sound (Antarctica) Sea Ice Runway*

Description:

- Provides design, construction, and maintenance details, dimensional criteria, and structural evaluation criteria for compacted snow, glacial ice and ice runways used by wheeled or ski-equipped aircraft.

Reasons for Document:

- The criteria presented herein unify and standardize current airfield practices for Antarctica previously found in multiple documents. These criteria update guidance on thickness of snow topping on glacial ice runways and clarifies marking and lighting requirements.

Impact:

- Issuance of this document should not significantly impact future design costs, initial costs, energy savings, or life cycle cost as compared to current practices.

Unification Issues

- Not Applicable

TABLES

This Page Intentionally Left Blank

CHAPTER 1 INTRODUCTION

1-1 PURPOSE.

1-1.1 Facilities Criteria

This Facilities Criteria (FC) provides design, construction, and maintenance details, dimensional criteria, and structural evaluation criteria for compacted snow and/or ice runways used by wheeled aircraft. Three potential surface conditions are considered:

- Wheeled aircraft operations on glacial ice
- Wheeled aircraft operations on white ice (glacial ice capped with processed snow)
- Wheeled aircraft operations on sea ice

The dimensional criteria are the same for all surfaces. Although these criteria were developed from operational experience on the airfields at McMurdo Station, Antarctica, the concepts are generally applicable to any runway composed of glacial ice, white ice, or sea ice. Appendices B-12 and B-13 provide drawings of the layout of an operational glacial ice airfield which includes a skiway and sea ice airfield located on the Ross Ice Shelf and McMurdo Sound, Antarctica.

Note: The use of the name or mark of any specific manufacturer, commercial product, commodity, or service in this FC does not imply endorsement by the U.S. Air Force.

1-1.2 U.S. Antarctic Program.

The airfields in Antarctica are operated by the U.S. Antarctic Program (USAP) and primarily support Air Force aircraft. Three airfields have been used at McMurdo Station and one skiway has been maintained at the South Pole Station.

1-1.2.1 Williams Field Skiway.

Williams Field is located in an area that receives heavy annual snowfall and is built in an area with a deep snow layer overlying the Ross Ice Shelf. The Williams Field skiway is comprised of a compacted snow surface. This FC does not apply to Williams Field skiway or other skiways. See AFI 13-217 for skiway criteria.

1-1.2.2 Pegasus Glacial Ice Runway.

Starting in 1993, the Pegasus airfield supported C-130 Hercules and C-141 Starlifter aircraft from an exposed glacial ice surface. In 2002 a compacted snow surface (“white ice”) was placed over the glacial ice and C-130, C-141, and C-17 Globemaster III aircraft have since performed routine operations from this white ice surface.

1-1.2.3 Sea Ice Runway.

The sea ice runway on McMurdo Sound has previously supported C-130, C-141, C-5, and C-17 aircraft. For many years C-130 and C-17 aircraft have completed routine operations from an exposed graded sea ice surface. Since 2002, they have occasionally operated on a sea ice surface overlain by either a moderately processed thin snow cap or a thin layer of fresh, loose snow.

1-1.2.4 South Pole Skiway.

The skiway at South Pole Station is a high-altitude skiway constructed on compacted snow. It is served only by LC-130 and other ski-equipped aircraft. See AFI 13-217 for skiway criteria.

1-2 APPLICATION.

This FC applies to all Department of Defense (DOD) organizations responsible for design, construction, maintenance, and evaluation of snow and/or ice airfields.

1-2.1 McMurdo Station Operations.

1-2.1.1

It is anticipated that all of the field measurements and data collection prescribed in this FC can and will be accomplished by knowledgeable personnel within the USAP and deployed to Antarctica as part of their occupational performance. This does not preclude Air Force certification teams traveling to McMurdo Station to complete an evaluation; however, due to the logistics, coordination, cost, and uncertain nature of travel to and work in Antarctica, it is more likely that the USAP McMurdo Area airfield manager will be responsible for following all FC requirements for data collection.

1-2.1.2

Only Headquarters Air Mobility Command (HQ AMC) can determine the suitability of the airfield for operations of HQ AMC aircraft. It will be the USAP McMurdo Area airfield manager's responsibility to deliver all data and measurements, in the format prescribed in this FC, to the HQ AMC/A7OI contact (see paragraph 1-3) or designee. HQ AMC/A7OI will review the submittal and communicate its findings and decisions back to the airfield manager, who will be responsible for any remedial actions, waiver requests, and communicating the airfield status (e.g., open, closed, open with restrictions) to all impacted operational elements. When HQ AMC/A7OI determines that the airfield meets the criteria specified in this FC, HQ AMC/A3AS will be notified, and, in turn, will ensure HQ AMC/A3 provides approval for aircraft operations.

CHAPTER 2 CRITERIA

2-1 DIMENSIONAL CRITERIA.

Details for establishing airfields for the support of routine operations of Air Force aircraft can be found in UFC 3-260-01. Snow and ice runways in the Antarctic region are unique in a number of ways (e.g., seasonal operation only; low volume of air traffic; extremely remote location; sited on a level, “featureless” ice shelf; limited resources available for construction and maintenance). The criteria are based for the most part on Class B runway requirements; however, some terminology used in this FC differs from that used in UFC 3-260-01. Figures 2-1 and 2-2 show the typical layout, including shoulders, lateral clear area, and end clear area.

2-1.1 Runways.

Table 2-1 provides dimensional criteria for the layout and design of snow and ice runways. Minimum runway length shall be 3050 meters (10,000 feet) for fully loaded C-17 aircraft operations and 2440 meters (8000 feet) for fully-loaded C-130 aircraft unless otherwise directed by the major command (MAJCOM) Director of Operations (A3).

2-1.2 Runway Shoulders.

Shoulders are required along each outside edge of the runway. They must be prepared to the same strength as the runway surface (and be of the same surface material: glacial ice, white ice, compacted snow, or sea ice) and be free of obstacles. Shoulder geometric requirements are presented in Table 2-1. Because the shoulders are constructed to the same strength as the runway surface, C-130s and LC-130s can use the shoulders for turnarounds. However, to prevent the need for very sharp turns and potential damage to the runway surface, C-17s will not use shoulders for turns and instead turn around at widened runway ends, as shown in Figure 2-3.

2-1.3 Runway Graded Area.

A graded area is required adjacent to the runway shoulder. It is not considered a full-strength area for supporting aircraft; however, it is sloped approximately the same as the shoulder, as described in Table 2-11. Marker flags are installed within the graded area.

Table 2-1 Runway Dimensional Requirements for C-130, LC-130 and C-17 Operations

Item No.	Description	Requirement	Remarks
1	Length (minimum)	See Remarks	Minimum runway length will be determined by the MAJCOM/A3 for the most critical aircraft in support of the mission.
2	Width	46 m (150 ft)	Since snow and ice runways are devoid of traditional painted surface markings, the runway will appear to be 64 m (210 ft) wide – the distance between the inner marker flags.
3	Width of shoulders (minimum)	7.6 m (25 ft)	Remove all snow berms and snow drifts in shoulder areas. All glacial ice, white ice, compacted snow and sea ice in shoulders shall be prepared to required runway strength standards.
4	Longitudinal grade	2% maximum (up or down)	The maximum grade of any tangent, as well as the total elevation change from one threshold of the runway to the other, shall not exceed 2%.
5	Longitudinal grade change	No grade change greater than 0.5% is to occur within 300 m (1000 ft) from the runway end	Hold to minimum practicable. Grades may be both positive and negative but must not exceed the limit specified. Applies to runway and shoulders.

Item No.	Description	Requirement	Remarks
6	Rate of longitudinal grade change	Maximum 0.167% per 30.5 m (100 ft)	Grade changes will be held to a minimum and will be gradual. Application of this criterion will produce a vertical curve having a 182.9 m (600 ft) length for each percent of algebraic difference between the two grades. Minimum distance between grade changes is 61 m (200 ft). Grade changes cannot exceed 1.5% measured at 61-m (200-ft) intervals. Applies to runway and shoulders. **Note:** In addition to these grade requirements, the runway shall be checked for high-frequency, low-amplitude undulations that degrade rideability and may decrease aircraft stopping performance. Any dips, rises or “chatter” shall be noted and corrected by fine-grading and re-compacting the surface.
7	Transverse slope of runway	1.5% maximum	Transverse slopes can be flat and uniform, or crowned at the centerline. A crowned centerline is preferred. Sea ice runway is flat.
8	Transverse slope of shoulders	2% max. down 1% max. up	For a glacial ice surface, shoulders shall slope down from the runway edge. A white ice surface may slope down at 2% maximum or up at 1% maximum. Sea ice shoulders are flat.
9	Width of graded area	Minimum 12.2 m (40 ft)	The graded area is measured from the outside edge of the shoulder. Graded area will routinely have no more than 25 mm (1 in) of loose snow cover. (During clean-up following a drifting event, snow up to 300 mm [12 in] may exist immediately adjacent to runway markers while the runway proper and the shoulders are being maintained to the 25 mm (1 in) standard in order to resume critical flight operations. As soon as practicable, any drift snow in the graded area must be removed to maintain the overall runway standard.)

Item No.	Description	Requirement	Remarks
10	Transverse slope of graded area	2% maximum (up or down)	Ideally, graded area slope (up or down) will match that of runway shoulders.
11	Width of lateral clear area	79.5 m (260 ft)	The lateral clear area is measured outward from the outside edge of the graded area.
12	Transverse slope of lateral clear area	12% maximum (up)	Requirement is applied to imaginary plane extending from the outer edge of the graded area outward a distance of 79.5 m (260 ft). No object or surface feature may penetrate this imaginary plane.
13	Width of primary surface	244 m (800 ft)	Centered on the runway centerline and incorporates the runway, shoulder, graded area, and lateral clear area. No fixed or mobile objects may be located in this area unless the item is fixed by function and therefore a permissible deviation.
14	Distance between centerlines of parallel runways	305 m (1,000 ft)	Visual flight rules (VFR) without intervening parallel taxiway between the parallel runways. One of the parallel runways must be a VFR-only runway.
		633 m (2,075 ft)	VFR with intervening parallel taxiway.
		762 m (2,500 ft)	Instrument flight rules (IFR) using simultaneous operation (depart-depart) (depart-arrival).
		1311 m (4,300 ft)	IFR using simultaneous approaches.
15	Width of USAF mandatory zone of frangibility	152.5 m (500 ft)	Centered on the runway centerline. All items sited within this area must be frangible.
16	Length of USAF mandatory zone of frangibility	1829 m (6,000 ft)	Centered on the runway. All items sited within this area to the ends of the end clear zone must be frangible.

Figure 2-1 Typical Runway Layout for Bi-Directional Operations (Not to Scale)

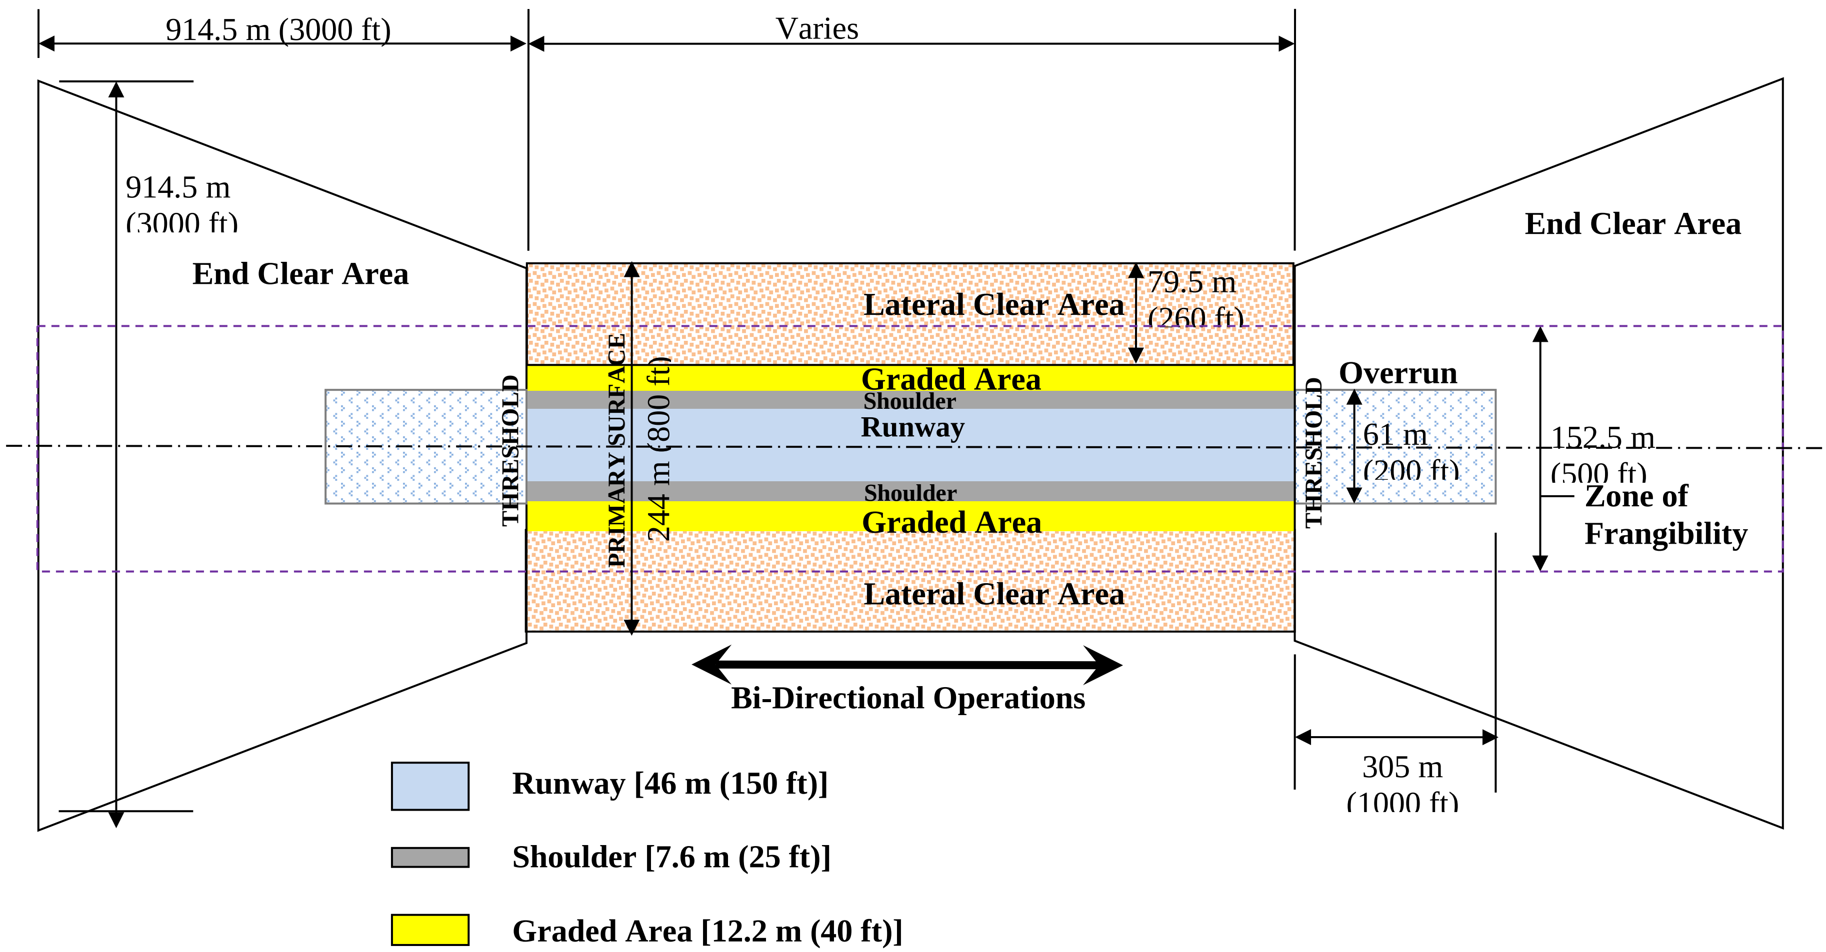

Figure 2-2 Typical Runway Layout for Uni-Directional Operations (Not to Scale)

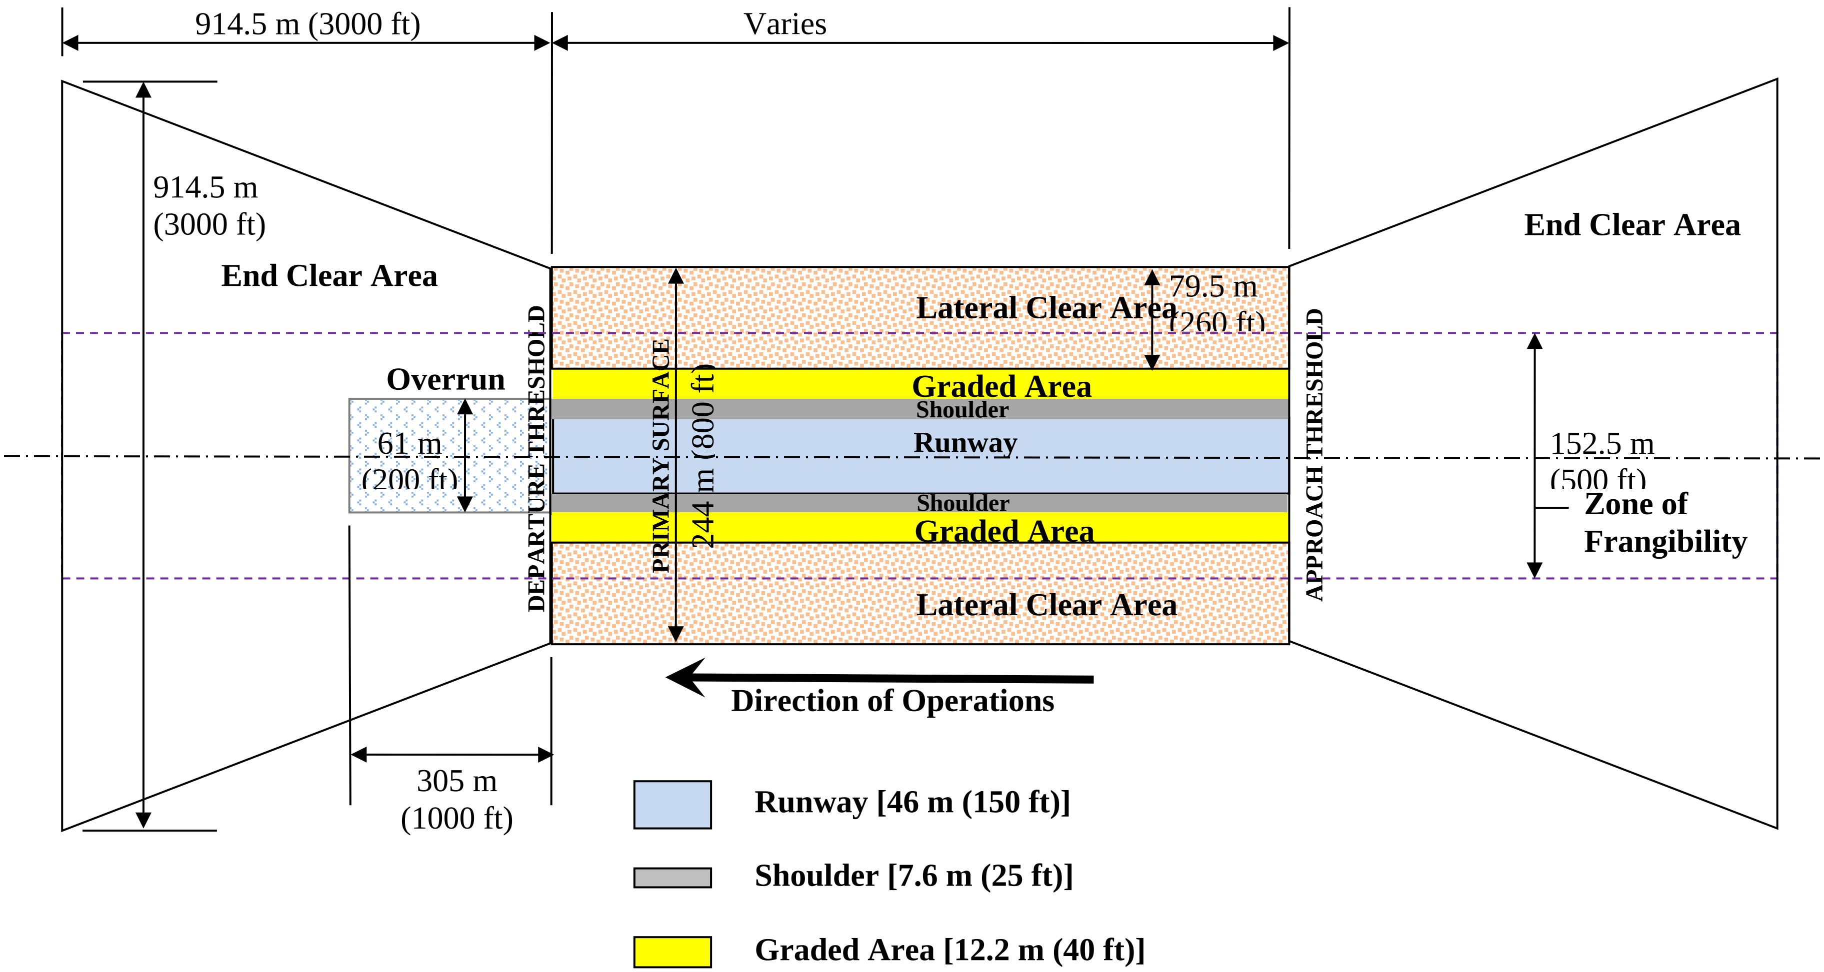


2-1.4 Overruns.

Overrun geometric requirements are presented in Table 2-2. The overrun must be constructed to the same structural standards as the runway surface. For bi-directional operations, an overrun must be provided at both ends. For uni-directional operations, an overrun is only required at the departure end of the runway.

2-1.5 Clear Areas.

Runway end clear areas are required and their dimensions are given in Table 2-2. The layout is shown in Figures 2-3 and 2-4. Clear areas must be free of fixed or mobile objects that are not specifically identified and positioned as described in this FC.

Table 2-2 Runway Overrun and End Clear Area Requirements for C-130, LC-130, and C-17 Operations

Item No.	Description	Requirement	Remarks
1	End clear area length	914.5 m (3000 ft)	Measured along the extended runway centerline. Begins at the runway threshold.
2	End clear area width at inner edge	244 m (800 ft)	Centered about runway centerline at the threshold.
3	End clear area width at outer edge	914.5 m (3000 ft)	Centered about runway centerline at 914.5 m (3000 ft) from centerline.
4	Overrun length	305 m (1000 ft)	The runway overrun area falls within the runway end clear area. The maximum longitudinal grade (up or down) in the overrun area is 2%.
5	Overrun width	61 m (200 ft) (Runway surface + shoulders)	The overrun area will have a transverse section matching the runway (i.e., include shoulder, graded area, and lateral clear area). See Table 2-1 for transverse dimensional criteria. The longitudinal grade of the first 91.5 m (300 ft) of the overrun shall match the grade of the last 914.5 m (3000 ft) of the runway.
6	Overrun longitudinal grade	Max. 2%	Up or down.

Item No.	Description	Requirement	Remarks
7	Approach-departure clearance surface	50:1	Approach-departure clearance surface begins at the runway thresholds at the same elevation as the centerline elevation and extends away from the runway 7620 m (25,000 ft). During flight operations, no mobile or fixed object may penetrate this imaginary plane.

2-1.6 Taxiways.

Dimensional criteria for taxiways are given in Table 2-3. Taxiways (including shoulders) will have surface strength properties matching those of the runway.

Table 2-3. Taxiway Dimensional Requirements for C-130, LC-130, and C-17 Operations

Item No.	Description	Requirement	Remarks
1	Width	23 m (75 ft) minimum	Since the taxiway is devoid of traditional surface markings, it will appear to be 38.5 m (125 ft) wide (the combined width of the taxiway and the shoulders).
2	Centerline radius of turns (C-130, C-17)	30.5 m (100 ft) minimum	Curves in taxiway must be no tighter than the listed minimum turning radii, measured along the taxiway centerline. Edge of taxiway fillets at runway/ taxiway/apron turns and/or intersections must be 46 m (150 ft) minimum radii.
3	Width of shoulder	7.6 m (25 ft)	Remove all snow berms and snow drifts in shoulder areas. Glacial ice, white ice, and sea ice in shoulders will be prepared to the same strength as the taxiway.

Item No.	Description	Requirement	Remarks
4	Longitudinal grade	3% maximum	Hold to minimum practicable. Grades may be either positive or negative. Applies to taxiway and shoulders.
5	Rate of longitudinal grade change	1% maximum over 30.5 m (100 ft)	Grade changes will be held to a minimum and will be gradual. Minimum distance between grade changes is 152.5 m (500 ft). Grade changes cannot exceed 1% measured at 30.5-m (100-ft) intervals. Applies to taxiway and shoulders.
6	Transverse slope of taxiway	3% maximum	Transverse slopes can be flat, uniform, or crowned at the centerline (crowned centerline is preferred).
7	Transverse slope of shoulders	3% maximum	An exposed glacial ice surface shall slope down from the taxiway edge. A white ice surface may slope upward to a maximum extent of 1%. A sea ice surface will be flat.
8	Runway-taxiway separation	93 m (305 ft)	Measured from the runway centerline to the parallel taxiway centerline.
9	Hold position	76.5 m (250 ft)	Measured from the runway centerline.
10	Infield area		All areas located between the runway and taxiways must be cleared of obstructions not fixed by function.
11	Clearance to fixed or mobile obstacles	61 m (200 ft)	Measured from the taxiway centerline.
12	Width of lateral clear area	42 m (137.5 ft)	Lateral clear area is measured outward from the outer edge of the shoulder. No object or surface feature may penetrate this imaginary plane.

Item No.	Description	Requirement	Remarks
13	Transverse slope of lateral clear area	12% maximum (up)	Requirement is applied to imaginary plane extending from the outer edge of the shoulder outward a distance of 79.5 m (260 ft). No object or surface feature may penetrate this imaginary plane.

2-1.7 Aprons.

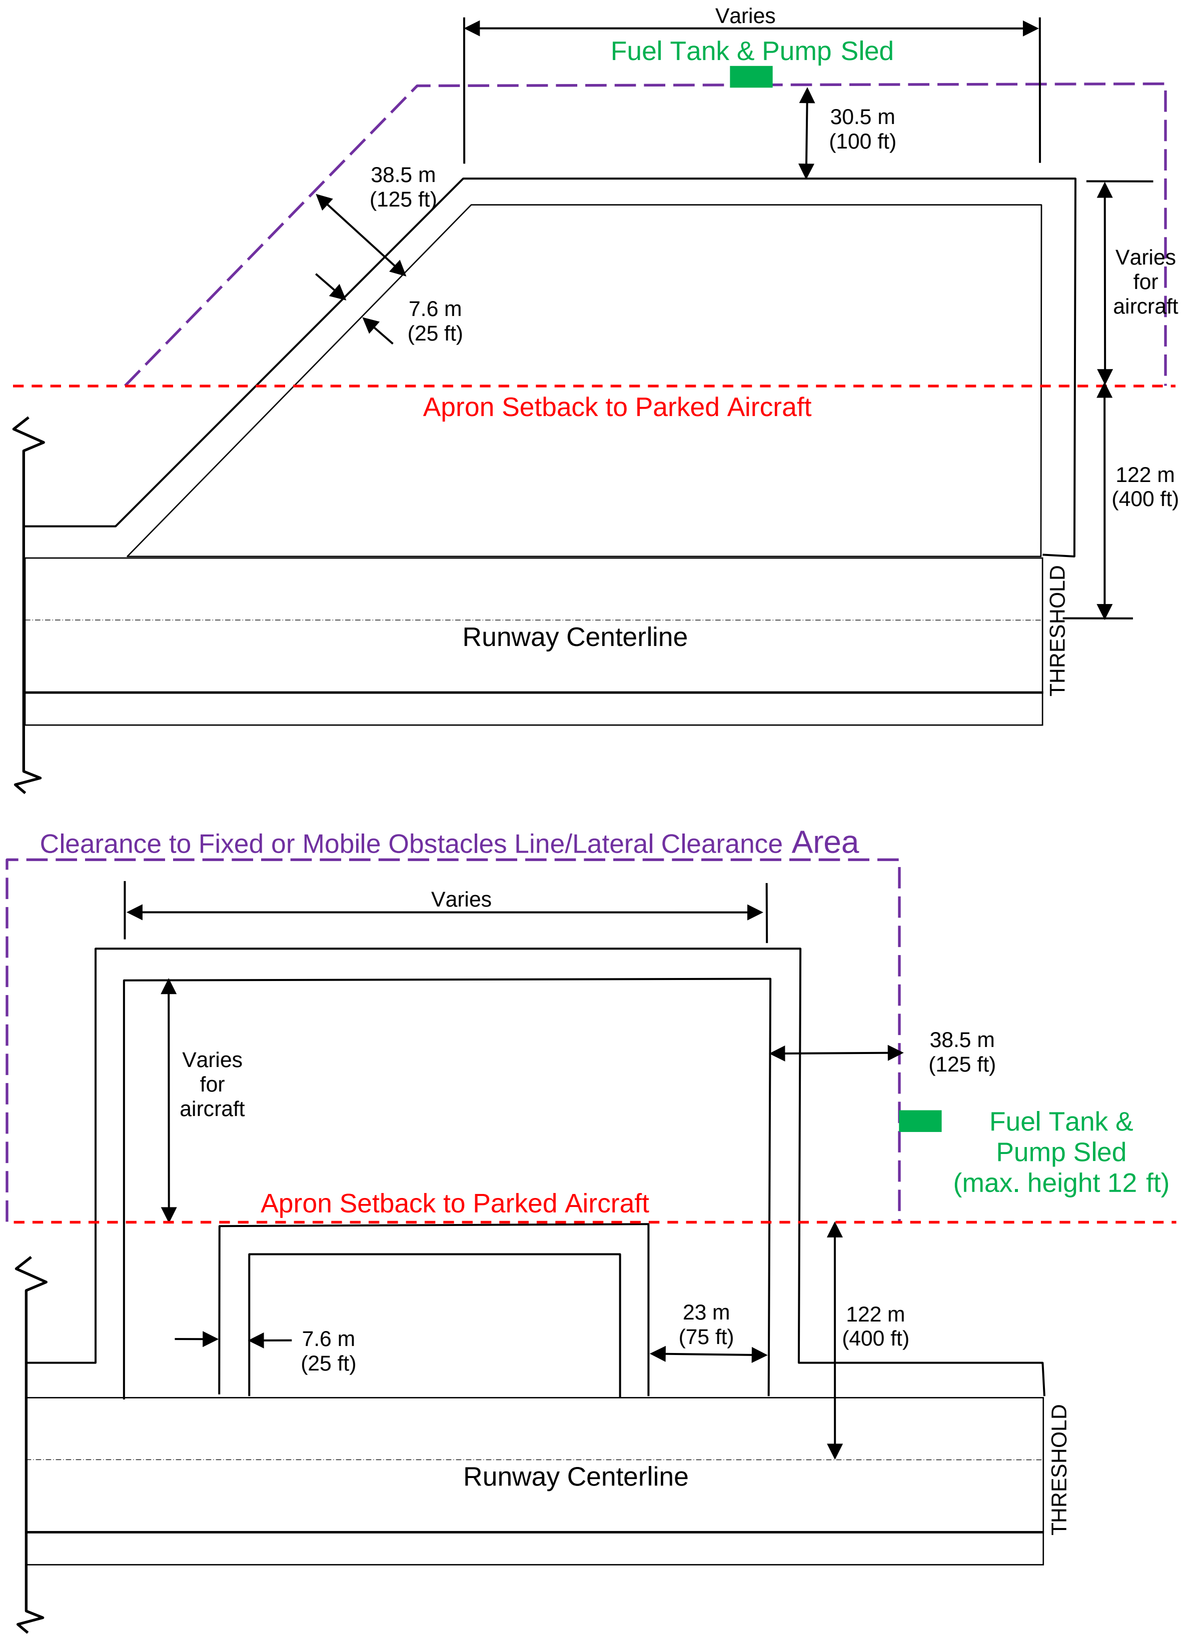
Dimensional criteria for aprons are given in Table 2-4 and plan views of suggested apron configurations are provided in Figure 2-3. Aprons will have surface strength properties matching those of the runway. An apron, parking area, or parallel taxiway is **required** if maximum on ground (MOG) will be greater than one aircraft.

Table 2-4. Apron Requirements for LC-130, C-130 and C-17 Operations

Item No.	Description	Requirement	Remarks
1	Apron size	Varies	Sized to accommodate number of aircraft on ground. Maximum visibility and minimum wingtip clearance must be maintained at all times. As a minimum, the pilot must be able to clearly see all parked aircraft when taxiing.
2	Apron grade	3% maximum	Ideally, uniform grade will exist over entire apron area.
3	Width of shoulder	7.6 m (25 ft)	Remove all snow berms and snow drifts in shoulder areas. Snow in shoulders will be prepared to the same strength as the apron.
4	Transverse slope of shoulders	3% maximum (down) 1% maximum (up)	An exposed glacial ice surface shall slope down from the apron edge. A white ice or compacted snow surface may slope upward to a maximum extent of 1%. Sea ice shoulders are flat.
5	Apron setback	122 m (400 ft)	Measured from the runway centerline to the near edge of the parking apron.

Item No.	Description	Requirement	Remarks
6	Clearance to fixed or mobile obstacles	38.5 m (125 ft)	Measured from the outer edge of the apron.
7	Width of lateral clear area	30.5 m (100 ft)	Lateral clear area is measured outward from the outer edge of the shoulder. No object or surface feature may penetrate this imaginary plane.
8	Transverse slope of lateral clear area	12% maximum (up)	Requirement is applied to imaginary plane extending from the outer edge of the shoulder outward a distance of 79.5 m (260 ft). No object or surface feature may penetrate this imaginary plane.
9	Wingtip clearance	15.2 m (50 ft)	Parked and taxiing aircraft must maintain 15.2 m (50 ft) wingtip clearance from obstructions at all times. Applies to parked aircraft as well as peripheral and internal taxilanes.
10	Centerline radius of turns	46 m (150 ft)	Lay out apron parking positions and taxi lanes to provide ample distance for aircraft to align properly in the parking position. Larger radii are needed on aprons because there are very few visual cues on the snow/ice surface for pilots to steer. In addition, sharp turns on loaded LC-130 skis are very difficult to execute.

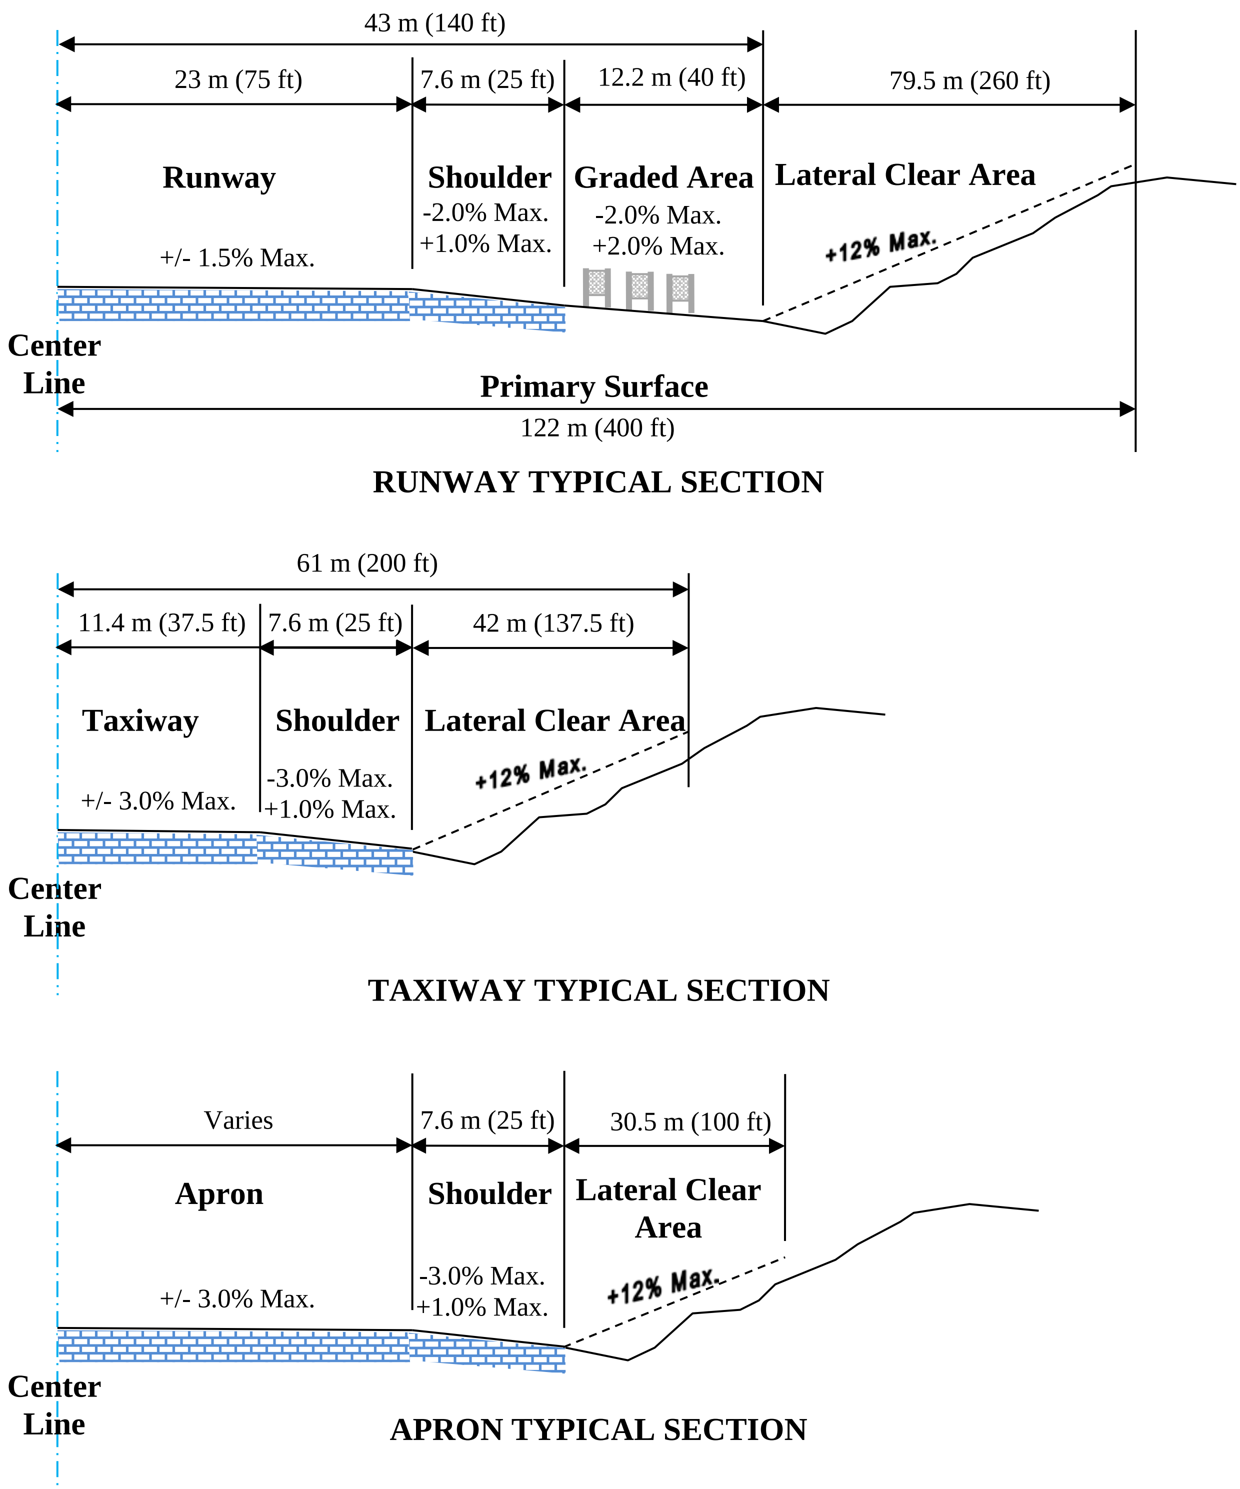
Figure 2-3 Typical Layout Arrangements for Taxiways and Aprons (Not to Scale)



2-1.8 Typical Sections.

Cross-section views of the runway, taxiway, and apron, showing the dimensions from Tables 2-1, 2-2, and 2-3, are shown in Figure 2-4.

Figure 2-4 Typical Cross-Section Dimensions for Runway, Taxiway, and Apron (Not to Scale)



2-2 SNOW/ICE SURFACE CONSTRUCTION, MAINTENANCE, AND STRUCTURAL EVALUATION CRITERIA.

2-2.1 New Runway Construction.

Construction of a new glacial ice runway is described in CRREL Monograph 98-1. For additional criteria on new construction, contact the individuals listed in paragraph 1-3.

2-2.2 Preparation for Initial Seasonal Use.

2-2.2.1 White Ice Runway Surface.

2-2.2.1.1 WinFly.

Prior to WinFly, the white ice runway surface will be graded smooth to remove drifts and snow accumulated during the austral winter. After grading and rolling, marker flags or cones will be installed as needed to support the WinFly flights.

2-2.2.1.2 Mainbody Flying.

Prior to Mainbody flying, the runway surface will be surveyed longitudinally and with transverse cross-sections to identify areas that do not meet the grading criteria stipulated in Tables 2-1 and 2-2. Bulldozers, snow blowers, and graders will be used to cut down slopes and place new snow on the runway surface where the snow cap is too thin. Some grading and dragging between roller passes may be required to make the surface smooth. After compaction is complete and strength testing has passed requirements, all marker flags will be installed per the requirements in paragraph 2-3.5.

2-2.2.2 Sea Ice Runway Surface.

Prior to initial use, clear the sea ice runway of loose snow to expose the sea ice. Check the surface for unacceptable roughness or undulations and serrate the surface with a grader blade, as needed, to smooth out the surface. In addition, fresh water may be added to the surface and allowed to freeze to fill in rough areas. Survey transverse cross-sections to verify snow moved off the runway surface does not conflict with the lateral clear area slope requirements. See the patching procedure in Appendix B-3 for additional repair criteria.

2-2.3 Maintenance During Use.

Ice irregularities, often hidden by snow cover, can do significant damage to wheels when struck at any speed. Surface preparation must include a thorough visual inspection of the landing area to look for ice irregularities and study snow depths and characteristics. Any unacceptable irregularities must be removed. Snow irregularities may be large enough to require the entire surface to be dragged or graded to fill low areas and remove high areas. All undulating surfaces must be graded to minimize the slope and prevent wheel damage.

2-2.3.1 White Ice Runway Surface.

The runway surface must be inspected following every wheeled aircraft operation. Any areas with rubber or soot deposits must be scarified and contaminated snow/ice removed to eliminate any dark material that can absorb sunlight and result in melting the surface. Between C-17 operations and after any snowfall deposits the entire surface shall be rolled with the proof load cart to keep the compacted white ice cap well compacted. When needed, thin lifts of snow may be cut from the berms on either lateral clear area and dragged onto the white ice runway surface then compacted with the proof load cart.

2-2.3.1.1

Maintaining the compacted snow surface will require periodic dragging to remove surface irregularities created by wind action (sastrugi) and to promote ice crystal deformation to harden the loose surface snow. Various types of drag devices have been successfully used. The compacted snow surface will be dragged immediately after fresh snow accumulation, windstorms, or when landings/takeoffs or cargo loading operations have disturbed the surface. Regular inspections by the airfield manager or a designated representative and pilot reports will determine if dragging or other maintenance action is required.

2-2.3.1.2

Aprons shall be groomed to harden the surface prior to supporting cargo loading operations.

2-2.3.2 Sea Ice Runway Surface.

New snow accumulation on the sea ice runway shall be either removed or compacted, depending on the depth. Thin lifts of snow can be compacted (25 millimeters [1 inch] or less compacted thickness) onto the runway surface with the proof load cart. This improves the friction and braking action on the runway.

2-2.4 Runway Strength Evaluation.

Annually, before commencing aircraft operations, the airfield surfaces will be evaluated following the structural evaluation criteria outlined in Appendices B-4 through B-11. In addition, the airfield manager is responsible for interim evaluations as conditions change and as repairs are made. All structural data and recommendations for weight-bearing capacity shall be transmitted to HQ AMC/A7OI for analysis and concurrence. See paragraph 2-6 for airfield certification procedures.

2-2.4.1 Glacial Ice Operating Surface.

The glacial ice surface must be evaluated for three failure modes: deformation, creep, and flexural. Methods for evaluating each mode are described in Appendix B-4.

2-2.4.2 White Ice Operating Surface.

The white ice surface must be evaluated for thickness and strength to avoid deformation failure. Methods for evaluating the white ice surface are described in Appendix B-5.

2-2.4.3 Sea Ice Operating Surface.

2-2.4.3.1

Sea ice is often categorized as first-year or multi-year ice. This characterization of the ice indicates much about its nature, with multi-year ice having significantly greater complexity. However, for the purposes of a sea ice runway for heavy wheeled aircraft, this FC treats both types the same, using overall ice thickness and ice temperature as governors for ice strength, which ultimately determines its ability to support a given aircraft operation.

2-2.4.3.2

The sea ice surface must be evaluated for three failure modes: deformation, flexural (landing and takeoff), and creep (parking). Methods for evaluating each mode are described in Appendix B-6.

2-2.5 Warm Weather Operations at Pegasus White Ice Runway.

Warm weather, typically occurring during the months of December and January, could restrict airlift operations on Pegasus white ice runway, requiring all aircraft to arrive and depart during restricted hours. The USAP will develop procedures for conducting airfield operations in warm weather to include monitoring, testing, and reporting requirements. The airfield manager is responsible for implementing the procedures.

2-3 AIRFIELD MARKINGS.

2-3.1 Airfield Marking Approach

Many snow/ice runways are VFR-only facilities and operated solely during daylight. However, due to their unconventional appearance (white surface, white surroundings), for compatibility with standard pilot experience, and for periods where landings are required but weather conditions are less than ideal, a minimum level of markings are required. The use of markings has evolved over the years and is expected to continue into the future. This FC does not address markings needed for night operations or skiways. See AFI 13-217 for skiway marking requirements.

2-3.2 Specific Requirements

Adopting the full extent and type of markings found at a conventional airfield is impractical for a snow/ice runway. Painted markings will degrade the snow/ice and quickly be covered by blowing snow or new snowfall. Conventional airfield directional signs will be quickly buried by snow. Sometimes other visual aids (lights) and electronic signals (navigational aid systems [NAVAIDS]) are available to assist with acquiring and lining up on the runway; therefore, a system of flags is used to indicate the limits of the runway. Required and optional markers are listed below.

Threshold markers	Required
Distance remaining and edge markers	Required
Approach line markers	Optional
Taxiway and apron flagging	Optional

2-3.3 Marking Criteria

Minimizing the number and surface area of markings is desirable for the purpose of reducing runway maintenance and increasing runway availability and longevity. Figure 2-5 shows the layout of a typical snow/ice runway, including the positions of threshold, distance remaining, and approach line markers. All markers will be made of durable, lightweight materials. Support posts must be frangible and present a tiny cross-section to the wind to minimize snow drifting, which will be accomplished by a minimum number of posts; bamboo canes are currently used with good results. The markers are ideally of a mesh material to minimize the impedance of the wind, both to limit wind loading on the support posts and, more importantly, to reduce snow drifting. Ideally, the base of a marker shall be more than 0.3 meter (1 foot) above the snow surface to avoid snow drifting. This height must be balanced against the need for adequate clearance between the base of an aircraft wing, engine, or propeller and the top of the marker. Currently, black or red fabric is used for marker flags. White numbers on the black fabric are used for distance-remaining markers. Flags without numbers are punched with up to five 50-millimeter (2-inch) -diameter holes to reduce wind resistance and bending force in the support posts. Note that all marker flags are well above the runway surface and that no surface markings are present to depict the runway centerline, shoulder edges, landing zone, or thresholds.

2-3.4 Temporary Markings

On glacial ice, white ice, and compacted snow parking aprons, temporary markings are sometimes applied to guide aircraft to parking positions. Reflective orange or red paint can be sprayed on the apron surface just prior to arrival to indicate the nose gear centerline path and stop point. When the marking is no longer needed, it shall be quickly scarified to avoid absorbing sunlight radiation that can lead to melting of the surface.

2-3.5 Marker Flags

Figure 2-6 shows details of the marker flags. Note that all markings are only present at the site during the flight periods. At all other times markers are removed from the site to discourage progressive snow accumulation.

2-3.6 Frangibility

All structures placed or constructed within the airfield environment are required to be frangible (to the maximum extent practicable). This applies for any aboveground construction within 76.5 meters (250 feet) of the runway centerline and an extension of that dimension for 914.5 meters (3000 feet) beyond the ends of the runway thresholds and within 61 meters (200 feet) of the taxiway centerline (except required NAVAIDS). Frangibility implies that an object will collapse or fall over after being struck by a moving aircraft with minimal damage to the aircraft.

2-3.7 Low Visibility Markers.

For operations during low-light or no-light periods, special high-intensity, retro-reflective and radar-detectable cones may be deployed at the locations shown in Figure 2-7. One type of suitable cone is manufactured by Reginald Bennett (RBI) International, Model Number 336.

2-3.7.1 Cone Dimensions and Characteristics.

Cones will be shaped like a square-base pyramid. Cones will be minimum 790 millimeters (31 inches) tall and 610 millimeters (24 inches) wide at the base. Cones used for marking the landing zone boxes will have red and green sides. Cones used for marking the runway edge will be silver on all sides.

2-3.7.2 Cone Layout.

Cones will be placed every 152.5 meters (500 feet) on each side of the runway next to the normal daytime flag markers (approximately 30.5 meters [100 feet] from centerline). The first 305 meters (1000 feet) of each approach end will have cones spaced 305 meters (1000 feet) apart with double cones to create a landing zone “box.” The cones shall be spaced laterally at a minimum of 1.8 meters (6 feet) apart to allow visual acquisition of two separate cones—any closer and they merge into one cone reflection. Two cones will be placed symmetrically about the centerline, spaced 1.8 meters (6 feet) apart at the departure end of the overrun.

2-3.7.3 Cone Installation.

Cones are secured to the ice runway using four lag screws, each 275 millimeters (11 inches) long and 9 millimeters (0.375 inch) in diameter, with 38-millimeter (1.5-inch) fender washers. Holes are pre-drilled in the ice, 6 millimeters (0.25 inch) in diameter and 300 millimeters (12 inches) deep.

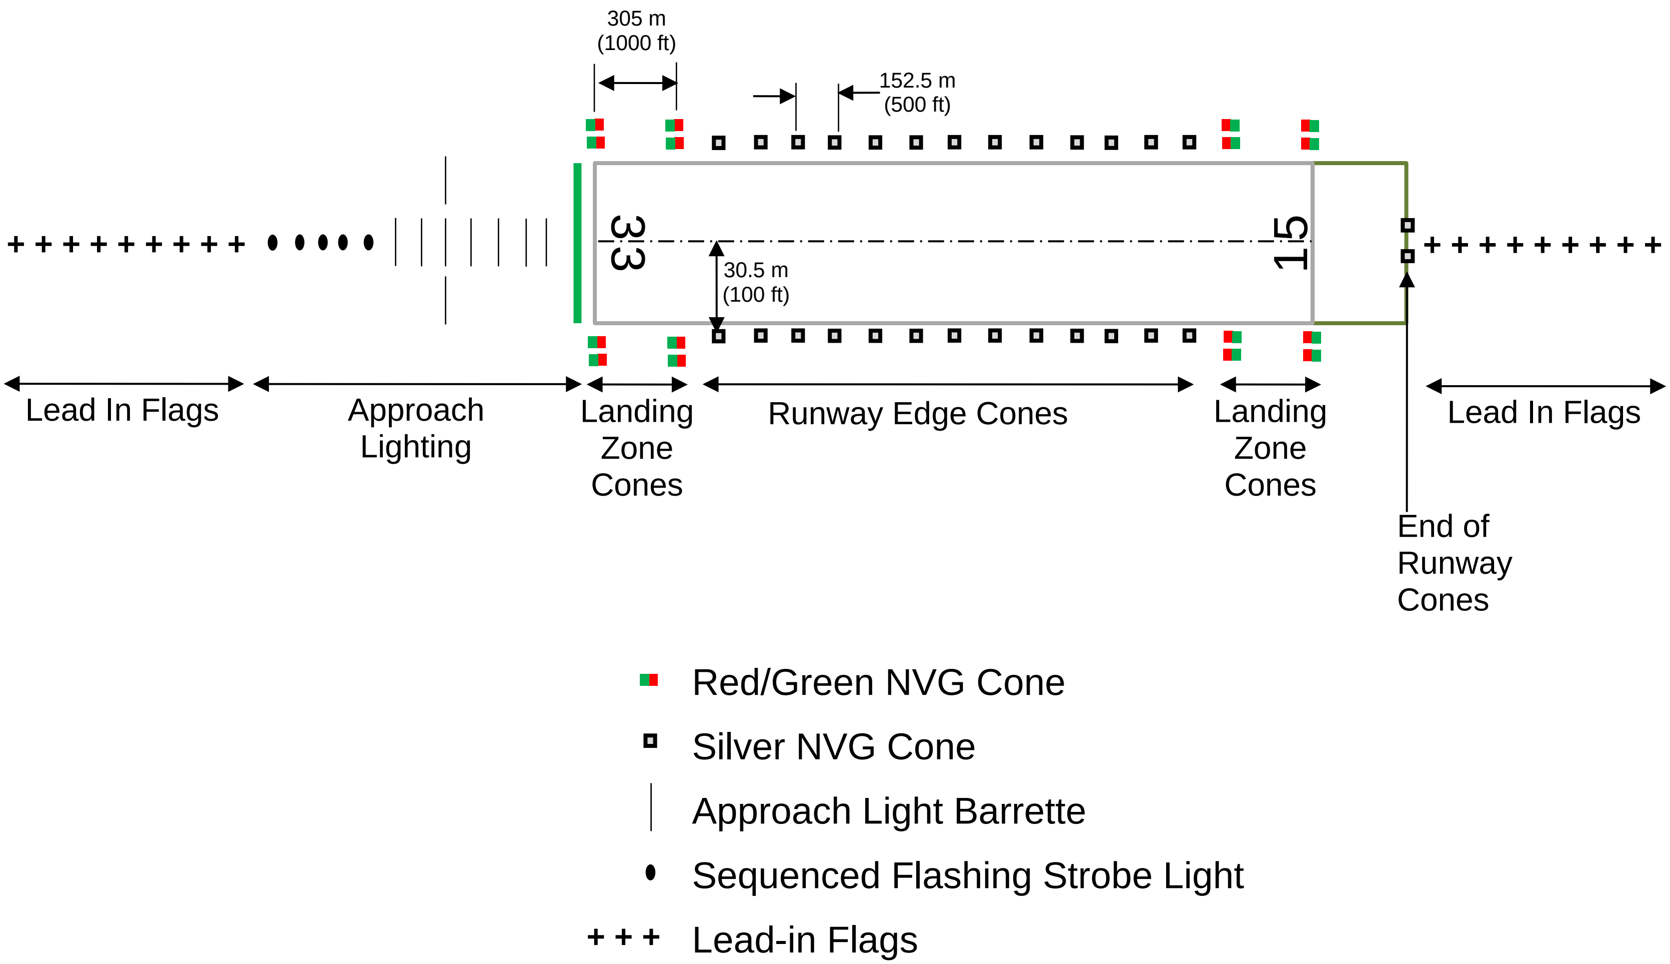
Figure 2-7 Low Visibility Cone Layout for Ice Runway



2-4 AIRFIELD LIGHTING.

2-4.1 Lighting Approach

A limited number of lights are helpful for runway alignment acquisition, particularly during less-than-perfect weather conditions. The use of airfield lighting on snow/ice runways has evolved over the years and is expected to continue into the future.

2-4.2 Desirable Lighting Components

Adopting the full extent and type of lighting found at a conventional airport is not practical for a snow/ice runway. Runway edge lights would interfere with maintenance of the snow or ice surface and providing power with above-ground cables is not practical. Snow/ice runways can be used without airfield lights as long as the field is properly marked and the airspace is controlled. However, airfield lights are highly desirable and can significantly improve the safety of flying operations, especially at locations such as Williams Field that have nearby topographical features that require circling approaches to land. The lighting components listed below are optional but desirable and listed in the order of importance. Airfield lighting systems that are operational shall be noted in the airfield manager's certification report to HQ AMC/A3AS (see paragraph 2-6).

Threshold lights	Optional
Approach lights (modified MALSR)	Optional
Precision approach path indicators (PAPI)	Optional
Runway end identifier lights (REIL)	Optional

2-4.2.1 Threshold Lights.

Install threshold lights in a line perpendicular to the extended runway centerline prior to the threshold a distance of not more than 3 meters (10 feet). The line of lights is symmetrical about the runway centerline and extends 5 meters (15 feet) outboard of the lines of the innermost runway edge marker flags (total of 36.5 meters [120 feet] from centerline). The threshold lights consist of elevated lights with green lenses. Lights are symmetric about the runway centerline and spaced 1.5 meters ± 50 millimeters (5 feet ± 2 inches) apart (total of 48 lights). Even when threshold lights are installed, threshold marker flags must still be installed as described in paragraph 2-3.5.

2-4.2.2 Approach Lights.

Approach lights are placed in a modified SSALR (simplified short approach lighting with runway alignment indicator lights [RAILs]) configuration and consist of two different types of lights: steady burn and sequenced flashing strobes. Steady-burn elevated white lights in groups of five are placed within the 427 meters (1400 feet) prior to the approach threshold at 61 meters (200 feet) spacing. An additional two groups of five lights are placed either side of the center barrette at 305 meters (1000 feet) from the threshold. Elevated sequenced flashing strobe lights (SFL) are installed on centerline and between 488 meters (1600 feet) and 914.5 meters (3000 feet) from the approach threshold at 61 meters (200 feet) spacing. Three to eight flashing strobes can be installed, depending on equipment availability. The SFL must flash in sequence from the outer end toward the runway threshold at a steady rate between 60 and 120 times per minute. The interval between flashes of adjacent lights must nominally be 1/30 second. See UFC 3-535-01, paragraph 3.5, for specific color, intensity, and aiming criteria.

2-4.2.3 Precision Approach Path Indicators (PAPI).

The PAPI is an unattended system that provides visual glide path criteria for landing an aircraft. Sighting and configuration requirements are listed below. See UFC 3-535-01 for additional details.

2-4.2.3.1 Configuration.

The standard PAPI system consists of a light bar with four light units (FAA L-880, per FAA AC 150/5345-28G) placed on the left side of the runway in the vicinity of the touchdown point. See Figure 3-12 in UFC 3-535-01 for an illustration of the configuration.

Note: At McMurdo Station airfields, a two-bar PAPI system is commonly used. This configuration is less desirable, but acceptable, and shall be noted in the airfield suitability report (see paragraph 2-6.1).

2-4.2.3.1.1

Each light unit must be frangible mounted. It must contain two lamps minimum (three lamps preferred) and an optical system that produces a horizontally split, two-color (white over red) light beam.

2-4.2.3.1.2

Beginning at the outboard-most units, each unit in a bar is aimed into the approach at a successively higher angle above the horizontal. When on a proper approach path, the pilot sees the two inboard lights in both bars as red and the two outboard lights as white. As the approaching aircraft settles below the proper path, the pilot sees an increasing number of red lights in each outboard light bar. As the aircraft rises above the path, the pilot sees an increasing number of white lights in each inboard light bar.

2-4.2.3.1.3

The edge of the innermost unit in each bar must be no closer than 15.2 meters (50 feet) from the runway edge and the units in a bar must be 9 meters (30 feet) apart. The beam centers of all light units must be within ±0.025 meter (1 inch) of a horizontal plane. This horizontal plane must be within ±0.30 meters (1 foot) of the elevation of the runway centerline at the intercept point of the visual glide path with the runway. The units in a bar must all be within 0.025 meter (1 inch) of a line drawn perpendicular to the runway centerline. The distance from threshold to the PAPI shall be the shortest distance that will accommodate the criteria in paragraph 2-4.2.3.2.

2-4.2.3.1.4

Two-Bar PAPI System. In a two-bar system, the units are aimed such that when on a proper approach path the pilot sees the inboard light bar as red and the outboard light bar as white. As the approaching aircraft settles below the proper path, the pilot sees an increasing number of red lights in the outboard light bar. As the aircraft rises above the path, the pilot sees an increasing number of white lights in the inboard light bar.

2-4.2.3.2 Photometric Requirements.

See UFC 3-535-01, paragraph 3-7.3, for PAPI photometric criteria.

2-4.2.3.3 Siting Considerations.

Siting a PAPI must consider, as a minimum, the following: existing or planned instrument landing system (ILS) glide slope; the established glide path (aiming angle, typically 3 degrees); the threshold crossing height (TCH) for the selected aircraft height group; and the runway gradient (longitudinal slope) from the threshold to the PAPI location. See UFC 3-535-01, paragraph 3-7.4, for criteria regarding additional siting considerations.

2-4.2.4 Runway End Identifier Lights (REIL).

The REIL provides the pilot with rapid and positive identification of the runway threshold during approach for landing. The REIL assists the pilot to make landings in VFR conditions and in non-precision instrument approaches in IFR conditions.

2-4.2.4.1 Configuration/Location/Aiming.

A REIL system consists of synchronized flashing lights placed symmetrically about the runway centerline in the vicinity of the runway threshold. The optimum location is 12.2 meters (40 feet) from the runway edge and in line with the threshold lights. The lights may be located laterally up to 23 meters (75 feet) from the runway edge and longitudinally up to 12.2 meters (40 feet) downwind (away from the runway) from the threshold lights to 27.5 meters (90 feet) upwind. Adjust the location of both lights as equally as possible to maintain the symmetry of the installation. The difference in locations must not be more than 3 meters (10 feet) laterally or longitudinally. The elevation of both lights must be within 3 meters (10 feet) of the runway centerline at the threshold. See UFC 3-535-01, paragraph 3-6, for additional information.

2-4.2.4.2 Photometric Requirements.

The color and intensity requirements for sequenced flashing lights apply to REIL.

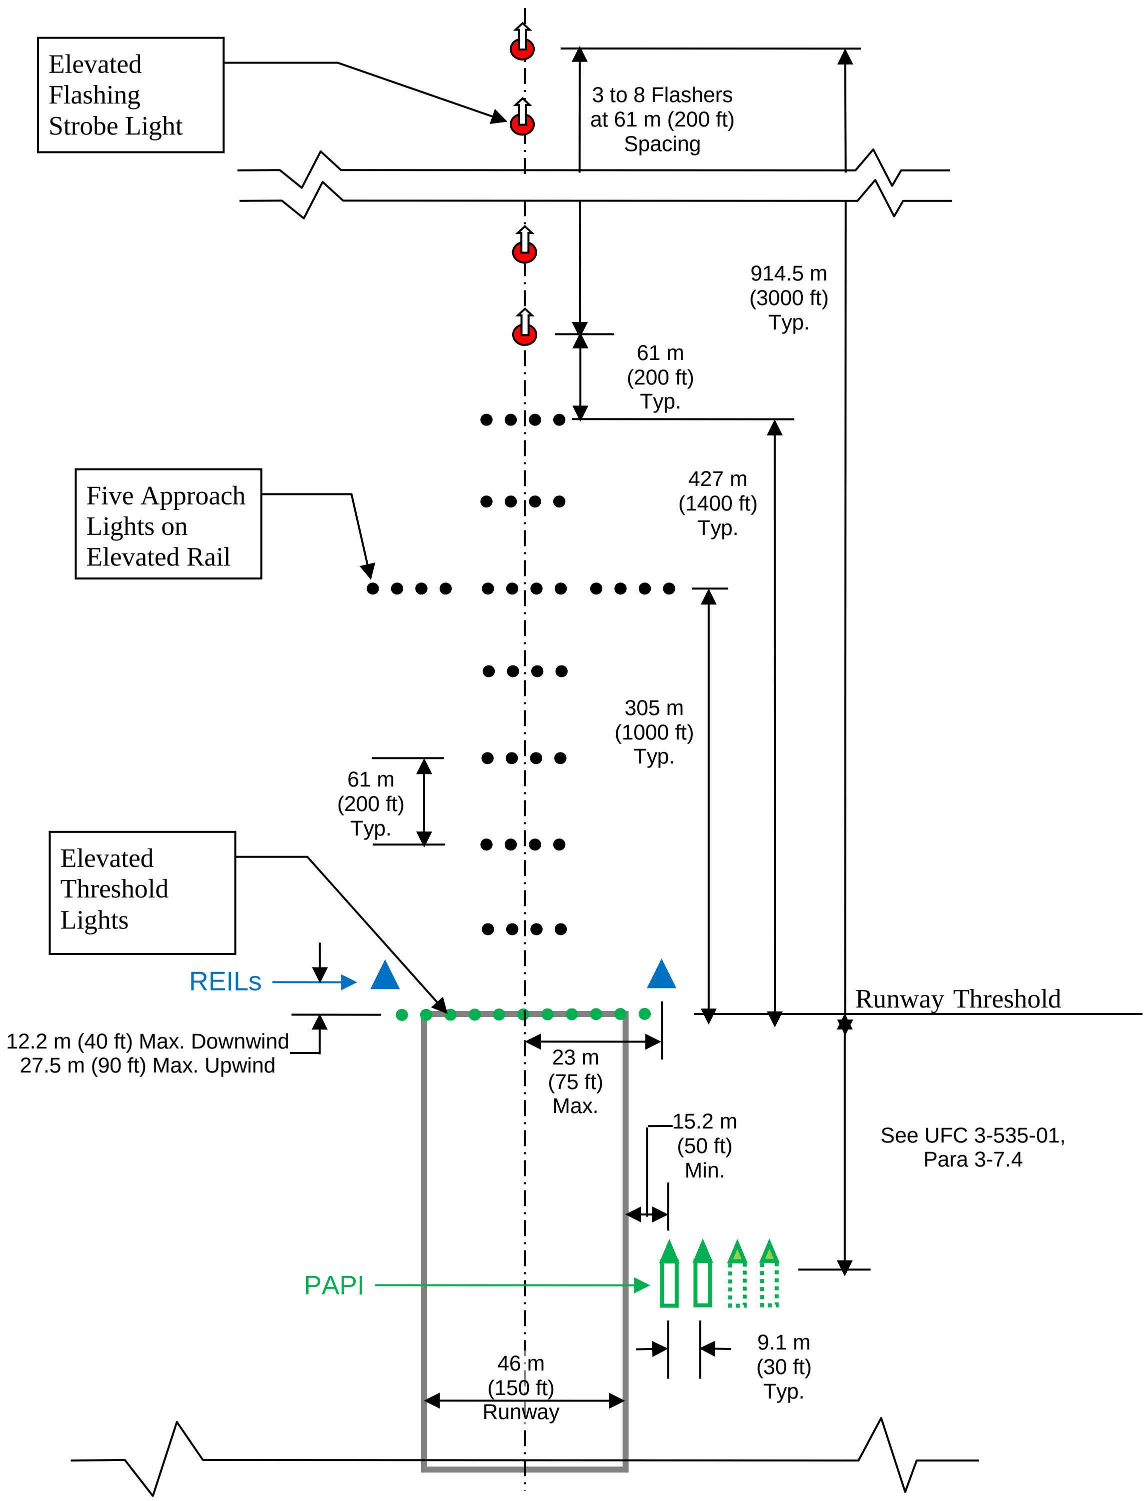
2-4.2.4.3 Power Requirements.

The system may be powered by solar cells, separately by generator, or by a power adapter unit connected to the threshold runway light circuit. There is no requirement for standby power.

2-4.3 Light Installation

Figure 2-8 shows the layout of lights on a typical snow/ice runway, including the positions of approach lights and threshold lights. Lights may be powered by solar cells or generators. All lights must be installed on frangible supports. Generators must be positioned outside the runway lateral clear area and the runway end clear area. All installations are above the surface; however, power cables may be trenched into glacial ice, white ice, and compacted snow airfields to allow the use of central and displaced power generation. **Trenches must never be cut into a sea ice airfield.**

Figure 2-8 Lighting Layout for Snow/Ice Runways



2-4.4 Lighting Details

Figures 2-9, 2-10 and 12-11 show details of the lights that may be installed on snow/ice runways. Note that lights are typically only present at the site during normal flying periods. At all other times, all equipment (except electrical cable set in trenches) is removed from the site to discourage drifting snow accumulation.

2-4.5 Taxiway and Apron Lighting

Lights are not typically installed for snow/ice airfield taxiways or aprons because operations on these features are almost exclusively during daylight. If operating during darkness, the airfield manager is responsible for using follow-me vehicles, temporary lighting, or other suitable systems to guide the aircraft.

Figure 2-9 Typical SSALR Elevated 6.1-m (20-ft) Light Barrette

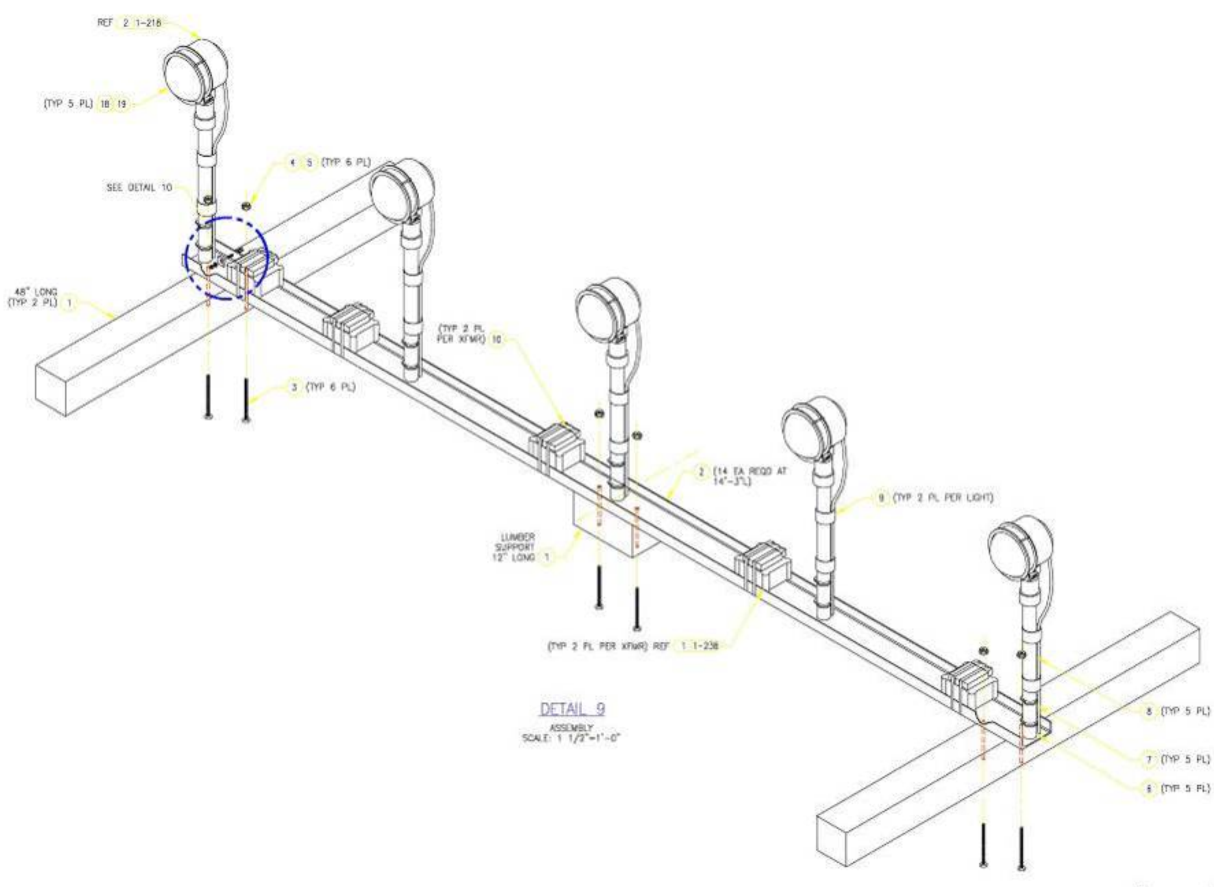


Figure 2-10 Typical Threshold Light Installation for Snow/Ice Airfields

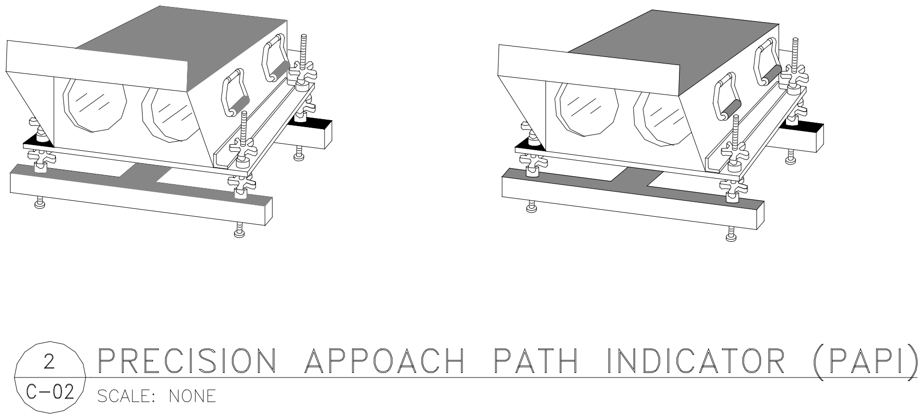
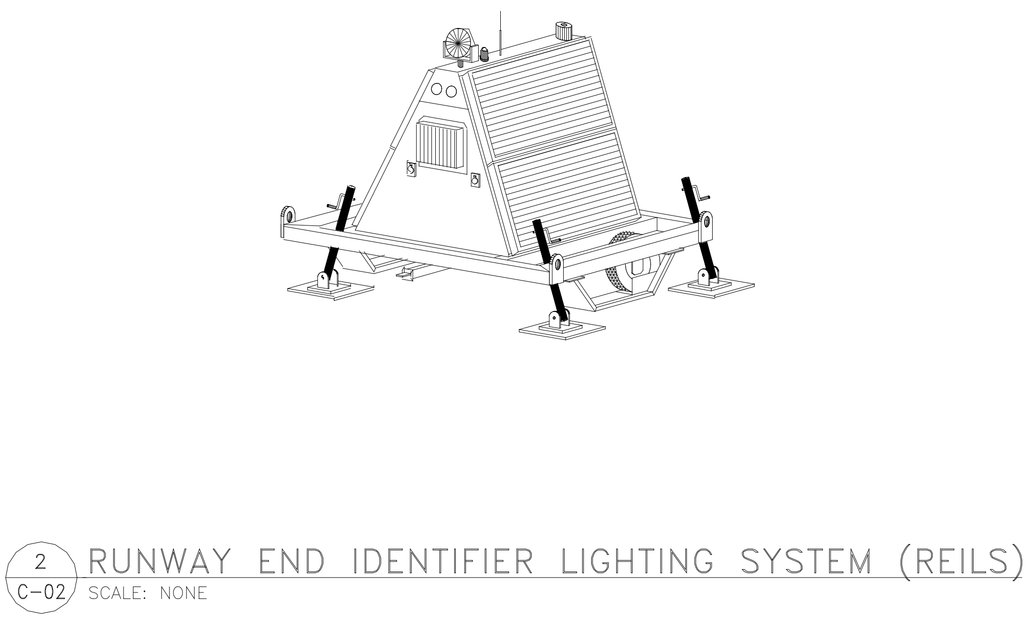
Figure 2-11 Lighting Details for Snow/Ice Airfields





2-5 ELECTRONIC NAVIGATIONAL AID SYSTEMS (NAVAIDS).

2-5.1 NAVAIDS - General

Although some snow/ice runways are VFR-only facilities and operated solely during daylight (such as field science camps), it is still desirable to have a limited number of electronic NAVAIDS to help guide the aircraft to the airfield. In some locations such as Williams Field, NAVAIDS are required to fly the runway approaches defined by terminal instrument procedures (TERPS) due to significant terrain obstacles in close relation to the airfield. Whenever NAVAIDs are installed, they greatly increase aircraft operational safety, particularly when weather conditions are less than ideal.

2-5.2 NAVAIDS Siting Criteria

Adopting the full extent and type of NAVAIDS generally found at a conventional airport (e.g., ILS localizer and glideslope antennas) would be difficult to acquire and maintain in a snow/ice environment. Generally, it is not necessary for a snow/ice runway to have the full complement of available NAVAIDS, but in some cases terrain may dictate the need for NAVAIDS. Some snow/ice runways can be used without NAVAIDS as long as the field is properly marked and the airspace is controlled (such as field science camps). However, NAVAIDS are highly desirable and can significantly improve the safety of flying operations. The NAVAIDS listed below are optional (unless dictated by TERPS) but desirable and listed in the order of importance.

Table 2-5 NAVAIDS

System	Required?	Siting Criteria
Microwave landing system (MLS)	Optional	AFI 11-230, para. 6.11
Tactical air navigation (TACAN)	Optional	UFC 3-260-01, Appendix B, Section 13
Airport weather observation station (AWOS)	Optional	FAA Order 6560.20
Mobile air traffic control tower (MATCT)	Optional	UFC 3-260-01, Appendix B, Section 17 UFC 3-260-01, para. B13-2.12
Wind indicators (cones)	Optional	UFC 3-535-01, para. 10-2 FAA AC 150/5345-27E, Type L-806 (Frangible)

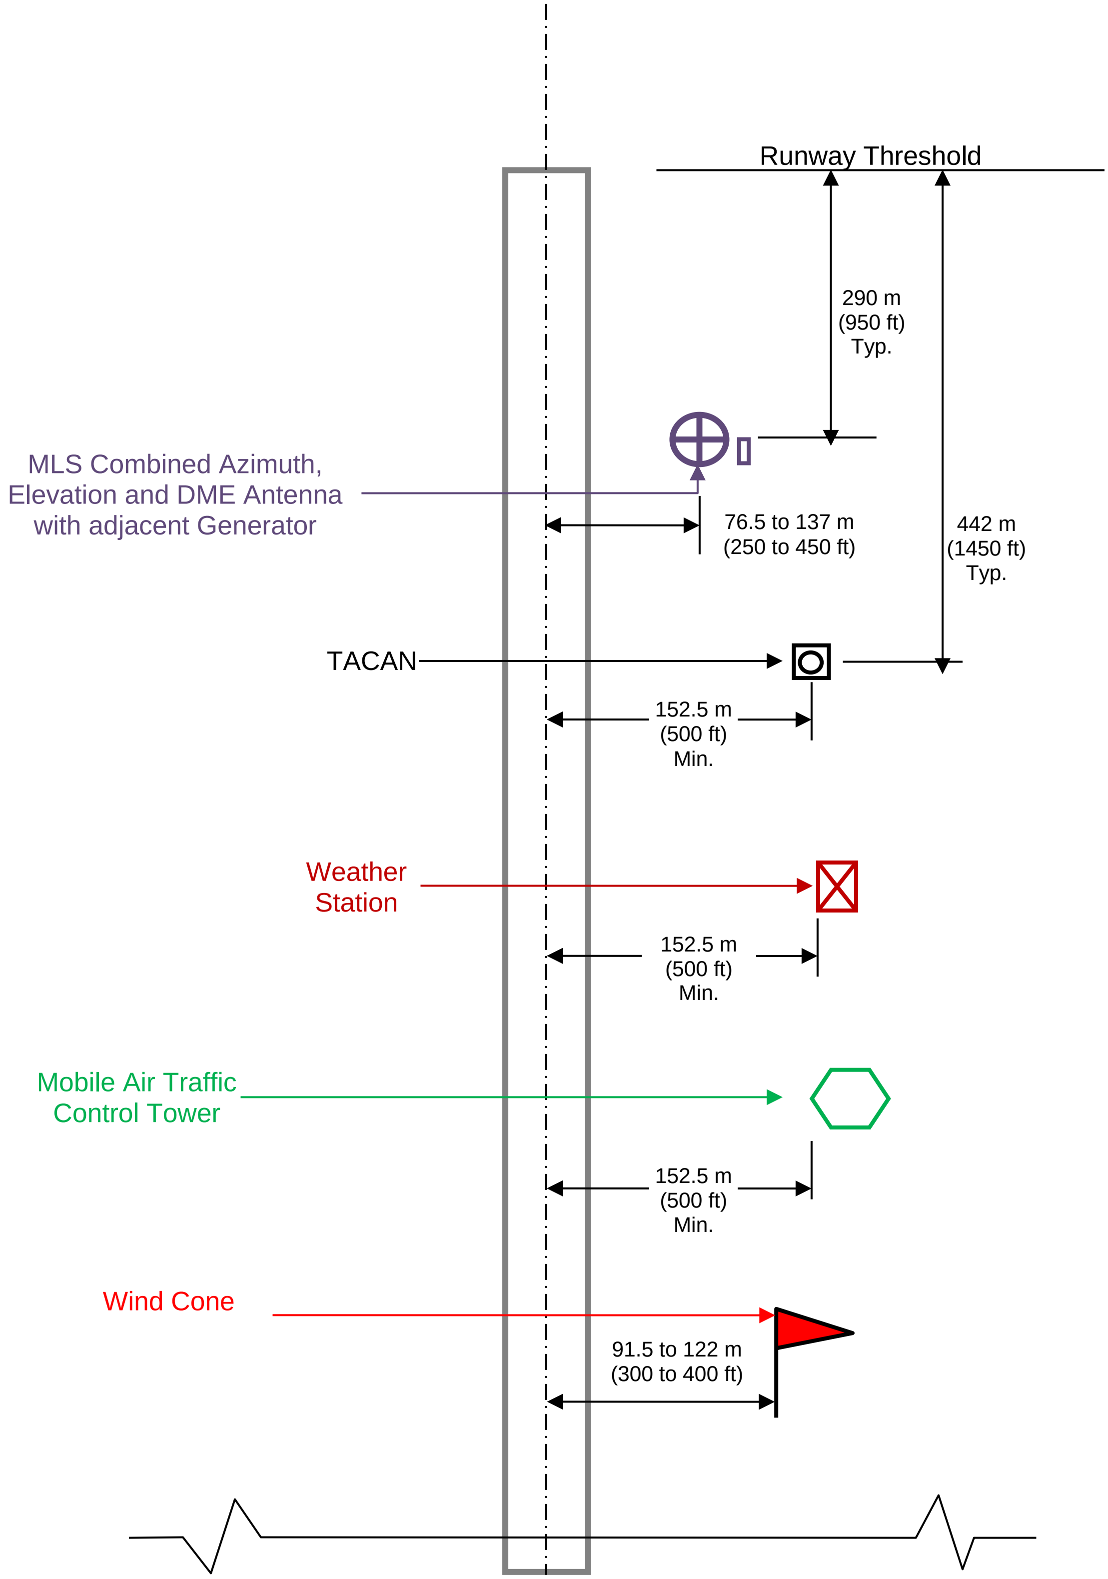
2-5.3 Positioning NAVAIDS

Figure 2-12 shows the positions for installing NAVAIDS (MLS, TACAN, AWOS, MATCT, and wind cone). These are strictly above-surface installations; however, subsurface wiring may be used for the NAVAIDS to allow central and displaced power generation.

2-5.4 NAVAIDS Implementation

Note that all NAVAIDS are generally only present at the site during the flying seasons. At most other times, all surface structures, including buildings and other support structures, are removed from the site to discourage progressive snow accumulation.

Figure 2-12 Snow/Ice Runway NAVAIDS Layout with Dimensions



2-6 AIRFIELD CERTIFICATION PROCESS.

2-6.1 Annual Certification.

2-6.1.1

The sea ice runway and white ice runway will be annually certified for operations by HQ AMC/A3. The airfield manager at McMurdo Station will initiate the request for certification by transmitting necessary information (dimensions, strength, cross-section, electronic NAVAIDS, lighting, markings) to HQ AMC/A7OI and HQ AMC/A3AS for review, comment, and to ensure all criteria are met. HQ AMC/A7OI provides the recommendation for certification for aircraft operations prior to the initial seasonal mission execution. The runway certification statement will be entered in the HQ AMC airfield suitability assessment maintained in the Global Decision Support System (GDSS) airfield database (AFD) in accordance with the Airfield Suitability and Restrictions Report (ASRR) and AMCI 11-211.

2-6.1.2

Due to the dynamic nature of the McMurdo airfields, environmental conditions change during a flying season or certification period, most often due to seasonal temperature fluctuations. The following changes to airfield conditions require notification to HQ AMC/A3AS for update to the GDSS AFD and, if applicable, waiver processing. Other changes to conditions (e.g., inoperable lighting system, missing edge marker flag) shall be issued as a Notice to Airmen (NOTAM) or airfield advisory by the airfield manager.

- Reductions in runway, shoulder, overrun, lateral clear area, or end clear area dimensions
- Reductions in allowable weight-bearing capacity (Sea Ice Monitoring Report)

2-6.2 Periodic Air Force Team Certification.

Although the primary responsibility for airfield data collection to verify design criteria falls with the on-site USAP airfield manager and staff, periodic evaluations by Air Force engineering personnel are needed for the reasons listed below. Evaluation of the Pegasus white ice runway by Air Force personnel will occur every third year.

2-6.2.1

Air Force engineers need to maintain an understanding of the extreme snow/ice runway environment and the challenges associated with building and maintaining a snow/ice airfield for use by Air Force aircraft.

2-6.2.2

HQ AMC/A7 is tasked to verify the interpretation of snow/ice runway airfield data and make a recommendation to certify the snow/ice runways for opening to aircraft traffic. The quality of the interpretation is substantially enhanced when the engineer has the on-site experience to understand how the data is collected and what it means.

2-6.2.3

The criteria established in this FC are currently only applied at McMurdo Station; therefore, updates to the FC are routinely needed to incorporate changes in equipment and airfield configurations.

2-6.3 Operational Waivers to Criteria.

The criteria in this FC are the minimum permissible for DOD aircraft (C-130, C-17, and C-5 operations). When deviations exist or occur, an operational waiver must be obtained before flight operations begin. The airfield manager or a designated representative will initiate a written waiver request through 13 AEG/CC and HQ PACAF/A3 to the Air Force component with operational control (OPCON) for Antarctic missions. The waiver must outline all criteria that do not meet the requirements of this FC. The appropriate airfield manager or airfield survey team will verify existing prepared landing zone (PLZ) dimensions and grades. HQ AMC/A7O and /A3V will assess the waiver request for viability and risk and make a recommendation to the Air Force component commander with OPCON for Antarctic missions. For Transportation Command (TRANSCOM)/AMC operational missions under OPCON of 18th Air Force, 18 AF/CC is the waiver authority in accordance with AFI 11-202V3.

Note: In addition to sending data and requests for deviations to HQ AMC/A3, data monitoring results shall be courtesy-copied to HQ PACAF/A7 and HQ AMC/A7.

APPENDIX B BEST PRACTICES

B-1 DCP AND RSP OPERATING INSTRUCTIONS

B-1.1 Device Configuration.

For application on snow and ice airfields, the dynamic cone penetrometer (DCP) device shall be operated with a fixed 60°, 20-millimeter (0.8-inch) diameter cone, and an 8-kilogram (17.6-pound) drop hammer. The Russian snow penetrometer (RSP) shall be operated with the standard 30°, 11-millimeter (0.4-inch) diameter cone, and a 0.8-kilogram (1.75-pound) drop hammer.

B-1.2 Test Method.

Penetrometer measurements can be taken at any time of day, at any air temperature, and in any weather conditions (but environmental conditions at the time of testing must be documented). Take snow strength measurements at the locations noted in the field data sheet (see Figure B-63). **Note:** Ideally, two persons will work together to take measurements and record penetrometer data.

B-1.2.1

Verify that a measuring mechanism is available to accurately note every 25 millimeters (1 inch) of penetration of the penetrometer shaft (e.g., distance marks on the penetrometer shaft or an adjacent measuring rod). The “zero” penetration mark is located at the top of the cone’s pointed end (i.e., at the lowest point on the penetration tip where the maximum penetrometer width occurs).

B-1.2.2

Gently place the tip of the penetrometer onto the snow surface and keep the shaft in a vertical position.

B-1.2.3

Push the penetrometer vertically into the snow until the widest part of the tip cone is flush with the surface of the snow (i.e., at the “zero” depth mark).

B-1.2.4

Gently raise the hammer weight until light contact is made with the top handle. The hammer must not impact the handle when being raised.

B-1.2.5

Allow the hammer to freely fall down onto the anvil, thus forcing the cone into the snow/ice.

B-1.2.6

Record how many hammer blows (drops) are needed to drive the penetrometer cone 25 millimeters (1 inch) into the surface, as measured by the markings on the shaft or detached measuring device. This will complete Blow Set 1. Note: 25 millimeters (1 inch) is the penetration goal for each blow set, but if the snow properties suddenly change and the cone quickly penetrates further than 25 millimeters (1 inch), simply note the actual penetration depth and number of blows in that blow set.

B-1.2.7

In the penetrometer field data sheet for that location, write down the number of blows under Blow Set 1 and the penetration of the cone (in millimeters) for that blow set.

B-1.2.8

Without moving the penetrometer begin Blow Set 2, driving the penetrometer another 25 millimeters (1 inch) into the snow by dropping the hammer as many times as needed to achieve this penetration.

B-1.2.9

Record the Blow Set 2 data into the appropriate blocks on the field data sheet. Continue the penetration test, 25 millimeters (1 inch) at a time, until the penetrometer tip firmly contacts the supporting glacial ice surface and penetration effectively stops. In deep compacted snow the entire rod may advance until the anvil contacts the surface.

B-1.3 Errors.

If the test data are suspicious or erroneous due to problems attributable to operator or equipment error, fix the problem, move the penetrometer 1 meter (3 feet) away from the original test location, and start the test again. Note the event in the "Comments or Observations" block of the field data sheet.

B-1.4 Soft Snow.

If the penetrometer tests indicate an area of soft snow (only one or two blows gives 25 millimeters [1 inch] of penetration), note the area on the data sheet and mark the location with a pole or flag for further testing and repair. Move 1 meter (3 feet) down the runway and start the test over.

B-1.5 Strength Index.

The strength index can be determined from the DCP and RSP tests using the formulas given in Appendix C-2. Alternatively, the Ice Runway Strength Survey Tool program, a software analysis routine, is available by contacting the National Science Foundation POC in paragraph 1-3. This software will ultimately be available in the Pavement Computer Assisted Structural Engineering (PCASE) package of applications.

B-2 GLACIAL ICE AND WHITE ICE RUNWAY PATCHING PROCEDURE

B-2.1 Introduction.

Infrequently, there may be damage to the runway surface from equipment gouging, solar-induced subsurface melt pool formation, or surface melting instigated by windborne or spilled contaminants. These areas will require clean-out, repair, and re-certification. The following patching procedure shall be followed. Repair these areas by removing the damaged snow and ice and replacing it with a crushed ice and water "patch" (in the glacial ice) and a new snow pavement (on the surface) that provides the required hardness/strength. The repair procedure is based on information in CRREL Monograph 98-1, page 57.

B-2.2 Tools.

The following tools are needed:

- Long-handled chisel
- Welder's slag hammer or rock hammer
- Coal shovel
- Source of cold, fresh water

B-2.3 Patching Procedure.

Thoroughly remove all contaminants (including melted and/or refrozen snow and ice) at the site of the repair and dispose of in accordance with site regulations. Remove any loose (but clean) snow and ice from the damaged area and place it to the side for later use. Clear the faces and edges of the cavity to allow close inspection of the ice along the sides and bottom.

B-2.3.1 Glacial Ice.

B-2.3.1.1

Use the chisel to excavate the area surrounding the failure area to make certain that all of the weak ice has been dislodged. If a large area of the surrounding ice is weak, use one of the large-scale test methods (see CRREL Monograph 98-1, page 47) to break up the weak ice and identify its limits.

B-2.3.1.2

Glacial ice removed from the failed area shall be further broken up with a hammer into pieces roughly the size of a fist or smaller. The crushed ice shall be packed into the cavity to fill the hole slightly above its top (approximately 75 to 100 millimeters [3 to 4 inches] higher). Remove any excess ice from the runway.

B-2.3.1.3

Slowly fill the hole containing the crushed ice with cold water (ideally very near 0 °C [32 °F]) to approximately 75% full. Fill the hole by directing the water around the perimeter of the hole. Mix the ice-water slurry in the hole with the chisel and shovel by vigorous vertical probing to ensure that all pore spaces are filled with water and to encourage water to flow into any cracks radiating into the surrounding ice. After about an hour, proceed to add water to approximately 50 millimeters (2 inches) below the ice surface. Smooth the surface with the backside of a shovel. Allow it to cool for three to four hours, after which time the surface usually will be frozen over.

B-2.3.1.4

Using the chisel, break the top of the ice surface in a number of places (10% of total surface area). Slowly re-flood the patch area to fill the air gap under the ice surface with cold water.

B-2.3.1.5

Use a brightly colored flag (e.g., orange) to mark the location of the patch on the ice surface. A corner of the flag can be frozen into the surface using cold water. If the runway is not in use, a bamboo or plastic pole with a flag can be pushed into the ice-water slurry to mark the location.

B-2.3.1.6

Note the approximate location of the patched area using the runway markers as a guide for the long axis and the knowledge of the runway width for the other axis. If air operations are in effect, the airfield manager, the air traffic controller, and the flight crew coordinator shall be notified that a fresh patch is on the runway and that this area will be avoided for at least 48 hours.

B-2.3.1.7

Allow the area to freeze for at least 48 hours before allowing traffic to resume; the flag shall then be removed. If possible, the patched area shall be “dressed” with the chisel-tooth grader blade to blend its edges into the surrounding ice surface and to provide a uniform surface texture.

B-2.3.1.8

Following repair of the glacial ice, the site must be re-certified using the procedures given in paragraph B-4 if the repair area is greater than 0.4 square meter (4.3 square feet).

B-2.3.2 White Ice.

B-2.3.2.1

For a white ice surface requiring repair, whether or not the previous procedures (paragraph B-2.3.1 et seq.) were required to patch the underlying glacial ice, ensure that all weak, contaminated, or damaged pavement is stripped from the glacial ice surface.

B-2.3.2.2

Fill the area with clean, fresh (no more than one-year-old) snow using hand or mechanical equipment, depending on the volume of snow required.

B-2.3.2.3

Level the snow surface with a light drag or snow plane, or a wide-tire (1 meter), low-ground-pressure (tire inflation pressure of 100 kilopascals (kPa) [14.5 pounds per square inch (psi)] or less) wheeled vehicle.

B-2.3.2.4

Use a compaction roller (used to initially construct the white ice surface) to level the entire patched area using 85% of the final tire pressure and gross load used at initial construction. Allow the snow to “rest” for 24 hours and repeat compaction rolling at 95% of the final tire pressure and gross load. After another 24-hour rest, repeat compaction rolling at 100% of the final tire pressure and gross load used during initial construction. The patched area will be ready to accept routine aircraft traffic following another 24-hour rest period, but this must be verified with certification tests as given in Appendix B-5.

This Page Intentionally Left Blank

B-3 SEA ICE RUNWAY PATCHING PROCEDURE

B-3.1 Introduction.

Infrequently, there may be damage to the runway surface from equipment gouging, solar-induced melt features, or surface melting caused by windborne or spilled contaminants. These areas will require clean-out, repair, and re-certification. The following patching procedure shall be followed. Repair these areas by removing the damaged snow and ice and replacing it with a crushed ice and water "patch" (in the sea ice) and a new snow pavement (on the surface) that provides the required hardness/strength. The repair procedure is based on information in CRREL Monograph 98-1, page 57. Note that this procedure is commonly used during runway construction, but when ice temperatures rise above about -6.5 °C (20 °F) this process is largely ineffective because of excessive freeze-up times.

B-3.2 Tools.

The following tools are needed:

- Long-handled chisel
- Welder's slag hammer or rock hammer
- Coal shovel
- Source of cold, fresh water

B-3.3 Patching Procedure.

Thoroughly remove all contaminants (including melted and/or refrozen snow and ice) at the site of the repair and dispose of in accordance with site regulations. Remove any loose (but clean) snow and ice from the damaged area and place it to the side for later use. Clear the faces and edges of the cavity to allow close inspection of the ice along the sides and bottom.

B-3.3.1 Sea Ice.

B-3.3.1.1

Use the chisel to excavate the area surrounding the failure area to make certain that all of the weak ice has been dislodged. If a large area of the surrounding ice is weak, use one of the large-scale test methods (see CRREL Monograph 98-1, page 47) to break up the weak ice and identify its limits.

B-3.3.1.2

Dispose of sea ice removed from the failed area. Pieces of glacial ice (not sea ice) roughly the size of a human fist or smaller shall be packed into the cavity to fill the hole slightly above its top (approximately 75 to 100 millimeters [3 to 4 inches] higher).

Packed snow may be used in the absence of sufficient glacial ice. Any excess material shall be removed from the runway.

B-3.3.1.3

Slowly fill the hole containing the crushed ice (or packed snow) with cold, fresh water (ideally, very near 0 °C [32 °F]) to approximately 75% full. Fill the hole by directing the water around the perimeter of the hole. Mix the ice-water slurry in the hole with the chisel and shovel by vigorous vertical probing to ensure that all pore spaces are filled with water and to encourage water to flow into any cracks radiating into the surrounding ice. If using packed snow, gently push down on the patch with the backside of a shovel only; do not probe and stir with a tool. After about an hour, add water to approximately 50 millimeters (2 inches) below the surrounding sea ice surface. Smooth the surface with the backside of a shovel. Allow it to cool for three to four hours, after which time the surface usually will be frozen over.

B-3.3.1.4

Using the chisel, break the top of the ice surface in a number of places (10% of total surface area). Slowly re-flood the patch area to fill the air gap under the ice surface with cold, **fresh** water.

B-3.3.1.5

Use a brightly colored flag (e.g., orange) to mark the location of the patch on the ice surface. A corner of the flag can be frozen into the surface using cold water. If the runway is not in use, a bamboo or plastic pole with a flag can be pushed into the ice-water slurry to mark the location.

B-3.3.1.6

Note the approximate location of the patched area, using the runway markers as a guide for the long axis and the knowledge of the runway width for the other axis. If air operations are in effect, the airfield manager, the air traffic controller, and the flight crew coordinator shall be notified that a fresh patch is on the runway and that this area must be avoided for at least 48 hours.

B-3.3.1.7

Allow the area to freeze for at least 48 hours before allowing traffic to resume; the flag shall then be removed. If possible, the patched area shall be “dressed” with the chisel-tooth grader blade to blend its edges into the surrounding ice surface and to provide a uniform surface texture.

B-3.3.1.8

Following the sea ice repair, the site must be re-certified using the procedures given in Appendix B-6 if the repair area is greater than 0.4 square meter (4.3 square feet).

B-3.3.2 Snow Cap.

B-3.3.2.1

For a runway surface operated with a snow cap, it is required to replace the cap after patching the sea ice.

B-3.3.2.2

Fill the area with clean, fresh (not more than one year old) snow using hand tools or mechanical equipment, depending on the volume of snow required.

B-3.3.2.3

Level the snow surface with a light drag or snow plane, or a wide-tire (1 meter), low-ground-pressure (tire inflation pressure of 100 kPa [14.5 psi] or less) wheeled vehicle.

B-3.3.2.4

If the snow cap being replaced was processed, use the same procedure originally applied to bring the snow patch to an equivalent level of strength. Allow the snow to “rest” for 24 hours before allowing routine aircraft traffic.

This Page Intentionally Left Blank

B-4 GLACIAL ICE STRUCTURAL EVALUATION PROCEDURE

B-4.1 Glacial Ice Runway Surface Evaluation—Deformation Failure.

The glacial ice surface must be shown to be capable of supporting C-130 and C-17 contact pressure levels for heavy wheeled aircraft without compressive or shear failure. These capacities will be demonstrated by one of the two following methods, depending on the circumstances: proof rolling to detect zones of weakness, or the experience of past operations.

B-4.1.1 Proof Rolling.

B-4.1.1.1

The primary source of ice weakness at the Pegasus site is caused by melt and re-freeze features. When they occur, they commonly show no surface expression and may give the runway a deceptive appearance of strength. Rigorous adherence to prescribed maintenance procedures can avoid such melt/re-freeze problems (see CRREL Monograph 98-1 for maintenance procedures). If there is any doubt, or if the conditions described in paragraph B4.1.1.2 apply, then the runway must be tested for structural strength.

B-4.1.1.2

Proof rolling tests are required if the surface temperature in the ice (measured at a depth of 10 millimeters [0.5 inch]) rises to or above –4 °C (25 °F) (as confirmed by solar-shielded, continuously recording temperature probes buried in the ice). If ice temperatures reach or exceed –4 °C (25 °F), the potential exists for subsurface melt-pool formation and the runway surface must be inspected for such potential melt-damaged areas by proof rolling. The testing will be performed with pneumatic tire(s) having a minimum inflation pressure of 7.7 kilograms per square centimeter (760 kPa or 110 psi). The vehicle shall have a minimum individual tire load of 16,000 kilograms (35,000 pounds). Coverage shall be at no greater than 1-meter (3-foot) lateral spacing over the entire width of the runway and shoulder surface. Successful proof rolling will generate no ice cracking resulting in a removable ice piece greater in size than 0.3 meter by 0.3 meter by 0.05 meter deep (12 inches by 12 inches by 2 inches deep). Any defective areas discovered will be removed, repaired, and retested according to the process outlined in Appendix B-2.

B-4.1.2 Past Operations.

Previous aircraft operations at the Pegasus runway have demonstrated that the existing ice surface has sufficient compressive strength to support aircraft with tire pressures up to 13.7 kilograms per square centimeter (1350 kPa or 195 psi). If aircraft operations were successfully supported by the Pegasus runway in the immediately previous flight period (as confirmed by close visual inspection of the runway for damage), and as long as the near-surface ice temperature has not risen to or exceeded –4 °C (25 °F) since the last flight period (as confirmed by continuously recording temperature probes buried in the ice), the ice surface will be considered adequate for aircraft with tire pressures up to the magnitude of the maximum operated during the prior flight period. If previous aircraft operations were not successfully supported, needed repairs and re-certification of the runway must be accomplished before further aircraft operations.

B-4.2 Glacial Ice Runway Surface Evaluation—Creep Failure.

Long-term parking at warm ice temperatures can lead to creep deformation of the glacial ice. At ice temperatures below –4 °C (25 °F) creep deformation is relatively slow. Since the Pegasus PLZ is operated principally as a “turn-around” runway (i.e., arriving aircraft debark within a few hours, spending limited time onsite), it is expected that creep deformation will be negligible. However, if aircraft will be parked for extended time periods then they will have to be moved periodically to avoid any difficulty during the initial rollout. It is recommended that no more than 25 millimeters (1 inch) of deformation occur below a parked aircraft tire. In general, this limit will be reached in one hour at an ice temperature of -2.5 °C (27.5 °F), two hours at -5 °C (23 °F), and three hours at -10 °C (14 °F).

B-4.3 Glacial Ice Runway Surface Evaluation—Flexural Failure.

B-4.3.1

The ice sheet at the Pegasus site is approximately 30 meters (100 feet) thick. Depending on the temperature and crystallographic structure and impurities content of the ice, this ice has flexural strength on the order of 5 to 10 kilograms per square centimeter (490 to 980 kPa or 75 to 150 psi). The large thickness of the ice sheet reduces the bending stresses in response to heavy wheeled aircraft to levels that can easily be carried by the ice. A PCASE analysis routine for rigid portland cement concrete, modified for glacial ice, was used to determine the minimum thickness of glacial ice needed to support the heaviest aircraft load (a fully burdened C-17) without flexural cracking. To be conservative, a flexural strength of only 0.4 kilogram per square centimeter (39.2 kPa or 5.7 psi) was used (this value is based on the weakest ice found in the area). Also, the sub-base material for this analysis is water since the Pegasus runway is floating on the sea. The results indicate that a C-17 at 263,600 kilograms’ (580,000 pounds) gross load requires an ice thickness of 2.25 meters (7.4 feet) for a safety factor of 1.0. Given that impurities and closed cracks certainly exist in the ice, a factor of safety of 3.0 is recommended. Thus, the Pegasus runway shall have an ice thickness of at least 6.8 meters (22.3 feet) to support the anticipated aircraft and loads.

Note: Sea ice has a much greater flexural strength than glacial ice so a significantly thinner layer of sea ice is sufficient to support aircraft.

B-4.3.2

The present 30-meter (100-foot) thickness of ice at the site suffices for all anticipated aircraft operations. However, if the site experiences appreciable thinning, or if this FC is used for another site, or aircraft other than the C-130 or C-17 are operated, a new analysis is prudent.

B-5 WHITE ICE STRUCTURAL EVALUATION PROCEDURE

B-5.1 White Ice Pavement Thickness.

B-5.1.1

There is no limit on the thickness of the white ice pavement on top of the supporting glacial ice. However, the white ice strength profile must be verified using a DCP or RSP. The white ice strength profile must meet the following two requirements:

1. The strength of the white ice layer must be greater than or equal to the values listed in Table B-1 throughout the layer.

2. The strength profile must show that there is no weak zone beneath a strong surface. The strength of the white ice may not decrease by more than 25% from the overlying material.

B-5.1.2

If either of the above conditions are not satisfied, contact the person(s) listed in paragraph 1-3 for recommendations on how to proceed.

B-5.2 White Ice Runway Surface—Deformation Failure.

It is required that the glacial ice (surface and flexural characteristics) be evaluated according to Appendix B-4 as part of the certification of a thin processed snow operating surface at the Pegasus PLZ. Being a thin processed snow pavement overlying a thick and sufficiently strong base, the principal structural requirement of the white ice is its ability to support tire contact pressures.

B-5.3 White Ice Runway Surface—Snow Pavement Strength Determination.

B-5.3.1

A penetration resistance index will be used as the basis for evaluation of snow strength. Measurements may be taken with either a DCP or an RSP. See Appendix B-1 for test procedures for both devices. The correlation between RSP and DCP index strengths is shown in Figure B-1. The correlation between DCP and the traditional pavement strength index—CBR, developed in soils—is shown in Figure B-2. A correlation by calculation between the RSP and CBR indices is shown in Figure B-3.

Figure B-1 Correlation Between RSP and DCP

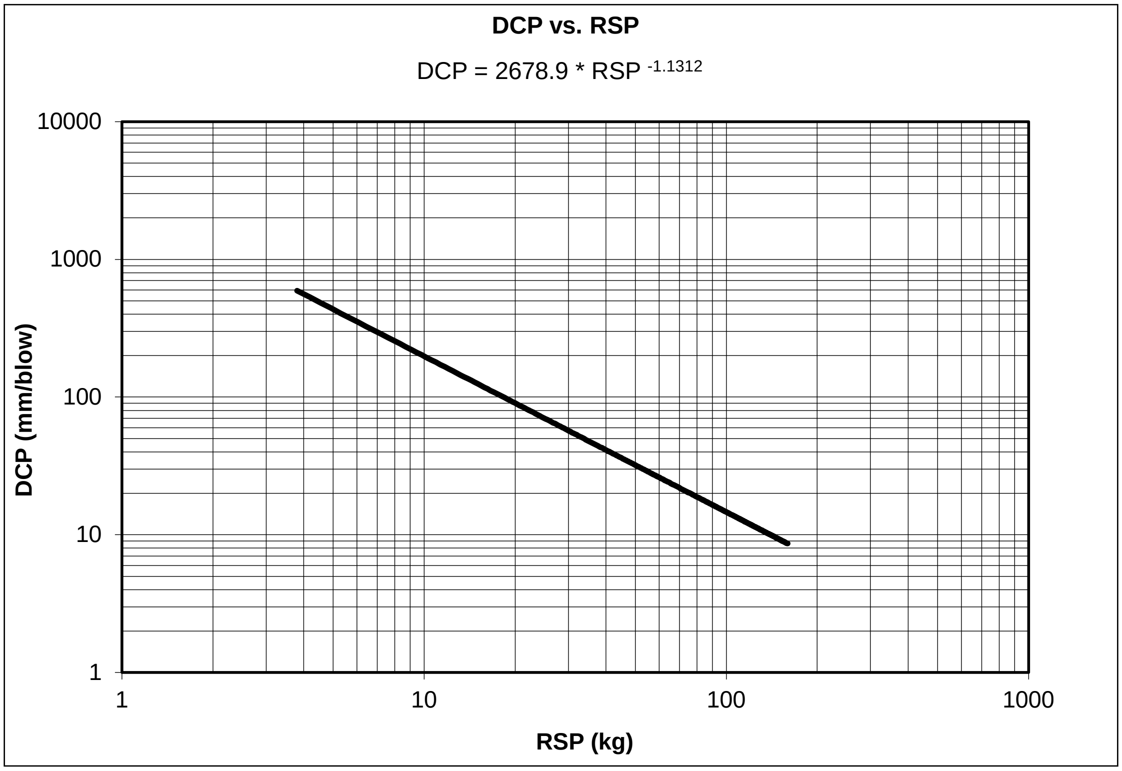

Figure B-2 Correlation Between DCP Index and CBR

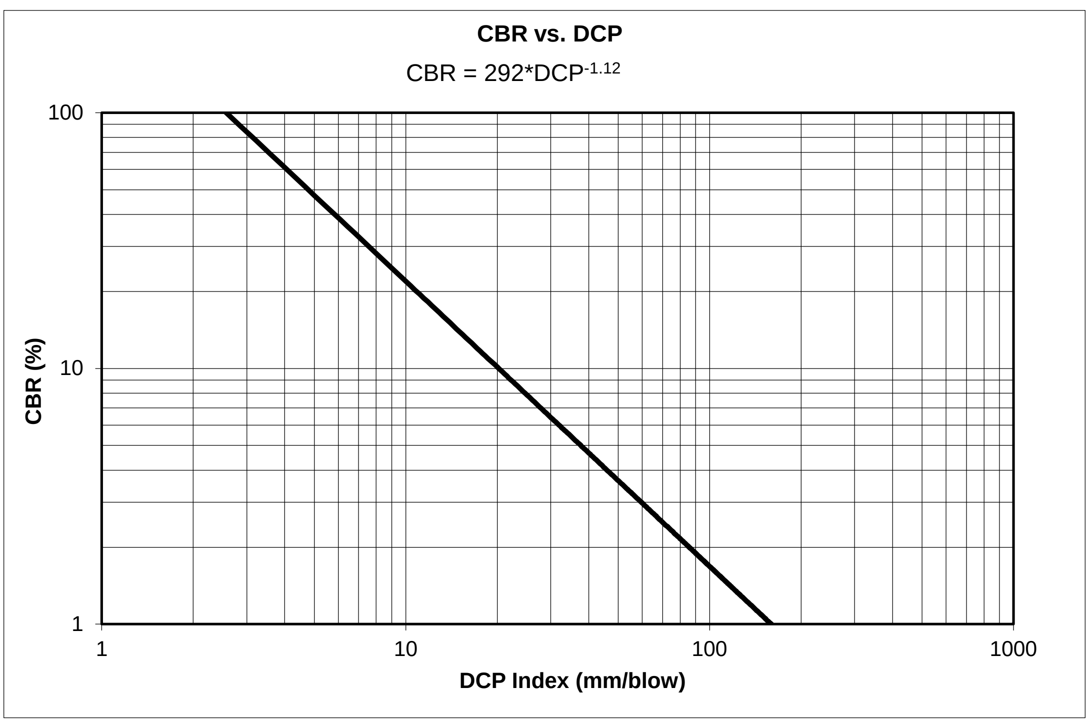

Figure B-3 Correlation Between RSP Index and CBR

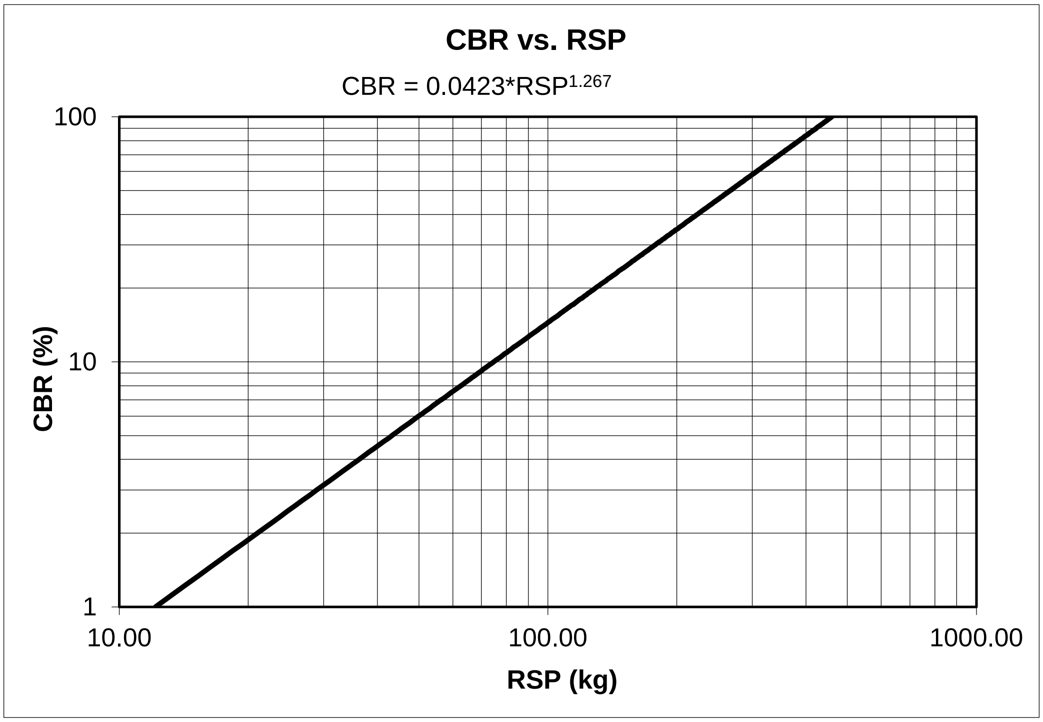


B-5.3.2

Performance of a strength survey shall follow the procedure given in Appendix B-11. For the runway to be considered adequate for aircraft operations, two conditions must be met, as described in paragraphs B-5.3.2.1 and B-5.3.2.2.

B-5.3.2.1

All individual penetrometer test site values must be equal to or stronger than the required minimum strength value listed in Table B-1 and shown in Figure B-4.

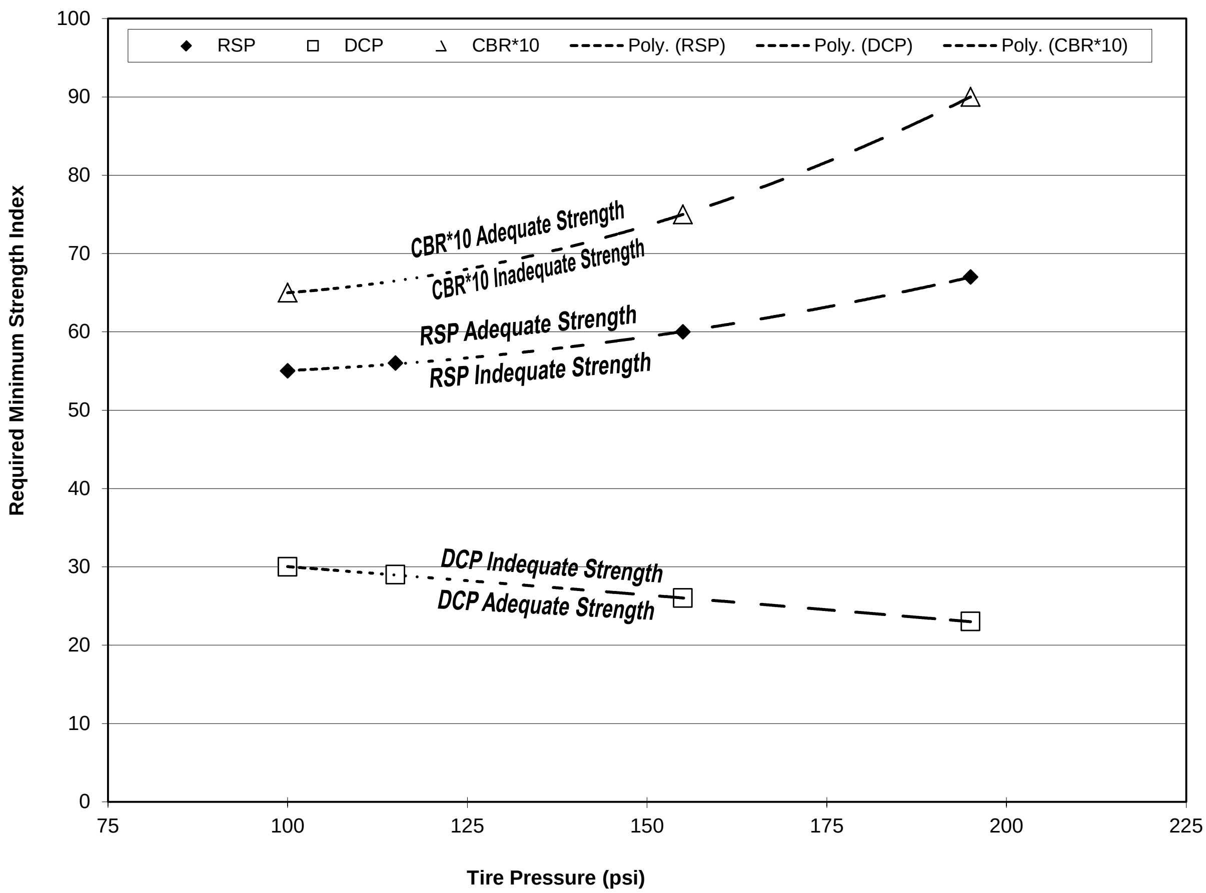
B-5.3.2.2

Maintenance (scarify and recompact) is required in areas that do not meet the minimum strength to increase the compacted snow strength. The area must be retested after maintenance is complete.

Table B-1 Minimum Snow Strength Required for White Ice Pavement

Aircraft	Tire Pressure (psi)	Minimum RSP Index	Maximum DCP Index	Minimum CBR Index
C-130	95	55	29	6.8
C-5A	111	56	28	6.9
C-17	155	61	26	7.7
757-200	180	65	24	8.4
P-3	200	69	22	9.1
767-300ER	205	70	22	9.3
A319	210	72	21	9.5

Figure B-4 Strength Criteria for White Ice Pavement



B-5.3.3

Appendix B-11 suggests a graphical method of quickly assessing the distribution of strength measurements using the White Ice Runway Strength Survey Tool program (contact the National Science Foundation operations manager [see paragraph 1-3] for a copy of this Microsoft® Excel-based program). **Note:** This approach makes it easier to locate regions of substandard snow strength so maintenance and repair activities can be quickly focused on trouble spots.

B-5.4 White Ice Runway Surface—Allowable Aircraft Loads/Contact Pressures.

B-5.4.1

Physical testing and aircraft validation activities at the Pegasus PLZ during the 2001–02 austral summer season (November to March) established the minimum thin snow pavement strength levels for C-130 and C-17 operations. These are shown in terms of several parameters in Table B-1. Note that with a thin processed snow pavement over a strong base material, white ice strength requirements are sensitive to aircraft contact pressure (tire pressure) but quite insensitive to aircraft gross load (since tire and gear load is being supported by the base material). Thus, Table B-1 values are for fully loaded or partially loaded aircraft operating at the noted tire pressures.

B-5.4.2

The allowable gross load and contact pressure will be applicable to aircraft both landing and taking off. These criteria are based on a condition of negligible surface deformation or rutting. Negligible is defined here as surface damage in isolated areas and not exceeding 25 millimeters (1 inch) in depth. The values in Table B-1 and Figure B-4 are conservative with respect to the vertical bearing load of wheeled aircraft; the values chosen ensure that surface deformations do not occur as a result of other aircraft loads, particularly shear loading of the white ice when aircraft brake or turn sharply.

This Page Intentionally Left Blank

B-6 SEA ICE STRUCTURAL EVALUATION PROCEDURE

B-6.1 Introduction

B-6.1.1

Sea ice is often categorized as first-year or multi-year ice. This characterization of the ice indicates much about its nature, with multi-year ice having significantly greater complexity. However, for the purposes of a sea ice runway for heavy wheeled aircraft, this FC will treat both types the same, using overall ice thickness and ice temperature as governors for ice strength, which ultimately determines its ability to support a given aircraft operation.

B-6.1.2

Annually, before commencing aircraft operations (in Antarctica, flights on the sea ice runway usually begin in early October each season), the sea ice runway will be evaluated using the structural evaluation criteria in this FC. In addition, the airfield manager will conduct interim evaluations for quality assurance and validation of localized repairs.

B-6.2 Sea Ice Operating Surface.

The sea ice operating surface is an exposed, graded sea ice surface, or an ice surface overlain by either a moderately processed thin snow cap (less than 50 millimeters [2 inches]) or a thin layer (less than 75 millimeters [3 inches]) of fresh, loose snow.

B-6.2.1 Sea Ice Runway Evaluation—Deformation Failure.

A sea ice surface must be shown to be capable of supporting C-130, C-17, and C-5 aircraft contact pressure levels without compressive or shear failure. The primary sources of ice surface weakness at a sea ice runway site are melt-pockets and brine leaching features. When these occur, they may show minimal surface expression and may give the runway a deceptive appearance of strength. Rigorous maintenance, including the use of a reflective snow cap, can avoid melt problems. Brine leaching occurs as a function of time and such weak areas may become prevalent if the runway is sited on progressively older (multi-year) sea ice. Generally, brine leaching features will not reach a point of concern for a sea ice runway until the ice is four years of age or older. If there is any doubt, or if the conditions described in paragraph B-6.2.1.2 apply, the runway's structural strength must be certified daily. Adequate surface strength will generally be demonstrated by some form of proof rolling to detect zones of weakness.

B-6.2.1.1 Proof Rolling.

Full-scale proof rolling tests (see CRREL Monograph 98-1) are required before the first flight of the season following sea ice runway construction.

B-6.2.1.2 Inspection Requirements.

During runway operations, if the ice temperature exceeds –5 °C (23 °F) for an exposed sea ice surface, or –3 °C (26.5 °F) for a processed or loose snow surface, then a **rigorous daily visual inspection**, especially in the aircraft wheel tracks, is required. Any surface failure detected will require patching (Appendix B-3) and re-certification.

B-6.2.2 Sea Ice Runway Evaluation—Flexural Failure (Landing and Take-Off).

B-6.2.2.1 Flexural Strength.

Flexural strength of sea ice is a function of ice temperature, ice thickness, and salinity. Correspondingly, the maximum load capacity of sea ice under aircraft loads is a function of flexural strength and the landing-gear-assembly geometry of each aircraft. Determining the maximum allowable aircraft load from ice thickness and temperature measurements establishes the load capacities for landings and takeoffs on a sea ice runway.

B-6.2.2.2 Ice Temperature Measurement.

B-6.2.2.2.1

Collecting ice temperature measurements through the entire ice sheet at many locations on a frequent basis along a sea ice runway is onerous when using traditional technologies (drilling). At McMurdo Sound, seasonal time periods have been established to simplify the analytical process. The method combines ice surface temperatures into “bins,” such that each “bin” represents a period of the operational season. Each time period contains a maximum and minimum surface temperature. Current criteria divide the operational season (October to February) into four periods:

- Mid-October to late November (Period 1: -20 °C to -10 °C [-4 °F to 14 °F])
- Late November to mid-December (Period 2: -10 °C to -5 °C [14 °F to 23 °F])
- Mid-December to late December (Period 3: -5 °C to -2 °C [23 °F to 28 °F] with at least a small temperature gradient (minimum of 1 °C per meter [0.7 °F per foot] within a vertical column of ice, with the warmest temperatures at the ice surface and cooler temperatures at some depth)
- Late December through January (Period 4: -3 °C to -2 °C [26 °F to 28 °F] with ice temperature uniform throughout an entire vertical column; this is called an “isothermal condition”)

B-6.2.2.2.2

At McMurdo Sound, collect ice temperatures (measured at a depth of 150 millimeters [6 inches]) at a minimum of four locations on the runway proper and at two locations in the apron/parking area. Temperature data will be collected at a minimum of the following frequencies to verify that the calendar-suggested period is confirmed by ice temperatures. In all cases, actual ice temperatures will govern which period's standards to apply.

- Period 1: Once every two weeks
- Period 2: Once every week
- Period 3: Three times per week and 24 hours before each C-17 aircraft flight
- Period 4: Once every day

B-6.2.2.3 Ice Thickness Measurement.

B-6.2.2.3.1

Sea ice thickness is the most critical parameter to be established for calculating safe aircraft operations. Sea ice thickness—much more than ice temperature—tends to be slow to change and quite ubiquitous in the McMurdo Sound region. Its annual trend, irrespective of the initial ice thickness in late August, is well established from more than 20 years of data. However, under some circumstances, ice thickness can have considerable local variations. When this situation exists, and ice thicknesses are near the limits for desired aircraft operations, a statistical approach is used to establish sea ice thickness.

B-6.2.2.3.2

For initial certification, actual ice thickness must be measured at no less than 16 random locations spread throughout the runway surface, with no less than half located within a 15-meter (50-foot) -wide swath down the center of the runway. Since a statistical approach is used, more measurements will lead to greater confidence levels. Following the initial set of thicknesses used to certify opening the sea ice runway, it is acceptable to reduce the number of sea ice thickness measurements to a minimum five on the runway and one on the apron. When only five tests are completed on the runway, the minimum measured thickness will be the controlling thickness for strength evaluation purposes.

B-6.2.2.3.3

Thickness measurements must begin at least 10 days before the intended onset of flight operations. Measurements will continue throughout the entire duration of flight operations. Measurement frequency will be the same as for temperature measurements (see paragraph B-6.2.2.2).

B-6.2.2.3.4

Increased measurement density is only required during operating periods when the average thickness of the sea ice is nearing the point where it may limit gross aircraft weights and parking times for the aircraft type to be operated. For large aircraft, this will likely be the case any time first-year sea ice is encountered. Appendix B-7 describes the process for establishing the statistically sea ice thickness used for evaluation.

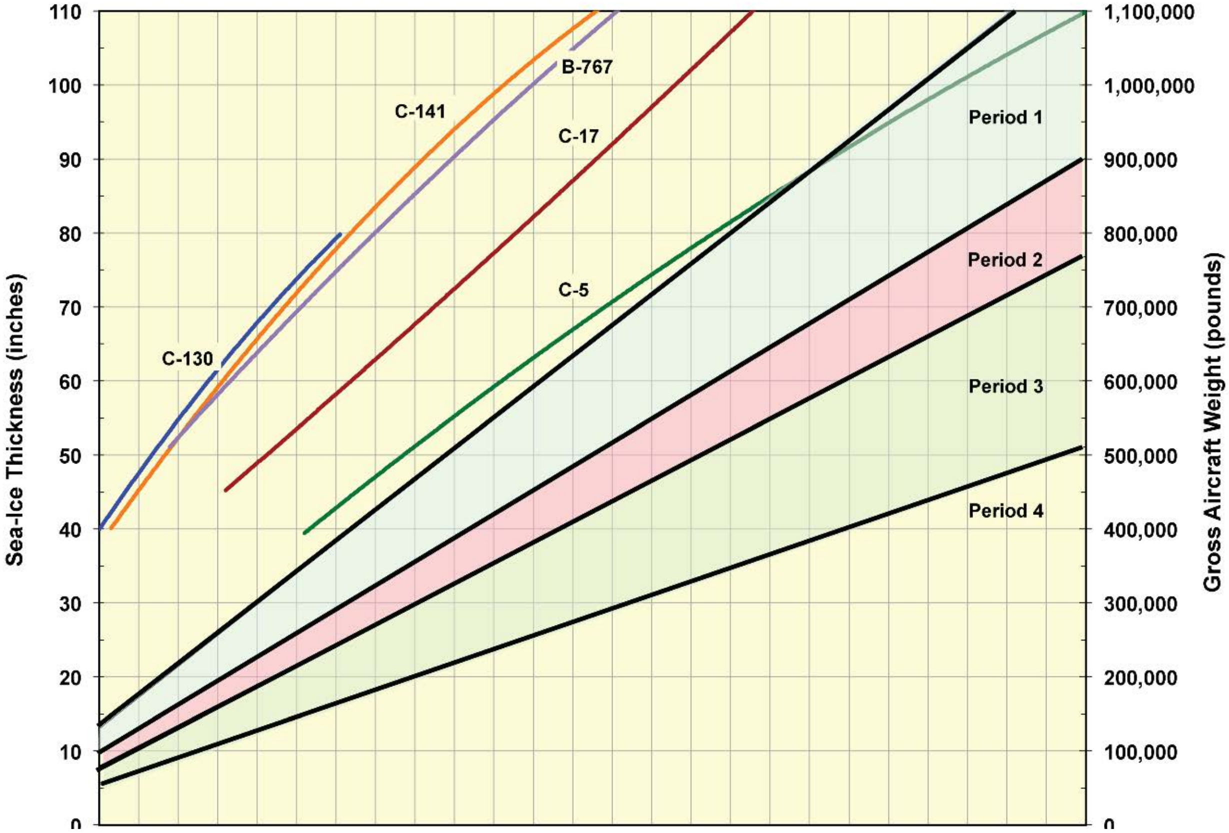
B-6.2.2.4 Factors of Safety.

Maximum allowable ice stresses have been determined for each of the four temperature-based operational periods using a computer program designed to calculate the flexural beam strength of sea ice. The allowable stresses have factors of safety between 1.3 and 1.4 (25% to 30% of flexural strength).

B-6.2.2.5 Maximum Allowable Stresses.

Maximum allowable stresses calculated for the four periods of the operational season at McMurdo Sound, combined with ice thickness and landing gear assembly geometry, were input to a model maintained by CRREL to predict the maximum allowable loads of C-130, C-17, and C-5 aircraft operating on the sea ice in McMurdo Sound. A range of sea ice thickness values experienced throughout the operational season were input and the model calculated the maximum allowable aircraft load given as a function of the sea ice runway thickness and the period of operation. Results from the model are presented in Figure B-5 and constitute the operational strength criteria for landing, taxiing, and take-off. The curves in Figure B-5 were developed based on the parameters described above, and each is specific to aircraft type and gear assembly geometry. The Figure B-5 nomograph may be worked from either direction; that is, if one knows the ice thickness and aircraft type to be operated, the maximum landing and take-off load may be calculated. Conversely, knowing what aircraft type and load are desired to be flown to/from the sea ice runway, the required ice thickness can be determined.

Figure B-5 Landing and Take-off Nomograph for the McMurdo Sound Sea Ice Runway



Notes:

(1) The relationship between ice thickness, temperature and aircraft load is specific to each aircraft and cannot be used for any other aircraft. Other aircraft of interest will require a new model run to develop allowable load/thickness curves (see FC paragraph 1-3 for contact information if a new analysis is needed).

(2) Examples of uses for this nomograph are provided in Appendix B-7. See Appendix B-14 for metric conversion factors.

(3) The nomograph has limited ability to provide a precise answer because of the thickness of lines on the chart, interpolation of temperature or load within bands on the chart, and an individual's technique. While time-consuming, the model used to develop the nomograph can be operated to produce tabulated results that provide a more user-independent solution. Examples of such tables were produced for the C-17 and are included in paragraph B-9.2.

B-6.2.3 Sea Ice Runway Surface Evaluation—Creep Failure (Parking).

B-6.2.3.1

Long-term parking at warm ice temperatures can lead to creep deformation of the sea ice. Long-term parking is defined here to mean any time an aircraft is stationary anywhere on sea ice for more than 30 minutes. At ice temperatures below –5 °C (23 °F), creep deformation is relatively slow. Since the sea ice runway at McMurdo Sound is operated principally as a "turn-around" runway (i.e., arriving aircraft debark within a few hours, spending limited time on site), it is expected that creep deformation will be negligible. However, if aircraft will be parked for extended time periods, or very heavy loads or thin ice conditions are present, aircraft may have to be periodically moved to avoid excessive creep deformation of the sea ice. A maximum allowable deflection limit of 10% of the ice thickness has been set for parked aircraft. Field tests indicate no major cracking or failures on sea ice until deflections are in excess of 25% of the ice thickness (Vaudrey, 1977). The 10% deflection value was selected because this is the freeboard limit for the ice sheet; although the ice is safe at this point (10% deflection), water could penetrate through existing cracks and holes to the runway surface, raising concern and causing operational difficulties (Barthelemy, 1992). Parking curves have been developed for each aircraft. The curves indicate the maximum time an aircraft can remain stationary as a function of the period (ice temperature), ice thickness, and aircraft type and load. The aircraft must change parking locations if it remains on the ice longer than indicated by the curves. The center of the new parking position must be at least 152.5 meters (500 feet) removed from the original location.

B-6.2.3.2

Care must also be exercised for other concentrated loads, such as fuel tanks. A similar analysis for the safe residence time for a given concentrated infrastructure load for the prevailing ice temperature and thickness will allow for decisions about total loads and placement geometry. Such infrastructure loads must also be taken into account when locating primary or secondary aircraft parking spots.

B-6.2.3.3

Operational strength criteria for aircraft parked on sea ice are presented in Figure B-6. Contact the person(s) listed in paragraph 13 for recommendations on how to analyze for infrastructure or long-term (12 or more hours) group aircraft parking loads.

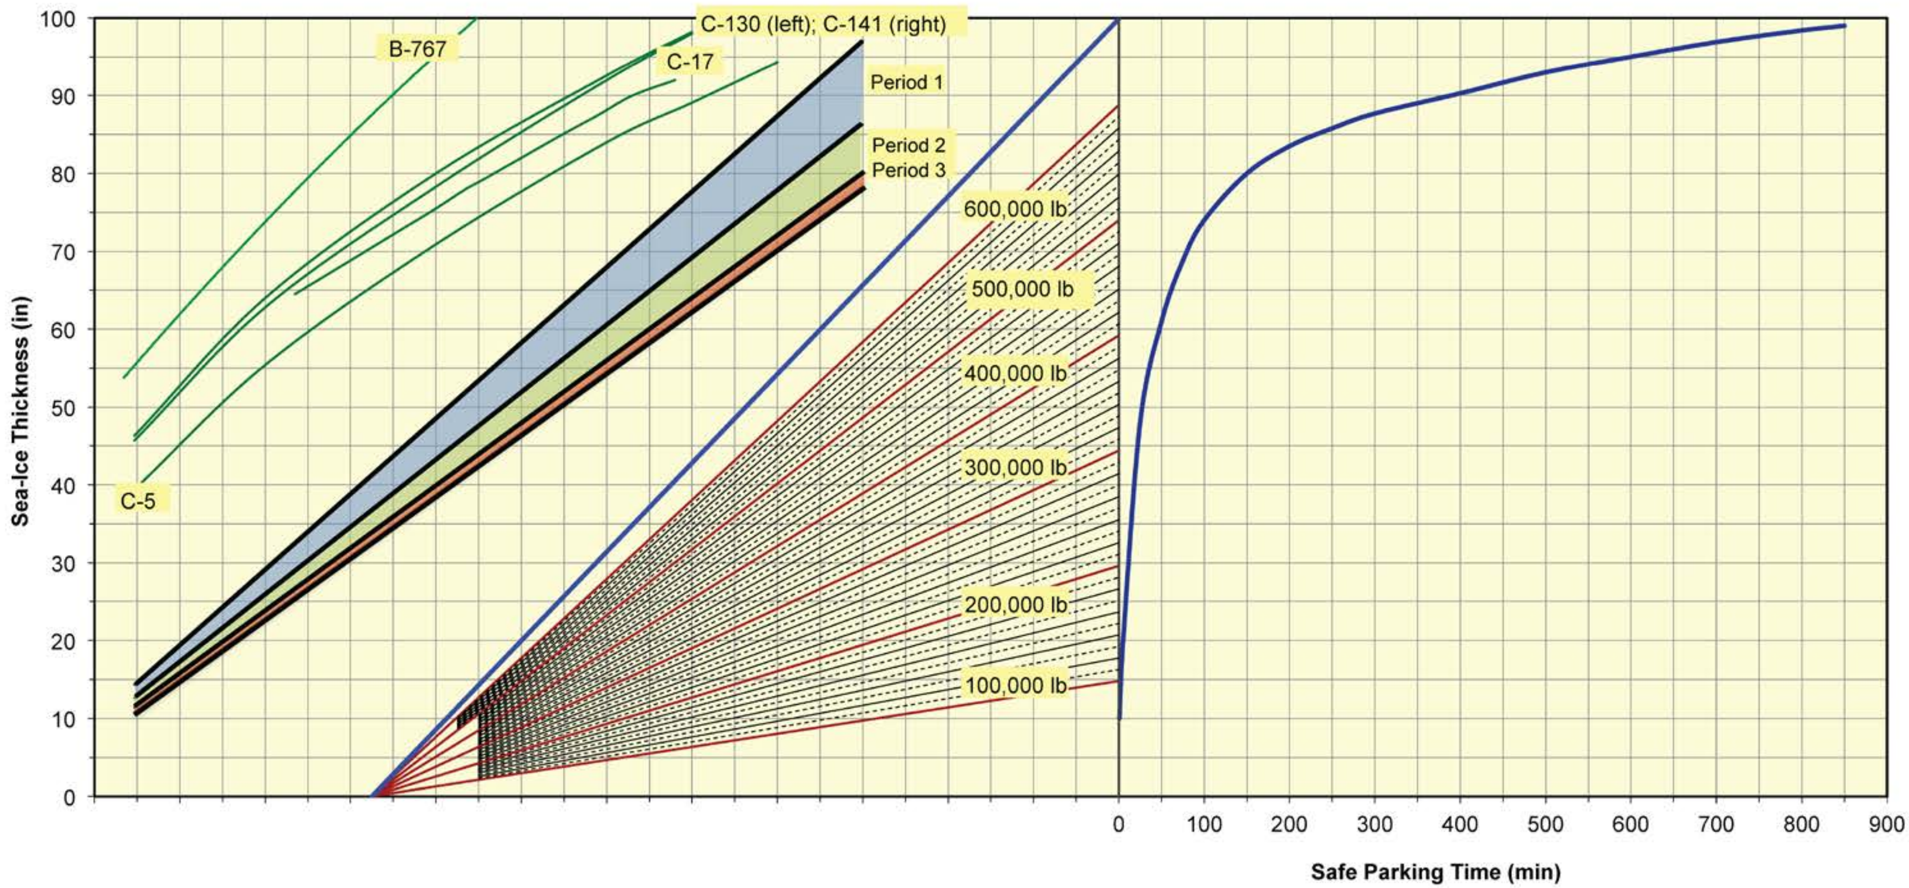
Figure B-6 Notes:

(1) Examples of nomograph use are provided in Appendix B-8. See Appendix B-14 for metric conversion factors.

(2) The nomograph has limited ability to provide a precise answer because of the thickness of lines on the chart, interpolation of temperature or load within bands on the chart, and an individual’s technique. While time-consuming, the model used to develop the nomograph can be operated to produce tabulated results which provide a more user-independent solution. Examples of such tables were produced for the C-17 and are included in paragraph B-9.2.

Figure B-6 Allowable Parking Times for the McMurdo Sound Sea Ice Runway

(See Appendix B-8 for Usage Directions, Appendix B-9 for an Example Conversion of the Nomograph to Solution Tables for the C-17, and Appendix B-14 for Metric Conversion Factors)



B-6.2.4

WARNING

Both landing/take-off and parking criteria must be determined and compared before each aircraft operation. In most cases, the minimum required sea ice thickness will be different for landing/take-off and for parking. The **GREATER** of the two calculated thicknesses must be used in planning for the aircraft mission. At times, adjustment of one or more controllable variables can allow performing an aircraft mission that, as initially planned, would not be allowed. See examples in Appendix B-8 for an illustration of this process.

B-6.2.5

The primary source of ice mass weakness at the sea ice runway site is weakening during mid- to late-season operations as sea and air temperatures rise. Cracks may also form in the sea ice sheet at any point during the operational season due to tidal and other ice forces active in the region. Though not unsafe, the cracks may limit mobility and must be repaired before aircraft operations. The sea ice crack-repair procedure is described in Appendix B-3.

B-6.2.6

A format for guiding sea ice runway certification is outlined in Appendix B-4. Recall that two conditions must be met for the runway to be considered structurally adequate for aircraft operations, as described in paragraphs B-5.3.2.1 and B-5.3.2.2.

B-6.2.7

This FC is written specifically for C-130, C-17, and C-5 aircraft. The load capacity of a sea ice runway changes according to aircraft landing-gear assemblies. Contact the person(s) listed in paragraph 1-3 for recommendations on how to proceed if operational needs are encountered when the ice thickness and temperature restrict necessary flight operations or if a different type of aircraft or landing gear configuration is proposed for operation on the McMurdo Sound sea ice runway.

B-7 EXAMPLE CALCULATIONS TO ESTABLISH THE STATISTICAL SEA ICE THICKNESS VALUE

B-7.1 Example Data

Twenty runway thickness measurements were made on the sea ice (all measurements in inches): 110, 74, 104, 77, 72, 74, 83, 79, 72, 77, 71, 72, 84, 78, 81, 78, 69, 88, 70, and 74.

B-7.2 Data Manipulation

Rank the measurements in ascending order on a spreadsheet and then calculate the percent of thickness measurements equal to or greater than each unique value.

B-7.3 Data Plotting

Plot thickness versus percent “equal to or greater than” as shown in Figure B-7.

B-7.4 Data Application

Enter Figure B-7 at 85%. Continue to the plotted curve then down to the evaluation thickness of 72 inches for this example.

B-7.5 Data Validation

If a test measurement is so low that it is clearly an outlying data point (e.g., 10% less than the next lowest measurement) and therefore not representative of other tests on the runway, then additional tests must be completed to determine the extent of the thin area and whether special consideration is required. When the extent is determined, a separate structural analysis of the thin area may be appropriate, resulting in applying appropriate aircraft weight restrictions to the thin area.

Note: Sea ice thickness typically increases daily as the season progresses. Therefore, up-to-date thickness measurements are essential to determining the appropriate evaluation thickness.

Figure B-7 Tabular and Graphical Examples of Statistical Analysis of Sea Ice Thickness Data to Determine a Representative Value

(Defined as the thickness for which <u>less than 15%</u> of the samples are thinner)

Thickness Measurement [inches]	Number of Tests Equal to or Greater than Each Value	Percent of Tests Equal to or Greater Than Each Value
69	20	100%
70	19	95%
71	18	90%
72	17	85%
72	17	85%
72	17	85%

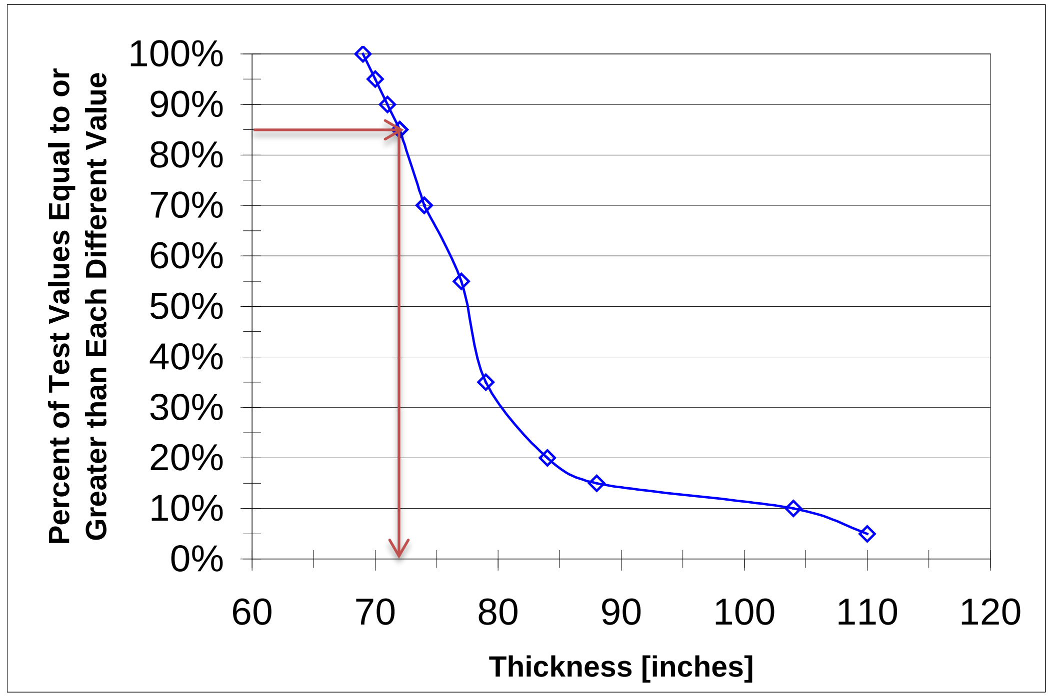
110	1	5%



B-8 EXAMPLE CALCULATIONS USING LANDING AND TAKE-OFF AND PARKING NOMOGRAPHS

B-8.1 Example 1.

B-8.1.1

A measured mean sea ice thickness of 1.83 meters (72 inches) exists on McMurdo Sound. The date is 1 November and the measured mean sea ice temperature for the past week is –17 °C (1 °F). An oversize load, critical to USAP operations, is required in McMurdo Sound. Because of the cargo’s size and critical nature, it must be delivered by C-5. In planning for this flight operation, what is the maximum safe gross aircraft landing load given the current sea ice conditions?

B-8.1.2

On the landing and take-off nomograph (Figure B-8) locate 1.83 meters (72 inches) on the left-side vertical axis and draw a horizontal line intersecting the C-5 curve (a). Draw a vertical line from this intersection point to a position representing the scaled location of –17 °C (1 °F) (vertically between the Period 1 band limits of –20 °C (-4 °F) (upper line in band) and –10 °C (14 °F) (lower line in band) (b). From this position, draw a horizontal line to the right-side vertical axis where it can be seen that a maximum C-5 gross weight of 620,000 pounds can be safely supported for take-offs and landings (c).

B-8.2 Example 2.

B-8.2.1

Preliminary flight planning for the USAP field season favors operating C-17 aircraft well into Period 2 ice conditions. The final C-17 flight is desired for 12 December. The anticipated gross C-17 weight will be about 370,000 pounds for this final flight. What sea ice thickness will be required to support landing this planned flight?

B-8.2.2

On the landing and take-off nomograph (Figure B-9) locate 370,000 pounds on the right-side vertical axis and draw a horizontal line to a position representing the scaled location of 12 December vertically between the Period 2 band limits of about 25 November (upper line in band) and about 15 December (lower line in band) (a). Draw a vertical line from this point to the C-17 curve (b). From this intersection point, draw a horizontal line to intersect the left-side vertical axis, showing that about 78 inches of sea ice must be present for safe take-offs and landings.

B-8.2.3

Planners can use historical ice data to determine if there is a good likelihood of this ice thickness being present at a particular time. In any case, as the time nears 12 December, actual measured sea ice thicknesses will govern (via use of the nomograph as depicted in Example 1 [Figure B-8]) exactly what gross C-17 weight can safely be supported.

B-8.3 Example 3.

B-8.3.1

The C-5 operation presented in Example 1 (Figure B-8) determined that a maximum gross weight of 620,000 pounds for landing and take-off is dictated by the sea ice conditions. It is known that about 1.5 hours will be required after the C-5 is parked for off-loading, refueling, and pre-flight preparations. Can the C-5 at 620,000 pounds safely park on the sea ice for 1.5 hours?

B-8.3.2

On the parking nomograph (Figure B-10) locate 72 inches on the left-side vertical axis and draw a horizontal line to intersect with the C-5 curve (a). Then draw a vertical line from this intersection point to a position representing the scaled location of –17 °C (1 °F) vertically between the Period 1 band limits of –20 °C (-4 °F) (upper line in band) and –10 °C (14 °F) (lower line in band) (b). From this position, draw a horizontal line to a point representing the gross aircraft weight (vertically scaled location between provided weight curves) (c). Now draw a vertical line upward to the reflection surface (d). A horizontal line from the reflection surface is then drawn to intersect the parking curve (e). Lastly, a vertical line is then drawn to intersect the horizontal safe parking time axis where it can be seen that the C-5 mission considered will only allow about 25 minutes of parking time before creep failure of the sea ice.

B-8.3.3

Two possibilities exist for alleviating this situation. First, and easiest, is to minimize the gross weight of the C-5. While the landing nomograph (Figure B-8) indicates that a maximum gross weight of 620,000 pounds can be safely landed, a lesser weight is certainly also safe. If the C-5 gross arrival weight could be reduced to about 475,000 pounds, a parking time of about 75 minutes could be achieved. If the aircraft cannot be reduced to this load level, an alternative is to minimize the landing/parking weight as possible and plan for moving the parked aircraft one or more times during the off-loading process. This is quite inefficient and requires significant planning but has occasionally been necessary. The distance moved must be greater than two times the overall width of the aircraft (wingspan) and can be in any direction. As soon as the aircraft is parked in its new location the parking time clock restarts.

B-8.4 Example 4.

B-8.4.1

A two-hour parking time is required to achieve unloading and back-loading of a C-17 mission very late in the life of the annual McMurdo Sound sea ice runway (30 December). It is expected that the C-17 will have an average weight of 500,000 pounds during a large part of its parked time. What sea ice thickness will be necessary to support this flight?

B-8.4.2

On the parking nomograph (Figure B-11), locate 120 minutes on the horizontal safe parking time axis and draw a vertical line to intersect the parking curve (a). From this intersection point, draw a horizontal line to the reflection surface (b). From there, drop vertically to the 500,000 pounds aircraft load line (c). A horizontal line from this point to a temperature-representative point within Period 3 follows (d). Then draw a line vertically to intersect the C-17 curve (e). From here, a horizontal line can be seen to intersect the sea ice thickness axis at about 90 inches (f).

B-9 TABULATED RESULTS FROM APPLICATION OF LANDING/TAKE-OFF AND PARKING NOMOGRAPHS TO C-17 AND BOEING 767-300ER AIRCRAFT AT MCMURDO SOUND SEA ICE RUNWAY

B-9.1 Nomographs - General

The nomographs for safe landing/take-off (Figure B-5) and safe parking time (Figure B-6) have limited ability to provide a precise answer because of the thickness of lines on the chart, interpolation of temperature or load within bands on the chart, and an individual's technique. By applying the mathematical relationships used to generate the nomographs, tables of values for discrete temperatures and loads can be produced.

B-9.2 C-17 Nomographs

Figure B-12 depicts the safe landing and take-off loads (in pounds) for the C-17 aircraft between the temperature limits represented by McMurdo Sound Period 1 to Period 4. Figures B-14 to B-37 give safe parking times (in hours) for individual temperatures at 10,000-pound (4500-kilogram) increments of gross C-17 weight.

B-9.3 B767 Nomographs

Figure B-13 depicts the safe landing and take-off loads (in pounds) for the B767-300ER aircraft between the temperature limits represented by McMurdo Sound Period 1 to Period 4. Figures B-38 to B-61 give safe parking times (in hours) for individual temperatures at 10,000-pound (4500-kilogram) increments of gross B767-300ER weight.

Figure B-12 Tabular Representation of Landing/Take-Off Nomograph for C-17

(Values in Table are Gross Aircraft Weight in Pounds)

Ice Temperature (All Period 1, 2 and 3 ice for McMurdo Sound)

Sea Ice Thickness (inches)

B-10 TEST PLAN FOR SEA ICE RUNWAY WHEELED AIRCRAFT OPERATIONS CERTIFICATION

B-10.1 Introduction.

This test plan documents and explains the required steps, methods, and tools required to certify the sea ice runway for wheeled aircraft operations. The primary attributes that govern certification are dimensions and grades, markings, pavement strength (short and long term), and ice temperature profiles.

B-10.2 Certification Process.

B-10.2.1 Dimensions and Grades.

B-10.2.1.1

Measure features in the airfield area (as depicted in Figures 2-1, 2-3, and 2-5). Use available and expedient survey methods and tools (e.g., taping, measuring wheel, transit, laser) to verify that the dimensions and grades of the following airfield components are as required in Tables 2-1 through 2-4.

- Runway
- Shoulders
- Overrun area (each end, if present)
- Taxiway
- Apron (refuel, load/unload, turnaround)
- End clear areas
- Lateral clear areas

B-10.2.1.2

Verify dimensions and grades of each feature at the approximate locations shown in Figures 2-1, 2-3, and 2-5. Note that some areas and zones will blend seamlessly (without indication) into other areas, such as where the runway width transitions to the shoulders. In these situations, simply measure and verify that the combined dimensions of the features are per specification.

B-10.2.1.3

On Figures 2-1, 2-3, and 5, place a check mark (✓) by each dimension and grade that has been measured and approved and place an X by any dimension that fails the inspection, noting where the failure is located. Measurements that fail the inspection must be documented and brought to the attention of the airfield manager.

B-10.2.2 Markings, Lighting, and NAVAIDS.

UFC 3-535-01 governs the placement of markings and NAVAIDS.

B-10.2.2.1

Check that markings, lighting, and NAVAIDS are in the correct positions and properly annotated as described in paragraphs 2-3, 2-4, and 2-5. **Note:** Direct on-snow marking is prohibited.

B-10.2.2.2

Verify that the bottom of the marker (flag) is at least 0.3 meter (1 foot) above the snow surface. Marker dimensions (which vary depending on required markings) must conform to Figure 2-6, Detail 3.

B-10.2.2.3

Check that flags are attached to frangible (break-away or bend-away) poles. Suitable poles can be made of common bamboo or lightweight plastic, but must not be metal or large, solid wood (e.g., 100-millimeter by 100-millimeter [4-inch by 4-inch] posts).

B-10.2.2.4

Each flag will be stretched out between two poles and attached to the poles by means that are wind-proof and sturdy (but removable), such as with clamps and cords.

B-10.2.2.5

On Figure 2-5, place a check mark (✓) by each flag that is properly placed and marked, and place an X by any missing, misplaced, or improperly marked flags. Flagging problems must be documented and brought to the attention of the airfield manager.

B-10.2.3 Sea Ice Temperature.

Note: Required with or without the presence of snow cap on sea ice surface.

B-10.2.3.1

The importance of temperature measurements for structural certification cannot be overstressed. Sea ice temperature is ideally measured with a continuously recording imbedded sensor string located at a number of representative locations. If such sensors are not available, manual temperature readings must be taken during the warmest (air temperature) three-hour period during the day. Collect ice temperatures (measured at a depth of 150 millimeters [6 inches]) at a minimum of four locations on the runway proper and at two locations in the apron/parking area. Temperature data will be collected at a minimum of the following frequencies:

- Period 1: Once every two weeks
- Period 2: Once every week
- Period 3: Three times per week; and 24 hours before each C-17 aircraft flight.
- Period 4: Once every day

B-10.2.3.2 Sea Ice Evaluation Temperature.

The sea ice temperature used for evaluating the structural capacity (referred to as the “evaluation temperature”) shall be determined by calculating the simple average of the measured temperatures at the (minimum) six locations sampled. For example, if the measured temperatures are 10, 12, 13, 11, 14 and 10 °F, the evaluation temperature is equal to (10+12+13+11+14+10) ÷ 6 = 11.7 °F. The evaluation temperature is then used, with sea ice thickness to determine safe landing and parking parameters.

B-10.2.4 Sea Ice Thickness.

B-10.2.4.1

The sea ice thickness used for evaluating the structural capacity (referred to as the “evaluation thickness”) will be determined using a statistical approach applied to the set of measured thickness data points. The evaluation thickness shall be equal to or less than 85% of all the measured thicknesses. This corresponds to an evaluation thickness of one standard deviation below the mean. If 10 or less thickness measurements are made then the lowest of the measured values shall be used as the evaluation thickness. An example calculation to establish the statistical sea ice thickness used for evaluation purposes is detailed in Appendix B-7.

B-10.2.4.2

Actual ice thickness must be measured at no less than 16 random locations spread throughout the runway surface, with no less than half being located within a 15-meter (50-foot) -wide swath down the center of the runway. Ideally, since a statistical approach is used, more measurements will lead to greater confidence levels. Thickness measurements must begin at least 10 days before the intended onset of flight operations. Measurements will continue throughout the entire duration of flight operations. Measurement frequency will be the same as for temperature measurements (see paragraph B-10.2.3.1).

B-10.2.5 Measurement Density.

Increased measurement density over that given in paragraph B-10.2.3.1 (for temperature or thickness) is only required during operating periods when the average thickness of the sea ice is nearing the point where it may limit gross aircraft weights and parking times for the aircraft type to be operated. For large aircraft, this will likely be the case any time first-year sea ice is encountered. See Appendix B-7 for a description of the process for statistically establishing sea ice thickness.

B-10.2.6 Approval and Documentation Storage.

The certification team leader and the airfield manager will sign the final results from the data analysis. These signed documents and the electronic and hardcopy data and analysis results will be provided to and maintained by the airfield manager and will also be provided to the certification team leader for forwarding to HQ AMC/A7OI.

B-11 TEST PLAN FOR PEGASUS RUNWAY WHEELED AIRCRAFT OPERATIONS CERTIFICATION

B-11.1 Introduction.

This test plan documents and explains the required steps, methods, and tools required to certify the Pegasus runway for wheeled aircraft operations. The primary attributes that govern certification are dimensions and grades, markings, pavement strength (hardness), and snow and ice temperature profiles. Use this test plan, the accompanying charts (Figures B-62 and B-63), and the Ice Runway Strength Survey Tool program to achieve a satisfactory runway evaluation and analysis.

B-11.2 Certification Process.

B-11.2.1 Dimensions and Grades.

B-11.2.1.1

Measure features in the runway area (as depicted in Figures 2-1, 2-2, and 2-3). Use available and expedient survey methods and tools (e.g., taping, measuring wheel, transit, laser) to verify that the dimensions and grades of the following characteristics are as required in Tables 2-1 through 2-4.

- Runway
- Shoulders
- Overrun area (each end, if present)
- Taxiway
- Apron (refuel, load/unload, turnaround)
- End clear areas
- Lateral clearance areas

B-11.2.1.2

Dimensions and grades of each feature will be verified at the approximate locations shown in Figures 2-1 through 2-4. Note that some areas and zones will blend seamlessly (without indication) into other areas, such as where the runway width transitions to the shoulders. In these situations, simply measure and verify that the combined dimensions of the features are per specification.

B-11.2.1.3

On Figures 2-1 through 2-4, place a checkmark (✓) by each dimension and grade that has been measured and approved, and place an X by any dimension that fails the inspection, noting where the failure is located. Measurements that fail the inspection must be documented and brought to the attention of the airfield manager.

B-11.2.2 Markings, Lighting, and NAVAIDS.

Markings and NAVAIDS placement is governed by UFC 3-535-01.

B-11.2.2.1

Check that markings, lighting, and NAVAIDS are in the correct positions and properly annotated as described in paragraphs 2-3, 2-4, and 2-5. **Note: Direct on-snow marking is prohibited.**

B-11.2.2.2

Verify that the bottom of the marker (flag) is at least 0.3 meter (1 foot) above the snow surface. Marker dimensions (which vary depending on required markings) must conform to Figure 2-6, Detail 3.

B-11.2.2.3

Check that flagging is attached to frangible (break-away or bend-away) poles. Suitable poles can be made of common bamboo or lightweight plastic but must not be metal or large, solid wood (e.g., 102-millimeter by 102-millimeter [4-inch by 4-inch] posts).

B-11.2.2.4

Each flag will be stretched out between two poles and attached to the poles by means that are wind-proof and sturdy (but removable), such as clamps and cords.

B-11.2.2.5

On Figure 2-5, place a checkmark (✓) by each flag that is properly placed and marked and place an X by any missing, misplaced, or improperly marked flags. Flagging problems must be documented and brought to the attention of the airfield manager.

B-11.2.3 Pavement Hardness (Strength).

B-11.2.3.1

Measure snow pavement hardness with a DCP or RSP at the locations shown in Figure B-62 (on the circles). Penetrometer measurements can be taken at any time of day, at any air temperature, and in any weather conditions, following the procedures presented in Appendix B-1. A field data sheet (Figure B-63) is provided for logging measurements made with a DCP. The various Pegasus runway surfaces are comprised of a compacted snow pavement built upon a very thick, solid ice base. All runway surface features meant to carry an aircraft wheel load will be required to achieve the same strength rating.

B-11.2.3.2

The layout of data entry in the field data sheet (Figure B-63) is designed to allow the certification team to walk the runway in an efficient path while taking DCP or RSP hardness and temperature measurements. This field data will later be entered at McMurdo Station into a computer database for analysis and results.

B-11.2.4 Compacted Snow Temperature.

B-11.2.4.1

Surface and subsurface temperatures will be measured with a portable thermometer on the day of review at the locations shown in Figure B-62 (marked with an X). Enter these data into the field data sheet (Figure B-63). Snow temperature measurements can be taken at any time of day, at any air temperature, and in any weather conditions, but ideally will coincide with strength measurements.

B-11.2.4.2

For the portable thermometer test, a stainless-steel temperature probe is pushed into the snow on the surface and at depths of 50 millimeters, 100 millimeters (4 inches), and 150 millimeters (6 inches) (or the base of the white ice pavement), and is held against the snow for 30 seconds to gain an accurate reading. If the snow is too hard to insert the probe, a small trench will be cut out of the snow pavement to allow the probe to be inserted horizontally. The temperature probe shall be calibrated yearly.

B-11.2.4.3

If glacial ice temperatures (from either the buried probes or portable thermometer measurements) are above or have been above –4 °C (25 °F), proof rolling tests are required to inspect for potential melt damage in the warm areas. Proof rolling is described in paragraph B-4.1.1 and further described in CRREL Monograph 98-1.

B-11.2.5 Data Reduction and Analysis.

With the field data sheet in hand, re-enter the penetrometer data (blows, and penetration per blow set) and the portable thermometer temperature data into the Ice Runway Strength Survey Tool program (contact the National Science Foundation POC in paragraph 1-3 for access to this Microsoft® Excel-based program). The program will process the data and graph the DCP index value for each runway location tested, and the results will also be automatically compared to the strength go/no-go criteria given in Table B-1. Finally, the temperature data will be automatically compared to the upper limit of –4 °C (25 °F), with a final result provided.

B-11.2.6 Approval and Documentation Storage.

The certification team leader and the airfield manager will sign the final results from the data analysis. These signed approvals and the electronic and hardcopy data and analysis results will be provided to and maintained by the airfield manager and will also be provided to the certification team leader for forwarding to HQ AMC.

C-2 DEFINITION OF TERMS

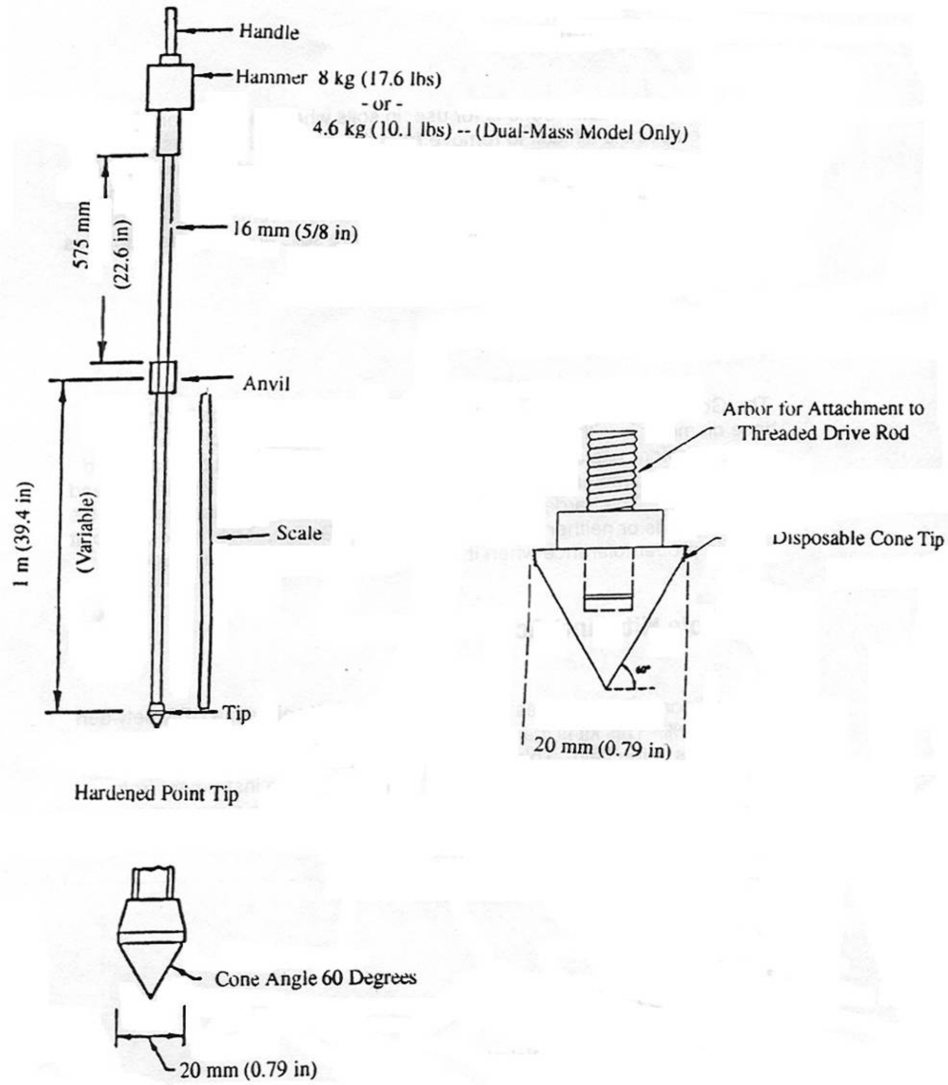
California Bearing Ratio (CBR): An index test of soil strength determined using a 1935.5-square-millimeter (3-square-inch) piston forced into the soil. The load required to achieve a 2.5- or 5-millimeter (0.1- or 0.2-inch) penetration (whichever provides lowest CBR value) is compared to a standard load for similar penetrations into a well-graded, crushed aggregate. The test is widely used for military structural airfield assessment; test procedures are in ASTM D1883.

Dynamic Cone Penetrometer (DCP): The DCP is a portable soil field test device to allow rapid measurement of soil strength (see Figure C-1). An 8-kilogram (17.6-pound) or 4.6-kilogram (10.1-pound) sliding hammer is used to drive a 60^{o}, 20-millimeter (0.8-inch) -diameter cone into the soil. The DCP strength index, in units of millimeters per blow, is calculated as:

$$\text{DCP Index} = (P/N)\ F$$

where P is the accumulated cone penetration after each set of N hammer blows, and F is a configuration factor (F = 1.0 for 8-kilogram hammer DCP; F = 1.742 for 4.6-kilogram hammer DCP). The DCP strength index has been correlated to more time-consuming tests like CBR and is widely used in the military for expedient soil strength assessments for roads and airfields. A complete description of the DCP and its use are contained in U.S. Army Waterways Experiment Station Instructional Report GL-92-3 and ASTM D6951. See Attachment 1 for penetrometer user information.

Figure C-1 Dynamic Cone Penetrometer (DCP)



Exposed Sea Ice Surface: Whether graded or not, an exposed sea ice surface has little or no snow present to act as a cover. Such a surface will present poor braking resistance at temperatures above -8 °C (18 °F).

Fresh, Loose Snow Surface: Natural unprocessed snow resting on a runway surface. Such a cover of snow enhances braking resistance at all temperatures and assists in protecting against the damaging effects of solar heating at temperatures above -8 °C (18 °F). However, too much snow will produce additional drag on tires, making takeoffs difficult. Loose snow in excess of 25 millimeters (1 inch) in depth shall be removed from the runway.

Glacial Ice Runway Surface: A durable weather- and abrasion-resistant surface generated from level grading of natural glacial ice (alpine-, continental-, or shelf-type) that is derived from naturally consolidated snow. For a more detailed description see CRREL Monograph 98-1.

Graded Sea Ice Surface: To remove natural undulations in a sea ice surface, including adhered patches of snow, a serrated grader blade is used, often with a laser-guided leveling system, to prepare the runway surface. This surface has a high degree of small-scale (12 to 100 millimeters [0.5 to 4 inches]) roughness which is felt as “chatter” in a fast-moving aircraft.

Processed Snow Surface: Also called “white ice,” this is a durable weather- and abrasion-resistant surface made from processing (e.g., compacting or tilling) natural snow that overlies the graded glacial ice or sea ice surface. The processed snow surface is smooth and has good braking and solar insulation-blocking characteristics.

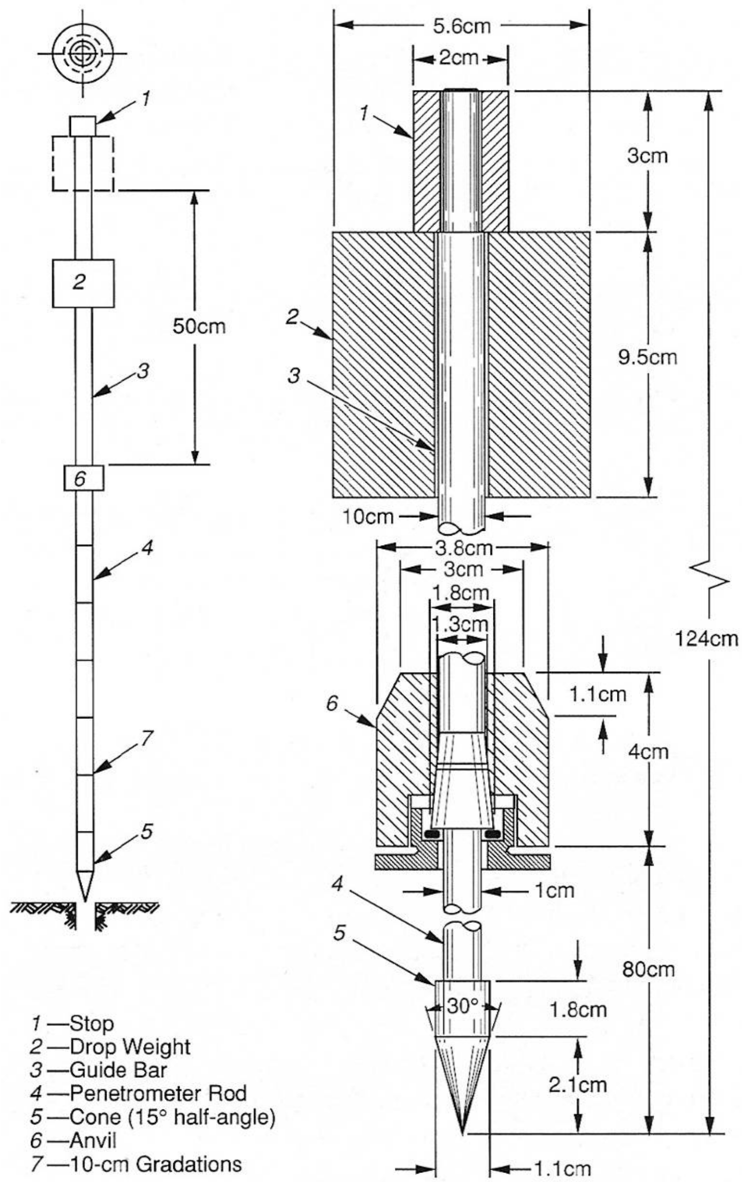
Prepared Landing Zone (PLZ): For the purposes of this FC, a PLZ refers to a landing zone constructed to support routine and moderately frequent (average one to two flights per day) wheeled cargo aircraft traffic, with no adverse effect on airframes, but that is not paved with traditional construction materials (i.e., asphalt or concrete). The amount of engineering effort required to develop a PLZ depends on the planned operation and the existing surface and weather conditions. Options for surface preparation are governed by the material present at the site and may include plowing, grading, planing, roller compaction, tilling, and vibratory compaction.

Russian Snow Penetrometer (RSP): The RSP is a portable test device to allow rapid measurement of snow strength (see Figure C-2). A 1.75-kilogram (3.85-pound) sliding hammer is dropped from a height of 500 millimeters (19.7 inches) to drive into the snow a 30^o cone with a maximum diameter of 11 millimeters (0.4 inch). During a test, penetration distance and the number of blows to produce it are recorded. The RSP index, in units of kilograms, is calculated as:

$$\text{RSP Index} = (W\ h\ n\ L^{-1}) + W + Q$$

where W is the mass of the drop hammer (kilograms), h is the height of the hammer drop (millimeters), n is the number of hammer blows to generate L (millimeters) penetration, and Q is the total mass of the penetrometer (kilograms) less its hammer. Details of penetrometer testing in processed snow can be found in CRREL Technical Report 153. See Appendix B-1 for penetrometer user information.

Figure C-2 Russian Snow Penetrometer (RSP)



Sastrugi: A long wavelike ridge of snow, formed by wind and found on the polar plains.

Sea Ice Runway Surface: The original exposed or level-graded surface of a floating slab of naturally frozen seawater.

Seasonal Operations: Seasonal operations denote aircraft activities being confined to certain periods of the year when flight and runway conditions are most favorable and when airlift is required. At McMurdo Station, the Pegasus runway is mostly operated when air temperatures are above -50 °C (-58 °F) and when sunlight is present. However, flights do sometimes occur in the shoulder seasons or during winter with alternative runway markers. The sea ice runway is only operated when (a) air temperatures are above -50 °C (-58 °F); (b) sunlight is present; and (c) when ice thickness and strength combine to allow safe landing and parking.

Record of Changes (changes are indicated by **1**\ ... /**1**/)

Change No.	**Date**	**Location**

This UFC supersedes UFC 3-260-16FA, *Airfield Pavement Condition Survey Procedures Pavements*, dated 16 January 2004, UFC 3-270-05, *Paver Concrete Surfaced Airfields Pavement Condition Index (PCI)*, dated 15 March 2001, and UFC 3-270-06, *Paver Asphalt Surfaced Airfields Pavement Condition Index (PCI)*, dated 15 March 2001.

FOREWORD

The Unified Facilities Criteria (UFC) system is prescribed by MIL-STD 3007 and provides planning, design, construction, sustainment, restoration, and modernization criteria, and applies to the Military Departments, the Defense Agencies, and DOD Field Activities in accordance with USD (AT&L) Memorandum dated 29 May 2002. UFC will be used for all DOD projects and work for other customers where appropriate. All construction outside of the United States is also governed by Status of Forces Agreements (SOFA), Host Nation Funded Construction Agreements (HNFA), and, in some instances, Bilateral Infrastructure Agreements (BIA). Therefore, the acquisition team must ensure compliance with the more stringent of the UFC, the SOFA, the HNFA, and the BIA, as applicable.

UFC are living documents and will be periodically reviewed, updated, and made available to users as part of the Services' responsibility for providing technical criteria for military construction. Headquarters, U.S. Army Corps of Engineers (HQUSACE), Naval Facilities Engineering Command (NAVFAC), and the Air Force Civil Engineer Center (AFCEC) are responsible for administration of the UFC system. Military Departments, the Defense Agencies, and DOD Field Activities should contact the preparing Service for document interpretation and improvements. Technical content of UFC is the responsibility of the cognizant DOD working group. Recommended changes with supporting rationale should be sent to the respective Service proponent office by the following electronic form: Criteria Change Request. The form is also accessible from the Internet site listed below.

- UFC are effective upon issuance and are distributed only in electronic media from the following source: Whole Building Design Guide web site http://dod.wbdg.org/.

Refer to UFC 1-200-01, *DoD Building Code (General Building Requirements)*, for implementation of new issuances on projects.

UNIFIED FACILITIES CRITERIA (UFC)
REVISION SUMMARY SHEET

Document: UFC 3-260-16, *O&M Manual: Standard Practice for Airfield Pavement Condition Surveys*

Superseding: This UFC supersedes UFC 3-260-16FA, *Airfield Pavement Condition Survey Procedures Pavements*, dated 16 January 2004, UFC 3-270-05, *Paver Concrete Surfaced Airfields Pavement Condition Index (PCI)*, dated 15 March 2001, and UFC 3-270-06, *Paver Asphalt Surfaced Airfields Pavement Condition Index (PCI)*, dated 15 March 2001.

Description: This UFC provides procedures for performing a pavement condition survey at all airfields with DOD missions. This UFC is intended for use by all personnel responsible for such surveys.

Reasons for Document: This revision addresses unification issues and the latest airfield pavement condition survey methodologies.

Impact: This document does not impact design cost, initial cost, energy savings, or life cycle costs.

Unification Issues: None

CHAPTER 1 INTRODUCTION

1-1 PURPOSE AND SCOPE.

1-1.1 This Unified Facilities Criteria (UFC) provides the procedure for performing a pavement condition survey at all airfields with present or potential DOD missions. This UFC is intended for use by all personnel responsible for such surveys.

1-1.2 The objectives of a pavement condition survey are to determine the present condition of the pavement in terms of apparent structural integrity and operational surface condition, to provide a common index for comparing the condition and performance of pavements at all air stations along with a rational basis for justification of pavement repair projects, and to provide feedback on pavement performance for validating and improving current pavement design, evaluation, and maintenance procedures.

1-1.3 The airfield pavement condition survey is a visual inspection of both rigid and flexible pavement for signs of pavement distress. The pavement condition index (PCI) is a numerical rating that indicates the type and severity of the inspected distress. The airfield condition survey and the resulting PCI are the primary means of obtaining and recording important airfield pavement performance data. This UFC describes the condition survey of both flexible pavements (all pavements with conventional bituminous concrete surfaces) and rigid pavements (jointed portland cement concrete [PCC] pavements) and the procedure for determining the PCI of the inspected pavement.

1-1.4 The pavement network is divided into branches that are in turn divided into sections. Each section is divided into sample units. The type and severity of pavement distress is assessed by visual inspection of the pavement sample units. The quantity of the distress is measured as described in Appendix A (flexible pavement) and Appendix B (rigid pavement). The distress data are used to calculate the PCI for each sample unit. The PCI of the pavement section is determined based on the PCI of the inspected sample units within the section. The distresses can be numbered using several conventions. Within this UFC, two numbering conventions are presented. One uses the convention adopted within the PAVER software, which starts the numbering of flexible distresses at 41 and continues through 57. For rigid pavement, the distresses start with 61 and continue through 76. This is done to ensure the distresses for the flexible and rigid airfield distresses have unique numerical identifiers and to allow for separate distresses for flexible and rigid roadways to have unique numerical identifiers from 1 to 39. The second convention provided in Appendix A and Appendix B is consistent with ASTM D5340 and is contained in braces: {#}. This numbering convention produces multiple distresses for the same numerical identifier and should be used with caution.

For additional information on performing pavement condition surveys for NATO countries, refer to STANAG 7181.

1-2 APPLICABILITY.

This UFC applies to all Service elements and contractors performing airfield pavement condition surveys.

1-3 GLOSSARY.

Appendix F contains a list of acronyms, abbreviations, and definitions.

1-4 REFERENCES.

Appendix G contains a list of references used in this document. The publication date of the code or standard is not included in this document. Unless otherwise specified, the most recent edition of the referenced publication applies.

CHAPTER 2 INSPECTION PROCEDURE

2-1 PAVEMENT SECTIONING.

The first step in the condition survey is the designation of pavement sections. Each branch, such as a runway or taxiway, is divided into sections that are definable in terms of the same design, the same construction history, the same traffic area, and generally the same overall condition. Generally, sections are determined from pavement design and construction records and can be further subdivided as deemed necessary based on a preliminary survey. It is important that all pavement in a given section be such that it is considered uniform. For example, the center portion of some runways in the traffic lanes are separate sections from the portion outside the traffic lanes.

2-2 SAMPLE UNITS.

2-2.1 Definition.

A sample unit is a defined portion of a pavement section designated only for the purpose of pavement inspection.

2-2.2 Sample Unit Sizes.

2-2.2.1 Asphalt-Surfaced Airfields.

For asphalt-surfaced airfields, each sample unit area is defined as 5,000 ± 2,000 square feet (465 ± 186 square meters). Note that sample unit sizes close to the recommended mean are preferred for accuracy.

2-2.2.2 Concrete-Surfaced Airfields.

For concrete airfields with joints spaced less than or equal to 25 feet (7.6 meters), the recommended sample unit size is 20 ± 8 slabs. For slabs with joints spaced greater than 25 feet (7.6 meters), imaginary joints less than or equal to 25 feet (7.6 meters) apart and in perfect condition are assumed. For example, if slabs have joints spaced 60 feet (18.3 meters) apart, imaginary joints are assumed at 20 feet (6.1 meters). Thus, each slab is counted as three slabs for the purpose of pavement inspection. This is needed because the deduct values were developed for jointed concrete slabs less than or equal to 25 feet (7.6 meters).

2-2.3 Examples.

Figures 2-1 and 2-2, respectively, illustrate the division of a jointed rigid pavement and flexible pavement section into sample units. Each sample unit is numbered where it is identifiable for future inspections, maintenance needs, or statistical sample purposes. Inspect each of the selected sample units and determine its PCI. The PCI of a pavement section is determined by the size-weighted average of the PCI of each sample unit inspected within the section.

Figure 2-1 Example Division of a Jointed Rigid Pavement Section into Sample Units of 20 Slabs

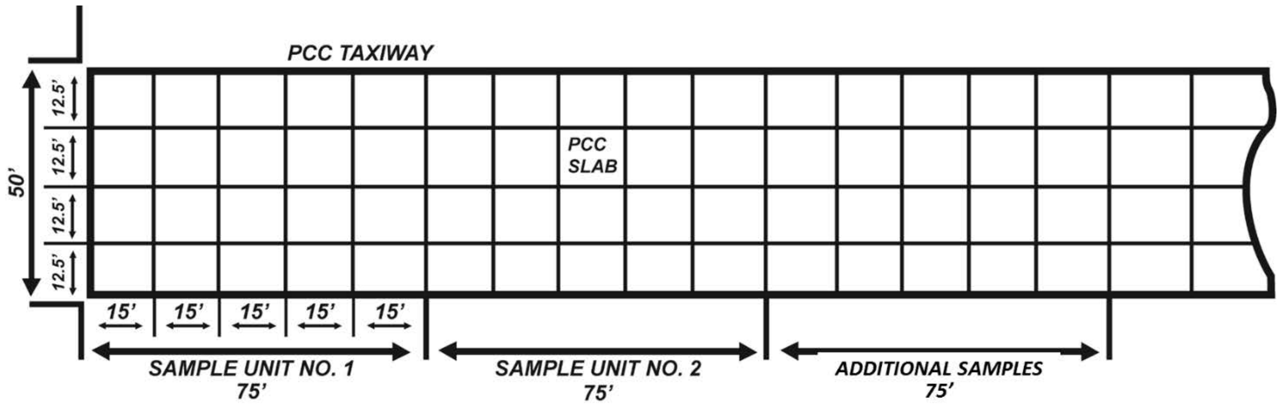

Figure 2-2 Example Division of a Flexible Pavement Section into Sample Units

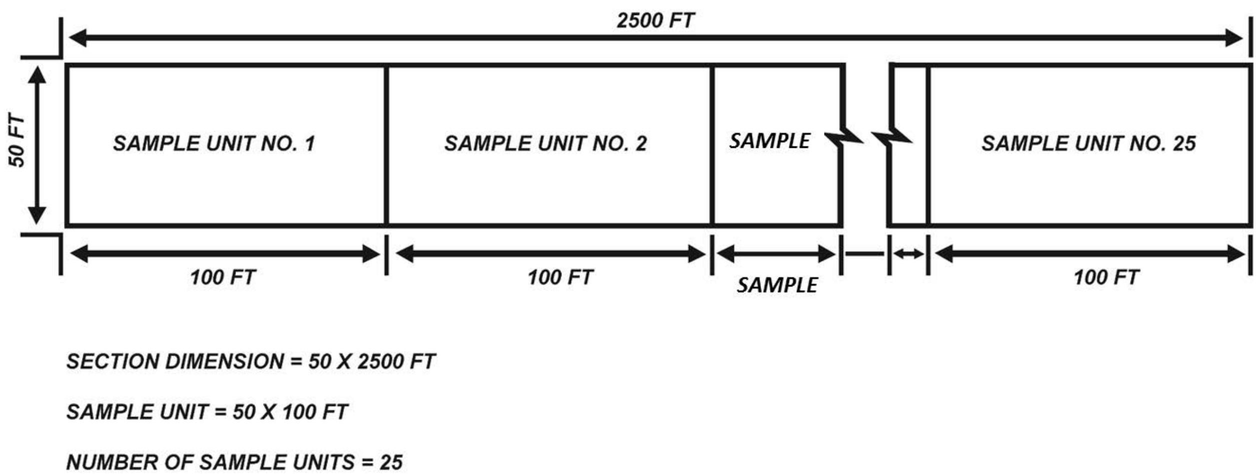


2-3 NETWORK-LEVEL INSPECTION.

2-3.1 Determining the Number of Sample Units to be Inspected.

A network-level survey is conducted by surveying a few sample units per section. Table 2-1 provides an example of criteria used by some agencies for determining the number of sample units to survey at the network level. The number of units to be inspected (n) is increased by 1 for every increase of five units in section (N) until N equals 15. When N equals 16 to 40, the value of n is set at 4. When the value of N is greater than 40, n is set at 10 percent of N and rounded up to the next whole sample unit. For example, if $N = 52$ then $n = 6$ (rounded up from 5.2).

Table 2-1 Example of Network-Level Sampling Criteria Used by Some Agencies

No. of Sample Units in Section (*N*)	No. of Units to be Inspected (*n*)
1 to 5	1
6 to 10	2
11 to 15	3
16 to 40	4
Over 40	10 percent of *N* (round up to next whole sample unit)

2-3.2 Selecting Sample Units to Inspect.

When selecting sample units to inspect as recommended in Table 2-1, ensure the sample units are representative (not random) of the overall condition of the section. The main objective for budget estimating and network condition assessment is to obtain a meaningful rating with the least cost.

2-4 PROJECT-LEVEL INSPECTION.

2-4.1 Determining the Number of Sample Units to be Inspected.

Management at the project level requires accurate data for the preparation of work plans and contracts; therefore, more sample units are inspected than are usually sampled for network-level management. The first step in sampling is to determine the minimum number of sample units (*n*) to survey to obtain an adequate estimate of the section's PCI. This number is determined for a project-level evaluation by using the curves shown in Figure 2-3. Using this number, a reasonable estimate of the true mean PCI of the section is obtained. There is a 95 percent probability that the estimate is within ±5 points of the true mean PCI (the PCI obtained if all the sample units were inspected).

The curves in Figure 2-3 were constructed using Equation 2-1:

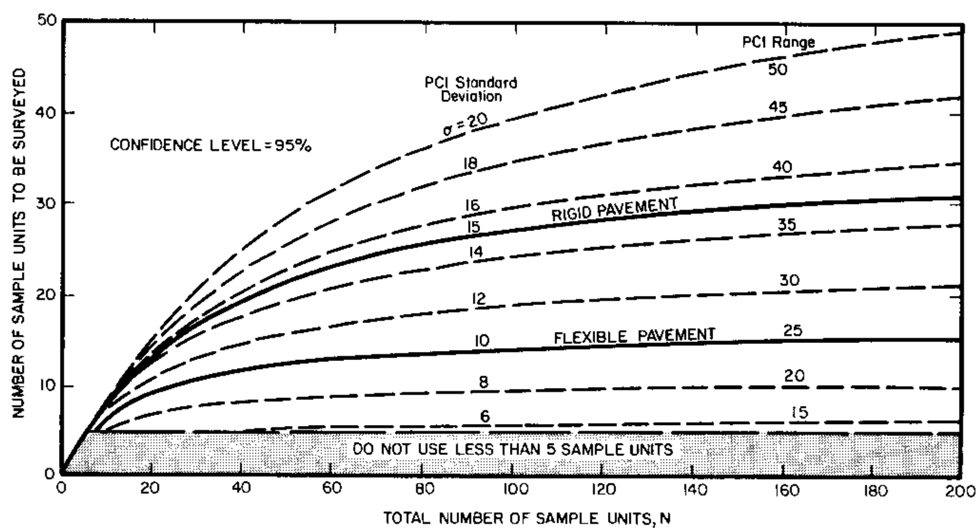
Equation 2-1 Minimum Sample Units

$$n = \frac{N(s^2)}{\frac{e^2}{4}(N-1) + s^2}$$

where:
n = minimum number of sample units
N = total number of sample units in the pavement section
e = allowable error in the estimate of the section PCI (The value e was set equal to 5 when constructing the curves of Figure 2-3.)
s = standard deviation of the PCI between sample units in the section

The curves in Figure 2-3 are based on the PCI standard deviation among sample units or PCI range (i.e., lowest sample unit PCI subtracted from the highest sample unit PCI). For the initial inspection, the PCI standard deviation for a pavement section is assumed to be 10 for asphalt concrete (AC) -surfaced pavements (or a PCI range of 25) and 15 for PCC-surfaced pavements (or a PCI range of 35). These values are based on field data obtained from many surveys; however, if local experience is different, use the average standard deviation reflecting local conditions for the initial inspection. For subsequent inspections, use the actual PCI standard deviation or range (determined from the previous inspection) to determine the minimum number of sample units to be surveyed. When the total number of samples within a section is less than five, survey all of the sample units.

Figure 2-3 Selection of the Minimum Number of Sample Units[1]



1 Shahin et al., 1976-1977

2-4.2 Selecting Sample Units to Inspect.

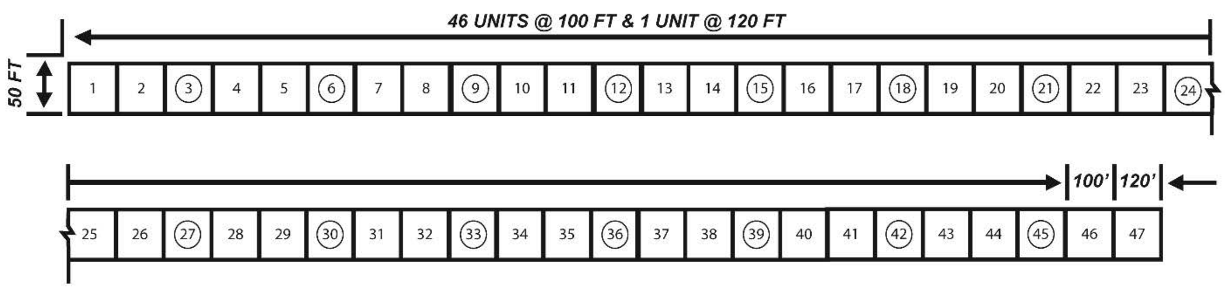
Space the sample units to be inspected equally throughout the section, with the first unit chosen at random. This technique, known as “systematic random,” is illustrated in Figure 2-4 and described by the following three steps:

1. The sample interval (*i*) is determined by $i = N \div n$, where N equals the total number of available sample units and n equals the minimum number of sample units to be surveyed. The sampling interval (*i*) is rounded to the smaller whole number (for example, 3.6 is rounded to 3.0).

2. Random starts are selected between sample unit 1 and the sampling interval (*i*). For example, if $i = 3$, the random start would be a number from 1 to 3.

3. The sample units to be surveyed are identified as S, $S+i$, $S+2i$, and so forth. If the selected start is 3 and the sampling interval is 3 then the sample units to be surveyed are 3, 6, 9, 12, and so forth.

Figure 2-4 Example of Systematic Random Sampling



TOTAL NUMBER OF SAMPLE UNITS IN SECTION (N)	*= 47*
MINIMUM NUMBER OF UNITS TO BE SURVEYED (n)	*= 13*
INTERVAL (i) = N / n = 47 / 13 = 3.6	*= 3*
RANDOM START (S)	*= 3*

2-5 SELECTION OF ADDITIONAL SAMPLE UNITS.

One of the major drawbacks to both systematic random sampling at the project level and representative sampling at the network level is that sample units in exceptionally bad condition may not necessarily be included in the survey. At the same time, sample units that have a one-time-occurrence type of distress (for example, utility cut patching) may be included inappropriately as a random sample.

To overcome these drawbacks, identify any unusual sample units and inspect them as additional units rather than as random or representative units. When additional sample units are included in the survey, the calculation of the section PCI is altered to prevent extrapolation of the unusual conditions across the entire section. This procedure is described in more detail in Chapter 3.

CHAPTER 3 PCI CALCULATION PROCEDURE

3-1 INTRODUCTION.

The PCI is calculated for each inspected sample unit. The PCI cannot be computed for the entire pavement section without computing the PCI for the sample units first. The PCI calculation is based on the deduct values, which are weighting factors from 0 to 100 that indicate the impact each distress has on pavement condition. A deduct value of 0 indicates that a distress has no effect on either pavement structural integrity or surface operational condition, whereas a value of 100 indicates an extremely serious distress.

3-2 CALCULATION OF A SAMPLE UNIT PCI FOR ASPHALT-SURFACED PAVEMENTS.

The PCI calculation procedure is illustrated for the sample unit example shown in Figure 3-1. The calculation steps are summarized in Figure 3-2 and paragraphs 3-2.1 through 3-2.4.

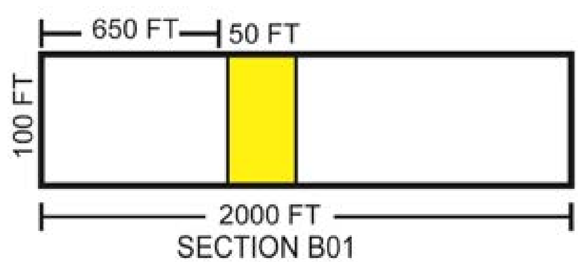

Figure 3-2 PCI Calculation Steps for Sample Unit

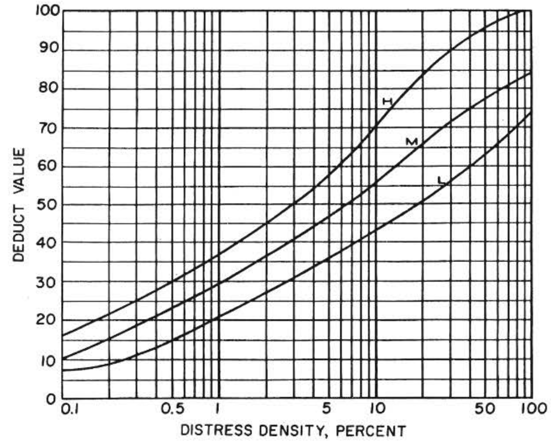
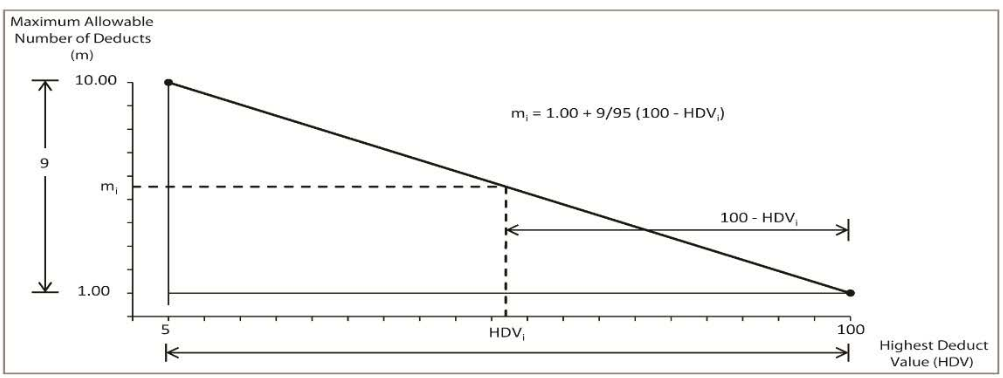
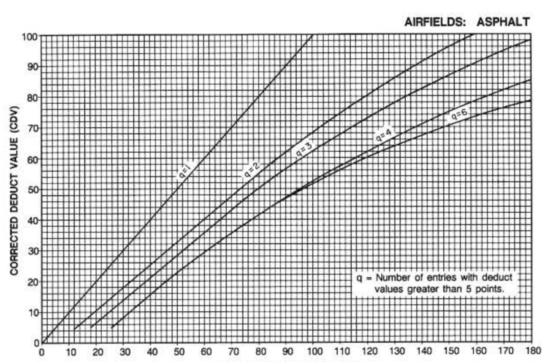
STEP 1: DETERMINE DEDUCT VALUES



STEP 2: DETERMINE MAXIMUM ALLOWABLE NUMBER OF DEDUCTS (m)



STEP 3: DETERMINE MAXIMUM CORRECTED DEDUCT VALUE



STEP 4: CALCULATE PCI

PCI = 100 - MAXIMUM CDV

3-2.1 Step 1: Determine Deduct Values.

Table 3-1 shows the results of the calculation of the deduct values for the distresses shown in Figure 3-1.

1a. Add the totals for each distress type at each severity level and record them as shown in Table 3-1. Distress quantities are measured in square feet (square meters), linear feet (meters), or number of occurrences, depending on the distress type.

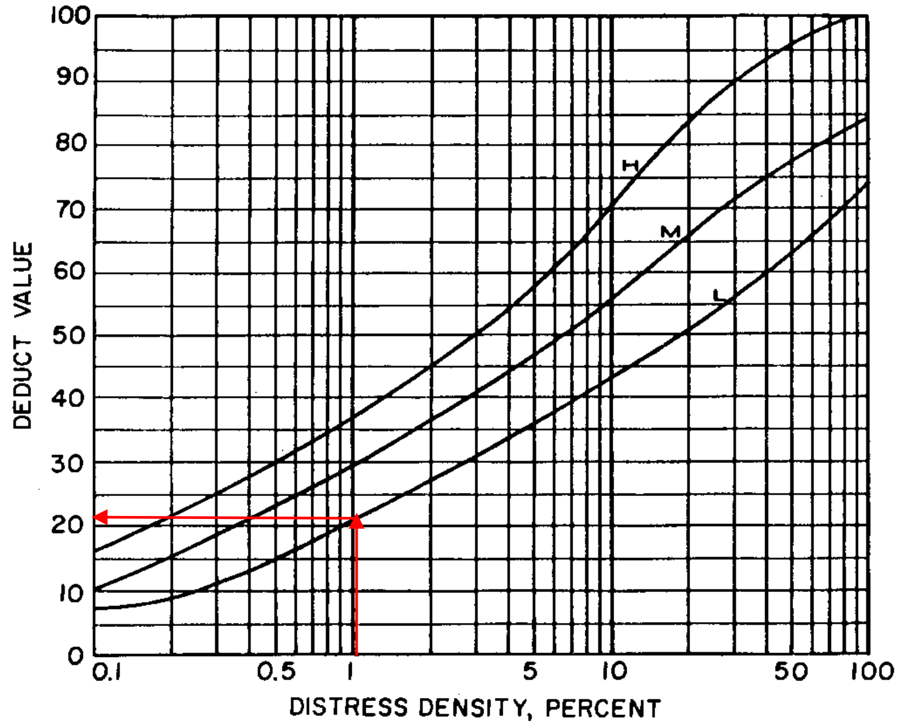
1b. Divide the quantity of each distress type at each severity level by the total area of the sample unit then multiply by 100 to obtain the percentage of density per sample unit for each distress type and severity.

1c. Determine the deduct value for each distress type and severity level combination from the distress deduct value curves. Figure 3-3 shows an example of a deduct curve for distress type 41, alligator cracking, for asphalt-surfaced airfield pavements. Deduct curves for all asphalt airfield distresses are provided in Appendix C.

Table 3-1 Calculation of Deduct Values for Distresses Shown in Figure 3-1

Paver Distress	ASTM Distress	Description	Severity	Qty (ft/ft^2)	Qty (m/m^2)	Density	Deduct
(41)	{1}	Alligator cracking	L	53 ft^2	4.9 m^2	1.06	21.0
(45)	{5}	Depression	L	75 ft^2	7.0 m^2	1.5	9.2
(48)	{8}	Longitudinal and transverse cracking	L	47 ft	14.3 m	0.94	4.8
(48)	{8}	Longitudinal and transverse cracking	M	16 ft	4.9 m	0.32	6.7
(53)	{13}	Rutting	M	25 ft^2	2.3 m^2	0.5	20.2
ft^2 (m^2) = square feet (square meters) ft (m) = feet (meters)							

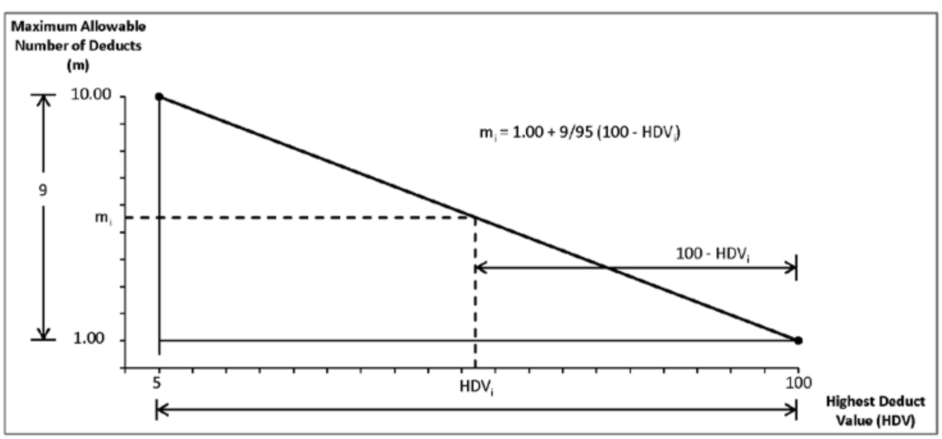
Figure 3-3 AC Pavement Deduct Curve for Alligator Cracking Distress



3-2.2 Step 2: Determine the Maximum Allowable Number of Deducts (*m*).

The maximum allowable number of deducts is calculated as shown in Figure 3-4 or using Equation 3-1.

Figure 3-4 Determination of Maximum Allowable Deducts (*m*) for Airfield Pavements



Equation 3-1 Allowable Number of Deducts for Airfields

$$m_i = 1 + \left(\frac{9}{95}\right)(100 - HDV_i)$$

where:
m_i = *allowable number of deducts, including fractions, for sample unit i*
HDV_i = *highest individual deduct value for sample unit i*

For example, in Table 3-1 (calculated from Figure 3-1) the allowable number of deducts is calculated as:

$$m_i = 1 + \left(\frac{9}{95}\right)(100 - 21.02) = 8.48$$

The number of individual deduct values is reduced to *m*, including the fractional part. If fewer than *m* deduct values are available then all the deduct values are used. For the example in Figure 3-1, all the deduct values are used since they are less than *m*.

3-2.3 Step 3: Determine the Maximum Corrected Deduct Value (CDV).

The maximum CDV is determined iteratively as described in these five steps:

3a. List the individual deduct values in descending order as shown in Figure 3-5, row 1. For example, the values in Table 3-1, which were calculated from the example shown in Figure 3-1, are sorted as follows: 21, 20.2, 9.2, 6.7, and 4.8.

3b. Determine the total deduct value by adding all individual deduct values. In the current example, the total deduct value is 61.9.

3c. Determine the CDV from *q* (number of deduct values over 5) and the total deduct value by looking up the appropriate correction curve. Figure 3-6 shows the correction curve for asphalt-surfaced airfield pavements. The CDV for row 1 is calculated as 31.

3d. Reduce to 5.0 the smallest individual deduct value that is greater than 5.0, as shown in row number 2 in Figure 3-5. Repeat steps 3b and 3c until *q* is equal to 1.

3e. The maximum CDV is the largest of the CDVs determined.

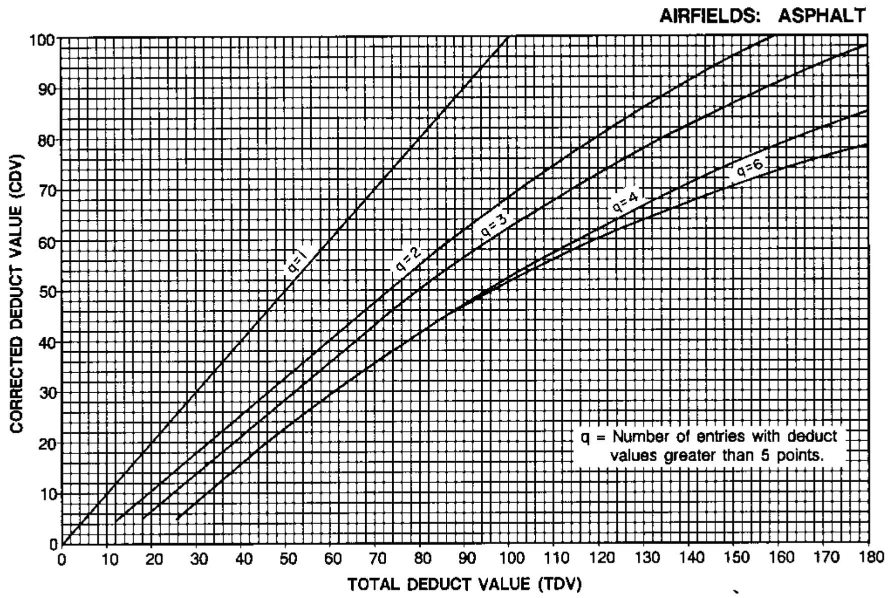
Figure 3-6 Correction Curves for AC-Surfaced Airfield Pavements



3-2.4 Step 4: Calculate PCI by Subtracting the Maximum CDV from 100.

For the example, the PCI equals 100 - 41 = 59.

3-3 CALCULATION OF A SAMPLE UNIT PCI FOR CONCRETE-SURFACED PAVEMENTS.

3-3.1 Step 1: Determine Deduct Values.

Table 3-2 shows the results of the calculation of the deduct values for the distresses shown in Figure 3-7.

1a. For each unique combination of distress type and severity level, add the number of slabs in which they occur. For example, Figure 3-7 lists three slabs with low-severity joint spalling.

1b. Divide the number of slabs from step 1a by the total number of slabs in the sample unit then multiply by 100 to obtain the percentage of density per sample unit for each distress type and severity combination.

1c. Determine the deduct values for each distress type and severity level combination using the appropriate deduct curve in Appendix D for concrete airfields.

Table 3-2 Calculation of Deduct Values for Distresses Shown in Figure 3-7

Paver Distress	ASTM Distress	Description	Severity	Quantity	Units	Density	Deduct
(63)	{4}	Linear cracking	M	2	Slabs	10	18.7
(63)	{4}	Linear cracking	L	5	Slabs	25	15.4
(72)	{13}	Shattered slab	L	1	Slabs	5	11.0
(74)	{15}	Joint spall	L	3	Slabs	15	4.8
(75)	{16}	Corner spall	L	6	Slabs	30	9.6

3-3.2 Step 2: Determine the Maximum Allowable Number of Deducts (*m*).

This step is the same as the comparable step for asphalt-surfaced pavements described in paragraph 3-2.2. For the example in Figure 3-7, based on a highest deduct value (HDV) of 18.66, m is calculated using Equation 3-1:

$$m_i = 1 + \left(\frac{9}{95}\right)(100 - 18.66) = 8.71$$

The maximum allowable number of deducts, m, was calculated to be 8.71. There are only five deduct values (18.66, 15.43, 11.02, 4.78, and 9.62) so taking a percentage of one of the deduct values is not necessary; however, if in the sample unit m was calculated to be 3.4, it would be necessary to take the three highest deduct values and 40 percent of the fourth-highest deduct value.

3-3.3 Step 3: Determine the Maximum CDV.

Determine the maximum CDV by following the procedures in paragraph 3-2.3 but using the appropriate correction curve in Appendix D for concrete airfields.

3-3.4 Step 4: Calculate the PCI by Subtracting the Maximum CDV from 100.

Figure 3-8 summarizes the PCI calculation for the example of PCC pavement data shown in Figure 3-7.

Figure 3-8 PCI Calculation Sheet for the Example Sample Unit Shown in Figure 3-7

PCC *m* = 8.8 > 5

</table>

3-4 CALCULATION OF THE PCI FOR A PAVEMENT SECTION.

If all surveyed sample units are selected either by using the systematic random technique or on the basis of being representative of the section and are equal in size, the PCI of the section is determined by averaging the PCIs of the inspected sample units. If the inspected sample units are not equal in size, use area-weighted averaging as shown in Equation 3-2.

Equation 3-2 Area Weighted Averaging for Unequally Sized Sample Units

$$PCI_s = PCI_r = \frac{\sum_{i=1}^{R}(PCI_{ri}\ A_{ri})}{\sum_{i=1}^{R} A_{ri}}$$

where:
PCI_s = PCI of pavement section
PCI_r = area-weighted average PCI of random (or representative) sample units
PCI_{ri} = PCI of random sample unit number i
A_{ri} = area of the random sample unit i
R = total number of inspected random sample units

If additional sample units are inspected in addition to the random or representative units, the section PCI is computed using Equations 3-3 and 3-4:

Equation 3-3 Area Weighted Average PCI for Additional Sample Units

$$\boldsymbol{PCI_a} = \frac{\sum_{i=1}^{A}(\boldsymbol{PCI_{ai}} \times \boldsymbol{A_{ai}})}{\sum_{i=1}^{R}(\boldsymbol{A_{ai}})}$$

Equation 3-4 Section PCI for Additional Sample Units

$$PCI_s = \frac{PCI_r\left(A_s - \sum_{i=1}^{A} A_{ai}\right) + PCI_a \times \sum_{i=1}^{A} A_{ai}}{A_s}$$

where:
PCI_a = area weighted average PCI of additional sample units
PCI_{ai} = PCI of additional sample unit number i
A_{ai} = area of additional sample unit I
A_s = total section area

For example, if in a section of 60,000 square feet (5,574 square meters), five random sample units were inspected and determined to have PCIs of 56 (5,000 square feet [465 square meters]), 72 (5,000 square feet [465 square meters]), 65 (5,000 square feet [465 square meters]), 69 (4,000 square feet [372 square meters]), and 61 (4,000 square feet [372 square meters]), and two additional sample units with PCIs of 42 (3,500 square feet [325 square meters]) and 39 (3,500 square feet [325 square meters]) were included, the PCI of the section would be:

$$PCI_r = \frac{(56 \times 5{,}000) + (72 \times 5{,}000) + (65 \times 5{,}000) + (69 \times 4{,}000) + (61 \times 4{,}000)}{5{,}000 + 5{,}000 + 5{,}000 + 4{,}000 + 4{,}000}$$
$$PCI_r = 64.57$$

$$PCI_a = \frac{(42 \times 3{,}500) + (39 \times 3{,}500)}{3{,}500 + 3{,}500}$$
$$PCI_a = 40.5$$

$$PCI_s = \frac{64.57(60{,}000 - 7{,}000) + 40.5 \times 6{,}500}{60{,}000}$$
$$PCI_s = 61$$

3-5 EXTRAPOLATING DISTRESS QUANTITIES FOR A PAVEMENT SECTION.

3-5.1 When a pavement has been inspected by sampling, it is necessary to extrapolate the quantities and densities of distress over the entire pavement section to determine total quantities for the section. If all sample units surveyed were selected at random, the extrapolated quantity of a given distress at a given severity level is determined as shown in the following example for an asphalt-surfaced airfield with medium-severity alligator cracking:

Surface type: AC

Section area: 49,000 square feet (4,552 square meters)

Total number of sample units in section: 10

3-5.2 Five sample units were surveyed at random and the amount of medium-severity alligator cracking was determined as shown in Table 3-3:

Table 3-3 Medium-Severity Alligator Cracking in Five Surveyed Sample Units

Sample Unit ID Number	Sample Unit Area ft^2 (m^2)	Medium-Severity Alligator Cracking ft^2 (m^2)
02	5,000 (465)	200 (18.6)
04	5,000 (465)	400 (37.2)
06	5,000 (465)	300 (27.9)
08	5,000 (465)	100 (9.3)
10	4,000 (372)	200 (18.6)
Total Random	**24,000 (2230)**	**1,200 (111.5)**

3-5.3 The average density for medium-severity alligator cracking then is 1,200 divided by 24,000, or 0.05. The extrapolated quantity is determined by multiplying density by section area (0.05 × 49,000 = 2,450 square feet [227.6 square meters]). If additional sample units were included in the survey, the extrapolation process is slightly different. In the above example, assume that sample unit number 01 was surveyed as an additional unit and that the amount of medium-severity alligator cracking was measured as shown in Table 3-4:

Table 3-4 Medium-Severity Alligator Cracking in an Additional Sample Unit

Additional Sample Unit ID Number	Sample Unit Area ft^2 (m^2)	Medium-Severity Alligator Cracking ft^2 (m^2)
01	5,000 (465)	2,000 (186)
Total Additional	**5,000** (465)	**2,000 (186)**

3-5.4 Since 5,000 square feet (465 square meters) were surveyed as additional in this example, the section's randomly represented area is 49,000 - 5,000 square feet (4,552 – 465 square meters) or 44,000 square feet (4087 square meters). The extrapolated distress quantity is obtained by multiplying the distress density by the section's randomly represented area then adding the amount of additional distress. In this example, the extrapolated distress quantity equals (0.05 × 44,000 square feet (4,087 square meters) + 2,000 square feet (186 square meters) or 4,200 square feet (390 square meters).

APPENDIX A DISTRESS DEFINITIONS - ASPHALT-SURFACED AIRFIELDS.

A-1 INTRODUCTION.

This appendix contains distress definitions and measurement methods for asphalt-surfaced airfields. This information is used to determine the PCI.

Note: Each distress definition is followed by a number in parentheses, indicating the PAVER distress code, and a number in braces, indicating the ASTM D5340 distress code, i.e.,
"Distress (#) {#}." See Table 3-5.

Table A-1 Frequently Occurring Problems in Asphalt Pavement Distress Identification

Situation	Action	Remarks
Alligator cracking and rutting in same area	Record each separately at respective severity level	
Bleeding counted in area	Polished aggregate is not counted in same area	
Polished aggregate in very small amount	Do not count	Polished aggregate is only counted when there is a significant amount
Any distress (including cracking) in a patched area	Do not record	Effect of distress is considered in patch severity level
Block cracking is recorded	For asphalt pavements, not including AC over PCC, if block cracking is recorded, do not record longitudinal and transverse cracking in the same area	
Asphalt overlay over concrete	Block cracking and joint reflection cracking are recorded separately	AC over PCC could have, for example, 100 percent block cracking and 100 feet of joint reflection cracking
Weathering (surface wear) and raveling in the same sample area	Weathering (surface wear) is not recorded if medium- or high-severity raveling is recorded	Raveling is always recorded

A-2 ALLIGATOR (FATIGUE) CRACKING (41) {1}.

A-2.1 Description.

Alligator (or fatigue) cracking is a series of interconnecting cracks caused by fatigue failure of the asphalt surface under repeated traffic loading. The cracking initiates at the bottom of the asphalt surface (or stabilized base) where tensile stress and strain is highest under a wheel load. The cracks propagate to the surface initially as a series of parallel cracks. After repeated traffic loading, the cracks connect and form multi-sided, sharp-angled pieces that develop a pattern resembling chicken wire or the skin of an alligator. The pieces are less than 2 feet (0.6 meter) on the longest side. Alligator cracking occurs only in areas subjected to repeated traffic loadings, such as wheel paths; therefore, it would not occur over an entire area unless the entire area was subjected to traffic loading. (Pattern-type cracking that occurs over an entire area that is not subject to loading is rated as block cracking, which is not a load-associated distress.) Alligator cracking is considered a major structural distress.

A-2.2 Severity Levels.

L Fine, longitudinal hairline cracks running parallel to each other with no or only a few interconnecting cracks. The cracks are not spalled.

M Further development of light alligator cracking into a pattern or network of cracks that may be lightly spalled. Medium-severity alligator cracking is defined by a well-defined pattern of interconnecting cracks, where all pieces are securely held in place (i.e., good aggregate interlock between pieces).

H Network or pattern cracking progresses so that pieces are well-defined and spalled at the edges; some of the pieces rock under traffic and may cause foreign object damage (FOD) potential.

A-2.3 How to Measure.

Alligator cracking is measured in square feet (square meters) of surface area. The major difficulty in measuring this type of distress is that often two or three levels of severity exist within one distressed area. If these portions can be easily distinguished from each other, measure and record separately; however, if the different levels of severity cannot be easily divided, rate the entire area at the highest severity level present. If alligator cracking and rutting occur in the same area, each is recorded separately at its respective severity level.

Figure A-1 Low-Severity Alligator Cracking

Figure A-2 Medium-Severity Alligator Cracking

Figure A-3 High-Severity Alligator Cracking

A-3 BLEEDING (42) {2}.

A-3.1 Description.

Bleeding is a film of bituminous material on the pavement surface that creates a shiny, glass-like, reflecting surface that usually becomes quite sticky. Bleeding is caused by excessive amounts of asphalt cement or tars in the mix and/or low air-void content. Bleeding occurs when asphalt fills the voids of the mix during hot weather and then expands onto the surface of the pavement. Since the bleeding process is not reversible during cold weather, asphalt or tar will accumulate on the surface.

A-3.2 Severity Levels.

No degrees of severity are defined. Note bleeding when it is extensive enough to cause a reduction in skid resistance.

A-3.3 How to Measure.

Bleeding is measured in square feet (square meters) of surface area. If bleeding is counted, polished aggregate is not counted in the same area.

Figure A-4 Bleeding

Figure A-5 Bleeding

A-4 BLOCK CRACKING (43) {3}.

A-4.1 Description.

Block cracks are interconnected cracks that divide the pavement into roughly rectangular pieces. The blocks may range in size from approximately 1 by 1 foot to 10 by 10 feet (0.3 by 0.3 meter to 3 by 3 meters). Block cracking is caused mainly by shrinkage of the AC and daily temperature cycling (which results in daily stress/strain cycling); it is not load-associated. The occurrence of block cracking usually indicates that the asphalt has significantly hardened. Block cracking typically occurs over a large proportion of pavement area but sometimes will occur in non-traffic areas. This type of distress differs from alligator cracking in that alligator cracks form smaller, multi-sided pieces with sharp angles. Also, unlike block cracks, alligator cracks are caused by repeated traffic loadings and therefore are located only in traffic areas (i.e., wheel paths).

A-4.2 Severity Levels.

L Blocks are defined by cracks that are non-spalled (sides of the crack are vertical) or only lightly spalled, causing no FOD potential. Non-filled cracks have 0.25 inch (6 millimeters) or less mean width and filled cracks have filler in satisfactory condition.

M Blocks are defined by either (1) filled or non-filled cracks that are moderately spalled (some FOD potential); (2) non-filled cracks that are not spalled or have only minor spalling (some FOD potential) but have a mean width greater than approximately 0.25 inch (6 millimeters); or (3) filled cracks that are not spalled or have only minor spalling (some FOD potential) but have filler in unsatisfactory condition.

H Blocks are well defined by cracks that are severely spalled, causing a definite FOD potential.

A-4.3 How to Measure.

Block cracking is measured in square feet (square meters) of surface area. It usually occurs at one severity level in a given pavement section; however, measure and record separately any areas of the pavement section having distinctly different levels of severity. For asphalt pavements, not including AC over PCC, if block cracking is recorded, do not record longitudinal and transverse (L&T) cracking in the same area. For asphalt overlay over concrete, separately record block cracking, joint reflection cracking, and L&T cracking reflected from old concrete.

A-5 CORRUGATION (44) {4}.

A-5.1 Description.

Corrugation is a series of closely spaced ridges and valleys (ripples) occurring at fairly regular intervals, usually less than 5 feet (1.5 meters) along the pavement. The ridges are perpendicular to the traffic direction. Traffic action combined with an unstable pavement surface or base usually causes this type of distress.

A-5.2 Severity Levels.

L Corrugations are minor and do not significantly affect ride quality (see measurement criteria below).

M Corrugations are noticeable and significantly affect ride quality (see measurement criteria below).

H Corrugations are easily noticed and severely affect ride quality (see measurement criteria below).

A-5.3 How to Measure.

Corrugation is measured in square feet (square meters) of surface area. The mean elevation difference between the ridges and valleys of the corrugations indicates the level of severity. To determine the mean elevation difference, place a 10-foot (3-meter) straightedge perpendicular to the corrugations so the depth of the valleys is measured in inches (millimeters). The mean depth is calculated from five such measurements. See Table A-2 and Figure A-12.

Table A-2 Corrugation Measurement Criteria

Measurement Criteria Severity	Runaways and High-Speed Taxiways	Taxiways and Aprons
L	< 0.25 inch (< 6 mm)	< 0.5 inch (< 13 mm)
M	0.25 to 0.5 inch (6 to 13 mm)	0.5 to 1 inch (13 to 25 mm)
H	> 0.5 inch (> 13 mm)	> 1 inch (> 25 mm)
