The Marshall HMA mixture criteria is used to determine the optimum asphalt content. Since these are cold polymer-modified emulsion systems, the stability and flow test procedures have been modified to allow for air and low temperature drying (at least 3 days of air curing, 18 to 20 hours of drying in an oven at 60 degrees C (140 degrees F) before compaction at 135 degrees C (275 degrees F)). The mixes are usually compacted with 50 blows per side. Under this procedure, several test specimens are prepared for combinations of aggregate and asphalt content. The asphalt contents are selected to provide VTM of 4.5 to 5.5 percent. The compacted test specimens are tested for the bulk specific gravity (ASTM D2726), stability, and flow values. Finally, the optimum asphalt cement content is determined using results from these tests. For thin micro-surfacing applications, the stability is not considered a primary factor in determining the optimum asphalt cement content. The surface characteristics of aggregates require adjustments in the VTM requirement to achieve the desired flow values.

4-5.3.2.3 Design Limitations.

a. **ISSA Design.** Torque values are measured in the laboratory under specific conditions; no correlation has been established with pavement performance in the field. Perform the mixing and wet cohesion test at various moisture contents, relative humidity, and temperatures to simulate the expected field conditions. In addition, it has been reported that aggregates that met ISSA torque standards for 60 minutes have failed to meet the torque values for 30 minutes. Laboratories also use a subjective analysis to determine torque. The sample is examined after the torque is applied, and if it fails, the torque value is determined from a visual examination of the condition of the sample; however, this analysis appears to negate the objectivity of the cohesion test. This indicates an area where the industry reexamines its procedures for cohesion tests and consider the effect of various aggregates on test results. The WTAT was correlated to field performance for only 6-millimeter (0.24-inch) thickness and Type 2 gradation. Accordingly, values of 0.54 kilogram per square meter (0.11 pound per square foot) are not used for other thicknesses and aggregate gradations. Further tests are needed to verify or establish new values. Also, limestone materials meet the WTAT standard for 1-hour soak periods but fail to meet maximum abrasion loss when a sample with a 6-day soak is tested. While the WTAT on a 6-day soak specimen is used for information only, industries review and adjust their current design standards. The reproducibility of the LWT is questionable. The arm that moves the wheel does not stay horizontal, but rather moves up and down during the test. This changes the pressure on the sample. Modify the arm to stay horizontal. At the present time, the weights used to apply pressure are bags of lead shot. These bags shift during the test and affect the applied pressure. Plates that are attached to the machine replace the bags. Sample preparation has been shown to affect the LWT results by a factor of as much as two. The test specimen flushes if water levels are not carefully controlled. This condition affects the sand adhesion. Improve current laboratory procedures for sample preparation so that samples are molded consistently. For aggregates, the LWT has shown to permit excessive amounts of binder, resulting in unacceptable mixtures. This is true for applications in high shear areas such as intersections. Performance data indicates that mixtures produced with these aggregates using a lower binder content (than required by the LWT) have performed well in extending the pavement service life. The specific gravity specification is subjective due to the sampling procedure. The entire LWT specimen is weighed wet and dry to obtain the specific gravity. After compaction, the same test is repeated. The problem is that only 50 to 60 percent of the specimen is compacted. Variations in the specific gravities of samples also skew LWT results.

b. **Marshall Design.** The applicability of this HMA test for micro-surfacing is questionable. The Marshall series uses specimens of varying asphalt contents that are dried, reheated to 135 degrees C (275 degrees F), and compacted to low void content. Micro-surfacing mixtures do not reach low void levels during the life of the mixture. Field observation has noted air voids of 10 to 15 percent after 1 to 2 years of placement. There is a need to correlate the voids measured during the design using the Marshall method with the actual field voids. One materials laboratory that has developed a cold Marshall test procedure to estimate field voids is currently correlating the field voids with the voids obtained by the modified HMA procedure. The HMA samples are prepared by compacting in a mold. Also, for reliable results, cure the sample in a uniformly distributed film throughout the thickness of the lift.

4-5.4 Surface Preparation.

Ensure the pavement surface has all loose material removed prior to application of the micro-surfacing material. Repair any structurally deficient pavement areas. Clean and seal cracks wider than 3 millimeters (1/8 inch) or filled with vegetation prior to application of the micro-surfacing.

4-5.5 Application.

Apply a tack coat to the pavement surface prior to application of the micro-surfacing. Immediately prior to application, wet the pavement surface with a water fogging. This fogging leaves the surface damp but with no free water. Ensure the minimum thickness of micro-surfacing material application at least exceeds the maximum nominal size of the aggregate in the mixture (usually 1¼ to 1½ times the maximum nominal size). This relates to minimum thicknesses of from 10 to 13 millimeters (3/8 to slightly over 1/2 inch). Where wheel ruts exceed 6 millimeters (1/4 inch) in depth, place a separate rut-filling layer prior to the complete overlay. The emulsion is usually heated to within 27 to 49 degrees C (80 to 120 degrees F) prior to mixing. Micro-surfacing applications are designed to be opened to traffic within 1 hour after placement. Temperature and humidity are the controlling factors for curing micro-surfacing after placement. As the temperature increases and the humidity decreases, the cure time decreases. Construction of a test section is very important for micro-surfacing due to changes in field conditions from lab conditions. Micro-surfacing is a quick-set system; therefore, changes or variations in field conditions require moisture, additive, or basic mix design changes to meet field conditions. Where possible, accomplish placement utilizing “nurse trucks” to allow for continuous placement. Nurse trucks are vehicles that are intended to carry aggregate, emulsion, and water to the application vehicle, whereby application of the micro-surfacing is a continuous operation. Whenever placement of the micro-surfacing is stopped, lift and clean the spreader box and ensure the transverse joint is squared. Paper strips or metal flashing is used to improve transverse joints. Construct longitudinal joints with a 50-millimeter (2-inch) overlap to assure complete coverage and to reduce rigid development. Use of an operator to control the rate of material flow along with careful control of the placement vehicle’s speed allows for accurate placement of the micro-surfacing.

CHAPTER 5 ASPHALT STABILIZATION

5-1 INTRODUCTION.

This chapter contains information for use of asphalt cement for stabilization of soil/aggregate materials and on stabilization of drainage layers. When any subsurface layer receives an asphalt treatment, the treatment is considered asphalt stabilization. In general, asphalt stabilization is utilized where good base course materials are not readily available and where the existing subgrade materials are sands or silts which meet design requirements for stabilization. Asphalt stabilization is used when a drainage layer is trafficked with construction equipment. UFC 3-250-11 contains detailed information on the design and construction of asphalt stabilized soils.

5-2 MATERIALS.

5-2.1 Soil/Aggregate.

There are a number of requirements for determining soil suitability for asphalt stabilization. The stabilization of fine-grained soils depends on the plasticity characteristics and amount of material passing the 75 μm (No. 200) sieve. Recommended gradations of materials for various types of asphalt stabilization are given in UFC 3-250-11. Soils with high plasticity are not stabilized with asphalt because of difficulty in thoroughly mixing the asphalt into the soil. These soils are only stabilized if pretreated with lime or cement to decrease the plasticity of the soil.

5-2.2 Asphalt.

The asphalt used for stabilization is either emulsified or cutback asphalt. Normally, the emulsions used are slow setting (SS) or possibly some medium setting (MS) emulsions. Rapid set (RS) emulsions are not used. Any type of cutback from rapid (RC) to medium (MC) to slow (SC) cure is used for asphalt stabilization. The use of emulsions versus cutbacks is dependent on the availability of materials, soil type, climate, and construction practice. The availability of cutbacks is limited in areas due to environmental concerns.

5-3 COMPOSITION AND MIXTURE.

For stabilized materials, the type of asphalt used is as important as how much is used. UFC 3-250-11 contains information on the type and amount of liquid asphalt to use. Design procedures for determining optimum asphalt content are given for both cutback and emulsified asphalts.

5-4 CONSTRUCTION.

Methods and procedures for constructing asphalt-stabilized materials are given in UFC 3-250-11.

5-5 DRAINAGE LAYERS.

Guidance for the design and construction of subsurface drainage features is given in FAA Advisory Circular 150/5320-5E, *Airport Drainage Design*. Open graded material (OGM) is the drainage feature that normally requires stabilization for construction stability or for structural strength to serve as a base for a flexible pavement.

5-5.1 Design.

Ensure the amount of asphalt used coats the aggregate and holds it in place but does not fill any voids. Normally 2 to 2.5 percent (by weight of total mixture) asphalt is sufficient for stabilization. As a rule, the more open graded the material is, the lower the asphalt content required for stabilization. The asphalt used is similar to the grade normally used in that location. Use a higher viscosity (stiffer) asphalt to provide increased stability.

5-5.2 Construction.

Place a stabilized OGM with a paver to minimize segregation and achieve the design grade and thickness. Usually asphalt cement is used as the binder and the OGM is run through a HMA plant to achieve required coating and to allow for placement. Liquid asphalts (emulsions or cutbacks) are used if conditions warrant. An OGM requires rolling the mixture only to seat the aggregate in place.

CHAPTER 6 MISCELLANEOUS MIXTURES

6-1 RECYCLED ASPHALT MIXTURES.

See UFC 3-250-07.

6-2 SAND-ASPHALT MIXTURES.

In regions such as coastal areas where sand of good quality (clean and angular) is the only local aggregate available, the sand is used to produce an economical base or surface course. Sand mixtures, produced from these clean angular sands, are considered for paving roads and streets where light loads are anticipated and where considerable savings are realized by using locally available sand. Mineral filler is often added to increase the density and stability of the mixture, but mineral filler is omitted in designing sand-asphalt mixtures for asphalt-stabilized base courses. Asphalt cement, cutback asphalt, or emulsified asphalt is used for binder. Cold-laid asphalt mixtures are mixed at a central plant, mixed with a travel plant, or mixed in place. HMA is mixed at a central plant. Sand mixes are fine textured, dense, and relatively impermeable. The stability and durability of the sand mixes depend on the quality and grading of the fine aggregate, the amount and grade of asphalt binder, and the degree of control exercised in construction operations. Ensure the sand is sufficiently well-graded to meet the specified aggregate requirements for the type of course to be constructed and is free from excessive amounts of foreign matter. In many cases, the design gradation is obtained by selecting and blending locally available sands.

6-2.1 Advantages and Disadvantages.

Sand-asphalt mixes are produced with locally available materials at a relatively low cost; however, the use of sand mixes is limited due to their relative lack of strength and durability. Sand asphalt mixtures normally require a relatively high asphalt content thus resulting in a high mixture cost.

6-2.2 Uses.

Sand mixes are not to be used as surface or intermediate courses for airfield and heliport pavements designed for high-pressure tires or for pavements designed for solid-rubber tires, steel wheels, or tracked vehicles. High-pressure truck tires and all-terrain vehicle (ATV) tires are not to be allowed on sand-asphalt mixes. Sand mixes are considered for asphalt-stabilized base courses for all types of traffic areas and for any course in non-traffic areas. Sand mixes are considered for surface and intermediate courses for pavements subjected to low-pressure tires (690 kilopascals (100 psi) or less) and low traffic volumes. In this case, make and test trial mixes in the laboratory. Sand-asphalt mixes have been used to provide temporary travel paths for construction vehicles over completed AC pavements. Ensure the maximum sized aggregate particle are 9.5 millimeters (3/8 inch) or less to prevent the traffic from making indentations on the underlying AC pavement.

6-3 SHEET ASPHALT.

Sheet asphalt is a refined type of hot sand-asphalt pavement in which the grading, quality of sand, amount of mineral filler, and asphalt cement content are carefully controlled. The percentage of asphalt required is higher than that used for sand asphalt. Sheet asphalt provides a smooth, impermeable, homogeneous surface course that gives the best service when traffic is spread evenly over the pavement. Normally, sheet asphalt is used for surface courses only and is constructed 38 to 50 millimeters (1½ to 2 inches) thick over an intermediate course.

6-4 ROCK ASPHALT.

Rock asphalt pavement is composed of crushed, natural asphalt-impregnated limestone or sandstone, or a combination of these, used alone or mixed with additional asphalt or flux oil. Rock asphalt pavement is laid cold in the same manner as cold-laid asphalt mixture. Rock asphalt is used only in surface courses for roads and are not to be constructed over 37.5 and 50.0 millimeters (1½ and 2 inches) thick for blended and fluxed rock-asphalt, respectively. Kentucky, Alabama, Texas, New Mexico, Oklahoma and Utah have natural rock-asphalt deposits where paving material is produced commercially. The character and quantity of the aggregate and asphalt in the material vary among the different deposits and vary within the same deposit. Rock asphalt pavement is prepared by blending into the natural asphalt a crushed impregnated limestone or sandstone or a combination of the two in proportions to produce a properly graded mixture with a specified asphalt content. Ensure the natural rock asphalt is enriched (that is, add more asphalt to the mixture) if the material does not contain asphalt in its natural state to produce a mixture meeting design requirements. Hot mixes are produced by heating crushed limestone impregnated with relatively hard asphalt, alone or with added sand, and mixing with additional asphalt cement in a conventional plant.

6-4.1 Advantages and Disadvantages.

The advantages and disadvantages are the same as those for plant-mix cold-laid asphalt mixtures. In addition, the use of rock asphalt pavement reduces cost because this mixture already contains binder material.

6-4.2 Uses.

Rock asphalt pavements are used for roads and streets not subjected to traffic by tracked vehicles. Rock asphalts are used as the aggregate in slurry seals, but only use predominantly sandstone rock asphalts in slurry since limestone rock asphalts polish under traffic and thus produce a slick pavement surface.

6-5 COLD-MIX ASPHALT.

Cold-mix asphalt pavements are used as a low-cost surface for low-volume roads or as a base course for high-volume roads and airfields. While cold mixes do not provide pavements with the same quality as hot mixes, cold mixes do perform for the purposes intended. Cold mixes are capable of being stored for several months and are useful for patching. Because fuel is not needed to heat cold mixes, these pavements are constructed at lower cost than hot mixes. Two disadvantages of using cold mixes are that usually a lower density is obtained in cold mixes than in the construction of hot mixes and that a curing period is needed to allow water or volatiles to evaporate so that shear strength is obtained.

6-5.1 Design.

6-5.1.1 Preliminary Work.

The first step in designing a paving mixture is to make a survey to ensure that the materials needed are available in quantities meeting job requirements and their use is economical in the pavement construction. Obtain sufficient samples of material during the survey to accomplish the tests described in this section of this UFC. Materials normally required for the paving mix are coarse aggregate, fine aggregate, mineral filler, and bitumen.

6-5.1.1.1 Sampling.

Test reports reflecting the results of sampling and testing of the aggregates and bituminous materials are prepared. Conduct a gradation analysis on the aggregates to determine whether the aggregates when blended meet the contract gradation specifications. Furnish representative samples of materials for laboratory testing. Divide samples into sizes meeting testing requirements in the laboratory, in a way that represents field conditions. Sufficient quantities of materials are obtained at the time of sampling to meet the ASTM requirements and for laboratory pavement design tests described in this section of this UFC. Normally, aggregates that produces 90 kilograms (200 pounds) of the desired gradation and 19 liters (5 gallons) of bitumen is sufficient for these tests.

6-5.1.2 Materials.

6-5.1.2.1 Tests on Aggregates.

Ensure aggregates for use in an asphalt mixture are clean, hard, and durable. Angular aggregates provide an increased stability in pavements compared to rounded aggregates. Tests of aggregates required in the design of HMA mixtures are also applicable to the cold-mix type. Table 6-1 lists typical aggregate gradation requirements for both dense- and open-graded mixtures. The gradation used depends on the application and the binder. Dense-graded mixtures are used in most applications; open-graded mixtures provide more workability in colder weather. Many proprietary cold-patch materials use an open grading along with a modified binder. The dense-graded aggregate gradations correspond to those recommended in this text for hot-mix, hot-laid asphalt mixtures, which are provided in Table 2-1 for HMA.

Generally, combine aggregates for paving mixes from a minimum of two stockpiles. Mathematical equations are available for making such combinations but are not presented in this UFC because they are lengthy and because trial-and-error procedures are normally easier. The method of combining stockpile sample gradations is described in section 2-4 on dense-graded HMA. Ensure the gradation of the aggregate falls within the limits of the gradation for the project specifications, such as those provided in Table 6-1. Ensure the final gradation presents a smooth curve when plotted with sieve size versus percent passing.

Table 6-1 Typical[1] Aggregate Gradations for Plant-Mix Cold-Laid Asphalt Mixtures

Sieve Size	Percent Passing Sieve by Weight			
	Dense-Graded		Open-Graded	
12.5 mm (1/2 in.)	100	--	100	100
9.5 mm (3/8 in.)	86±9	100	90–100	90–100
4.75 mm (No. 4)	66±9	85±9	20–55	40–75
2.36 mm (No. 8)	53±9	71±9	5–30	25–55
1.18 mm (No. 16)	41±9	57±9	0–10	10–30
600 µm (No. 30)	31±9	43±9	---	---
300 µm (No. 50)	21±8	31±8	0–5	3–15
150 µm (No. 100)	13±6	19±6	---	---
75 µm (No. 200)	4.5±1.5	6±3	0–2	0–6

[1] Actual gradations used depend on the application; open gradations provide for greater workability in colder weather.

6-5.1.2.2 Tests on Asphalt Cement.

Know the specific gravity of the asphalt cement to determine the percent by volume of bituminous materials in the mix. Because only the residual asphalt is used in calculating the percent binder, the amount of residual asphalt cement in cutback asphalts and asphalt emulsions are determined as specified in ASTM D402 and ASTM D244 for cutback and emulsified asphalts, respectively. Determine the specific gravity of the residual asphalt as described in ASTM D70.

In addition to cutback asphalts and emulsified asphalts, cold-mix asphalt pavements are made with asphalt cement and liquefier (cutback) produced to meet a project’s design requirements. This cutback asphalt is produced, usually for remote projects, by using kerosene to liquefy an asphalt cement. The type of asphalt cement used to make this liquid binder is varied easily to meet various climate conditions. The cutback binder produced has a relatively long shelf life, depending on the amount of cutback material (kerosene) that is added. When cutback asphalts are contained in a single tank, then only the standard pipelines and spray bar are required. Additional equipment is used for handling the kerosene and asphalt cement when this type of cutback binder is produced. Asphalt emulsions are advantageous in that damp aggregate is allowed to be used in the mixing process, whereas dry aggregates are required for the other binder materials. Normally, mixes made with asphalt emulsions cannot be stockpiled unless the emulsion has been specifically formulated for stockpiling purposes. The choice of asphalt material type depends primarily on economics and the type of equipment to be used. Table 6-2 provides a guide to the selection of the type and grade of asphalt cement. The table provides information on asphalt for mixes to be used immediately and on asphalt for mixes to be stockpiled for later use.

Table 6-2 Selection of Asphalt Type and Grade

Asphalt Parameter	Climatic Conditions During Construction or Storage		
	Cold (less than 16 °C, 60 °F)	Moderate (16–27 °C, 60–80 °F)	Hot (above 27 °C, 80 °F)
Kerosene, liters/metric ton (gallons/ton mix) to asphalt cement	8.3 (18.8[1]) (2.0 (4.5[1])) added to AC-20, 85–100 pen, and PG 58-22	7.1 (15.4[1]) (1.7 (3.7[1])) added to AC-20, 85–100 pen, and PG 58-22	6.3 (12.5[1]) (1.5 (3.0[1])) added to AC-20, 85–100 pen, and PG 58-22
Cutback asphalts	RC-70–RC-250	RC-250–RC-800	RC-800–RC-3000
Emulsified asphalts[2]	MS-2h SS-1h	MS-2–MS-2h SS-1–SS-1h	MS-2 SS-1

Note: RC = rapid curing; MS = medium set; SS = slow set.
[1] Amount of kerosene to be added when mixture is to be stockpiled for future use.
[2] Emulsified asphalts are available that are specifically formulated for stockpile use.

6-5.1.3 Design.

The following procedure is recommended for determining the amount of asphalt cement to be used in the paving mix for cold-mix pavements. This procedure is applicable only for dense-graded mixtures. This design procedure is similar to the procedure used for designing HMA mixes for roads and streets. Laboratory equipment and test procedures are required to conform to CRD-C 649 and CRD-C 650. There is no widely accepted standard method for the design of all types of cold mixes. The Asphalt Institute provides information on design and construction procedures for cold mixes in MS-14. Information specific to emulsions is available in MS-19. Base the selection of the design method on past experience and local practices.

6-5.1.3.1 Asphalt Contents for Specimens.

The quantity of asphalt cement required for an aggregate is an important factor in the design of a paving mixture. To start the laboratory tests, make an estimate of the optimum amount of asphalt cement for the aggregate to be tested. Laboratory tests normally are conducted for a minimum of five asphalt cement contents: two above, two below, and one at the estimated optimum content. Incremental changes of 1 percent are used for preliminary work, but increments of 0.5 percent are used where the optimum asphalt cement content is known and for final designs.

6-5.1.3.2 Proportioning of Aggregates.

As a preliminary step in mixture design and manufacture, determine the proportions of the different available stockpiled materials required to produce the desired gradation of aggregate. This step determines whether a blend is produced meeting design requirements and, if so, the proportion of aggregates to be fed from the cold feeders into the dryer. Sieve analyses are conducted on material from each of the stockpiles. The aggregates are combined as described in CHAPTER 2. After a blend has been prepared from the available materials meeting design requirements, samples of these materials are processed for use in the laboratory design tests as specified in CRD-C 649.

6-5.1.3.3 Determination of Optimum Asphalt Cement Content.

The optimum asphalt cement content is taken as the average of the asphalt contents corresponding to the mix properties in Table 6-7. The optimum asphalt cement content is the amount of asphalt cement that is incorporated into the mix. The percent of cutback asphalts and emulsified asphalts are corrected to give a residual asphalt content equal to the optimum asphalt content determined by the tests. Because all of the volatiles do not evaporate, decrease slightly the amount of bitumen to be added as determined by this mix design procedure. When the asphalt cement and kerosene-type mix is to be used, add the desired amount of kerosene to the actual paving mix in addition to the optimum asphalt content determined from the laboratory design.

Table 6-3 Selection of Optimum Asphalt Content

Mix Property	Value for Determining Optimum Asphalt Content
Unit weight of mix, lb/ft^3	Peak of curve
VTM, percent	4±1
VFA, percent	75±5

6-5.2 Plant Mix.

Quality control is increased for mixtures produced in a plant Vs mixtures mixed in place in the field. This increased control results in a much tighter gradation and binder content control, although overall costs are greater compared to in-place mixing.

6-5.2.1 Plant Operation.

The plant operation varies with the type of asphalt material used in the mix. For mixes using asphalt cement and kerosene, introduce the kerosene and asphalt cement onto the aggregate at different times. Drying of the aggregate is not a design requirement with asphalt emulsions, but for cutback binders, heat the aggregates. Ensure aggregates are not hotter than 93 degrees C (200 degrees F) when mixed with RC cutback asphalts and not hotter than 121 degrees C (250 degrees F) for mixing with MC grades or asphalt cement and kerosene. Ensure the asphalt materials are in the temperature ranges provided in Table 6-8 when introduced into the pugmill.

Table 6-4 Mixing Temperatures for Asphalt Materials

Bituminous Material Type	Grade	Temperature Range, °C (°F)
Emulsified asphalts	MS-2	38–71 (100–160)
	MS-2h	38–71 (100–160)
	SS-1	24–54 (75–130)
	SS-1h	24–54 (75–130)
Cutback asphalts (not used much due to environmental issues)	RC-70	38–57 (100–135)
	RC-250	57–79 (135–175)
	RC-800	77–96 (170–205)
	MC-70	38–57 (100–135)
	MC-250	57–79 (135–175)
	MC-800	77–96 (170–205)
Note: MC = medium curing; RC = rapid curing; MS = medium set; and SS = slow set.		

6-5.2.2 Plant Laboratory.

Use of a plant laboratory ensures that the aggregate meets design gradation requirements and that the mix contains the prescribed percentage of asphalt material. The plant laboratory contains this major equipment:

a. A hand- or power-driven mechanical sieve shaker. The sieve shaker is required to have a capacity of not less than eight full-height, 200-millimeter (8-inch) -diameter sieves.

b. A full-height, 200-millimeter (8-inch) -diameter sieve for each of the following sieve openings: 12.5 millimeter (1/2 inch), 9.5 millimeter (3/8 inch), 4.75 millimeter (No. 4), 2.36 millimeter (No. 8), 1.18 millimeter (No. 16), 600 micrometer (No. 30), 300 micrometer (No. 50), 150 micrometer (No. 100), and 75 micrometer (No. 200). The sieves are required to have square openings and conform to the requirements of ASTM E11.

c. An extractor or ignition test for measuring bitumen content within close tolerances.

d. A balance having a capacity of 2 kilograms (4.4 pounds) and sensitive to 0.1 gram (0.0035 ounce).

e. Marshall equipment for compacting and testing samples to verify mixture design.

6-5.2.3 Adjusting Mix Proportions.

Adjust mix proportions whenever tests indicate that specified tolerances are not being met. Fully automated plants produce consistent mixtures, provided that the equipment is calibrated and in good working condition. Variations in weighing techniques or faulty scales are detected readily and corrective measures taken by maintaining a close check on load weights. Ensure the total weight of each load of mixture produced only varies between plus or minus 2 percent from the total of the batch weights dumped into the truck.

6-5.2.4 Preparation of Construction Specifications.

6-5.2.4.1 Specifications.

Cold-laid asphalt mixtures are produced according to the provisions of guide specifications except when mix quantities, less than 100 metric tons (100 tons), are specified for limited use in repairs. In these cases, the procedures specified in the guide specification are not economical. When such an exception is allowed, locally available cold-laid bituminous mix produced according to local state highway department specifications are used. Contact the Pavements Discipline Working Group (DWG) or their designated representative for these exceptions. When the quantity equals or exceeds 100 metric tons (100 tons), approval from the Pavements DWG or their designated representative is required. Provide a copy of the specification or reference thereto and information regarding traffic conditions and facilities to be paved to facilitate discussions

6-5.2.4.2 Placing.

Although closer control of layer thickness and better prevention of segregation of the mix is achieved with a mechanical spreader, a motor grader is desirable for spreading plant-mix cold-laid pavements. Aeration of the mix to remove volatile material is often required to bring the mix to the design condition for compaction. A motor grader aerates the mix by blading it back and forth across the roadbed.

6-5.2.4.3 Compaction of Mixture.

At the time of compaction, the asphalt material in the mixture is required to provide the specified amount of cohesion so that the design density is reached. Cohesion of the mixture is controlled by the type of asphalt material, volatile content, and temperature of the mixture. Low cohesion causes the mix to be unstable under the roller, while high cohesion causes the mix to be too stiff to be compacted. Compact the mixture as soon as it supports the roller without undue displacement.

6-5.3 Road Mix.

Asphalt road mixes are normally mixed in place by travel plants or common types of road-building equipment, such as blade graders, disk harrows, drags, and pressure distributors. When allowed by design, the existing subgrade materials, loosened existing subgrade materials blended with imported materials, or properly processed imported materials placed on the existing base or subgrade have been used as aggregate in road mixes. When the amount of material passing the 75 microns (No. 200) sieve exceeds 20 percent, processing with asphalt is difficult and this material benefits from the addition of imported materials. A wide range of aggregates are used, and the gradation requirements are less strict than those for hot or cold plant-mixed types. The bitumen is often applied by a pressure distributor to the processed aggregate on the base or subgrade and then thoroughly mixed with the aggregate. A travel-type mixing plant combines the aggregates with an asphalt material and continuously discharges the mixture at the rear of the machine as the plant travels along the strip being paved. Using a travel plant permits accurate proportioning of the bitumen and aggregate and produces a uniform and higher quality mixture vs. a mixed-in-place method. Further, because viscous types of cutback asphalt are used, the curing time is reduced. Curing is usually required to reduce the volatiles in the cutback asphalt or water in the asphalt emulsion prior to spreading and compacting because excessive amounts of volatiles and water affect the compatibility of the mixture and the stability of the finished pavement. Manipulation with blades or other road machines speed curing.

6-5.3.1 Advantages and Disadvantages.

Much less equipment is required for construction using asphalt road mix than is required using AC, thus resulting in cost savings. Using locally available materials also results in significant cost savings. Asphalt road mix, however, does not have the strength or durability of HMA. The road-mix type of pavement provides an economical means of obtaining a surface for roads and streets when the required amount of pavement is small, when the natural soil meets aggregate design requirements, or when aggregates meeting design requirements are nearby. Apply seal coats with aggregate cover as a part of road-mix construction since road mixes are often open graded or of relatively low density and are therefore susceptible to oxidation and abrasion.

6-5.3.2 Uses.

When an asphalt road mix is properly designed and constructed on an existing subgrade meeting design requirements or using locally available aggregates, the quality of road-mix construction approaches that of cold mix produced in a central plant. Road mix is used for intermediate or surface courses, but because of the less accurate control, road mix is often considered inferior to plant mixtures. Road mix is not allowed for use above the base course for airfields. Road mix is used as a wearing course for temporary roads and streets or as the first step in stage construction for permanent roads and streets when these are to be supplemented by plant-mix surfaces as the demands of traffic increase and warrant the increased thickness. Seal coats reduce infiltration of air and water and thus improve the durability of road-mix pavements.

CHAPTER 7 RESIN MODIFIED PAVEMENT (RMP)

7-1. OVERVIEW.

RMP is a tough and durable surfacing material that combines the flexible characteristics of HMA with the fuel, abrasion, and wear resistance of PCC. RMP is best described as a cross between AC and PCC and is categorized between these two common types of paving materials. RMP is basically an open-graded AC mixture containing 25 to 35 percent voids that are filled with a resin modified Portland cement grout. The open-graded asphalt mixture and resin modified cement grout are produced and placed separately. The production of the materials and the mixture requirements for both the open-graded asphalt mixture and the cement grout differ slightly from conventional procedures. The open-graded asphalt mixture is designed to be the support layer and to determine the thickness of the RMP, which is 50 millimeters (2 inches). The open-graded mixture is placed with standard AC paving equipment but is not compacted. After placement, the open-graded asphalt material is simply smoothed over with a steel-wheel roller, a 3-metric ton (3-ton) maximum. Compaction of the open-graded AC material adversely decrease the voids and hinder grout penetration. After the asphalt mixture has cooled, the cement grout is poured onto the open-graded asphalt material and squeegeed over the surface. The cement grout is then vibrated into the voids with the steel-wheel roller to ensure full penetration of the grout. This process of grout application and vibration continues until all voids are filled with grout, which essentially completes the construction process.

RMP was developed in France in the 1960’s as a fuel and abrasion resistant surfacing material. The RMP, or Salviacim® process as it is known in Europe, was developed by the French construction company, Jean Lefebvre Enterprises, as a cost-effective alternative to PCC. The RMP process has been used on various types of pavements, including warehouse floors, tank hardstands and roads, and aircraft parking aprons. This surfacing material is best suited for pavements that are subjected to abrasive traffic, heavy static point loads, heavy fuel spillage, and channelized traffic. RMP has been constructed successfully in numerous countries, including France, Great Britain, South Africa, Japan, Australia, Saudi Arabia, and the United States.

7-2 MATERIALS

7-2.1 Open-Graded Asphalt Mixture

7-2.1.1 Aggregates

The required aggregate physical properties and the gradation limits for aggregates in the open-graded asphalt portion of RMP are listed in Table 7-1 and Table 7-2, respectively.

Table 7-1 Aggregate Physical Properties

Test	Specification Requirements
LA Abrasion (ASTM C131)	< 40 percent
Percent Fractured faces +4.75 mm (No. 4) -4.75 mm (No. 4)	 > 70 percent > 70 percent
Percent flat and elongated (ASTM D4791)	< 8 percent

Table 7-2 Gradation Limits for Open-Graded Asphalt Mixture

Sieve Size	Specified Limits, Percent Passing
19 mm (3/4 inch)	100
12.5 mm (1/2 inch)	54–76
9.5 mm (3/8 inch)	38–60
4.75 mm (No. 4)	10–26
2.36 mm (No. 8)	8–16
600 µm (No. 30)	4–10
75 µm (No. 200)	1–3

7-2.1.2 Asphalt Cement.

The asphalt cement used is required to be of the same grade as that normally used in the area. When possible, specify the stiffest (highest viscosity) asphalt cement available in that area to assist in providing a stable surface for the subsequent grouting operations. Ensure the asphalt cement meets the requirements of ASTM D946, ASTM D3381, or ASTM D6373/AASHTO M 320.

7-2.2 Cement Slurry Grout.

7-2.2.1 Aggregate.

The cement slurry grout requires silica sand meeting the gradation provided in Table 7-3. Silica sand is specified because of its soundness and durability. Ensure the silica sand meets the requirements for wear and soundness specified for the aggregate in the open-graded AC. Deviations from these aggregate requirements have resulted in significant constructability problems in the past. To date, no problems or distresses associated with possible alkali-silica reactivity (ASR) have been reported in any RMP. No information has been found on investigations of this possible phenomenon.

Table 7-3 Aggregate Gradation for Slurry Grout

Sieve Size	Percentage by Weight Passing Sieves
1.18 mm (No. 16)	100
600 μm (No. 30)	95–100
75 μm (No. 200)	0–2

7-2.2.2 Filler.

Normally, filler or material passing the 75 μm (No. 200) sieve is present in the aggregate used in the cement grout. When additional filler is required, ensure it is a Class F (ASTM C618) fly ash with a limit on the calcium oxide content of 5 percent by weight maximum. Ensure the fly ash has a minimum of 95 percent by weight of material passing the 75 micron (No. 200) sieve.

7-2.2.3 Cement.

Ensure the Portland cement used conforms to ASTM C150. Ensure the Portland cement used is Type I, II, III, or IV. Type I cement is commonly used for RMP applications. The other types are used where moderate to high sulfate resistance or high early strength is required.

7-2.2.4 Cross Polymer Resin Additive.

Cross polymer resin additives are available on the commercial market, Table B-4. Typical composition is five parts water, two parts cross polymer resin of styrene and butadiene, and one part water reducing agent. This product is used as a plasticizing and strengthening agent.

7-3 MIXTURE DESIGN.

7-3.1 Open-Graded Asphalt Mixture.

The optimum asphalt content for the open-graded asphalt mixture is determined through a modified Marshall mix design procedure. Marshall laboratory samples

152.4 millimeters (6 inches) in diameter by 63.5 millimeters (2½ inches) in height are produced using the determined JMF aggregate gradation and a series of asphalt contents ranging below and above an estimated optimum asphalt content value. The estimated optimum asphalt content is determined using a procedure developed in France and based on aggregate properties. The procedure is outlined below:

$$\text{Optimum asphalt content} = 3.25\,\alpha\,\Sigma_{0.2}$$

where

α = $\frac{2.65}{SG}$ where SG = apparent specific gravity of the combined aggregates

Σ = conventional specific surface area

= $0.21G+5.4S+7.2s+135f$

G = percentage of material retained on the 4.75 millimeter (No. 4) sieve

S = percentage of material passing the 4.75 millimeter (No. 4) sieve and retained on the 600 µm (No. 30) sieve

s = percentage of material passing the 600 µm (No. 30) sieve and retained on the 75 µm (No. 200) sieve

f = percentage of material passing 75 µm (No. 200) sieve

If, for example, the estimated optimum asphalt content calculated for a given aggregate gradation was 4.2 percent, then the asphalt contents used for the subsequent laboratory Marshall sample evaluation normally is 3.8, 4.0, 4.2, 4.4, and 4.6 percent. The 152.4-millimeter (6-inch) -diameter Marshall samples are compacted in the laboratory using a 4.536-kilogram (10-pound) hand hammer with a 152.4-millimeter (6-inch) -diameter impact plate. The samples are compacted at 121 degrees C (250 degrees F) using 25 blows on one side of the sample. Three samples are produced for each of the five asphalt contents used, and the resulting average voids data of percentage of VTM and voids filled are used to finalize the selection of optimum asphalt content. As a general rule, as the percent of asphalt increases, the VTM fluctuates over a relatively small range. Also, the voids filled increase slowly until the percentage shows a significant increase, indicating that further increases in asphalt content are working to fill the void spaces rather than coating the aggregate particles. This is an undesirable condition since an excess amount of asphalt cement in the RMP void structure hinders the slurry grout's penetration upon its application. Ensure the asphalt content selected is below the point where voids filled shows a significant increase and where the VTM is within the 25 to 35 percent range of values. The VTM of laboratory specimens and field cores prior to grouting are calculated using this formula:

$$VTM = \left[100 - \frac{WT_{air}\,(1)}{Volume\ SG_T} \times 100\right]$$

Where:

VTM	=	*voids total mix*
WTair	=	*dry weight of specimen*
Volume	=	*π/4 D^2H (measured)*
D	=	*diameter*
H	=	*height*
SG_T	=	*theoretical specific gravity*

7-3.2 Cement Grout.

The slurry grout JMF is developed using the range of properties listed in Table 7-4. Using these proportions, the following procedure is used. The slurry grout samples are prepared in the laboratory by first dry mixing the cement, sand, and fly ash in a blender until they are thoroughly mixed. Then the specified amount of water is added meeting viscosity requirements, and the grout mixture is blended for 5 minutes. After this 5-minute mixing period, the cross polymer resin additive is added and mixed with the grout for an additional 3 minutes. Immediately after the 3-minute mixing period, the grout is poured into the Marsh flow cone and tested for viscosity. A Marsh cone has dimensions of 155 millimeters (6.2 inches) base inside diameter, tapering 315 millimeters (12.6 inches) to a tip inside diameter of 10 millimeters (0.4 inch). The 10-millimeter (0.4-inch) -diameter neck has a length of 60 millimeters (2.4 inches). The viscosity, in seconds, is measured for each sample, and three different batches of each blend are tested to obtain an average viscosity value. The requirements for viscosity of the grout are provided in Table 7-5. The individual components of the grout are adjusted within the prescribed tolerances listed in Table 7-4 to obtain a desired grout viscosity.

Table 7-4 Resin Modified Cement Slurry Grout Mixture Proportions

Material	Percent by Weight
Silica sand	16–20
Fly ash	16–20
Water	22–26
Type I cement	34–40
Cross polymer resin	2.5–3.5

Table 7-5 Slurry Grout Viscosity

Time Elapsed After Addition of Polymer	Viscosity (Marsh Cone Flow Time)
0–30 minutes	8–10 seconds
After 30 minutes	9–11 seconds

7-4 EQUIPMENT.

The equipment used to place, transport, and mix the open-graded asphalt mixture is the same as that used to place dense-graded asphalt mixture, except for smaller steel-wheel rollers. This equipment includes sweepers, distributors, pavers, AC plants, and transport trucks. The equipment used to place the cement slurry grout consists of transit trucks, vibratory steel-wheel rollers, and hand tools.

7-4.1 Rollers.

The rollers used to seat the open-graded asphalt mixture and to vibrate the cement slurry grout into the open-graded mixture are (3 metric tons (3 tons) maximum) vibratory rollers. These rollers are used in the static mode only while seating the open-graded asphalt mixture and in the vibratory mode while placing the cement grout. During placing of the grout, ensure that a minimum of two vibratory rollers are available at the job site in case of breakdowns.

7-4.2 Hand Tools.

Hand squeegees are used to spread the cement grout over the pavement surface during application and to remove excess grout from the pavement surface once the grout application is completed. Hand brooms are used to smooth the texture of the joints during grout application and are used to roughen the texture of the entire grouted pavement surface immediately after the grout application.

7-5 PLACEMENT.

7-5.1 Open-Graded Asphalt Mixture.

The open-graded mix is mixed, transported, and placed by the same methods and procedures used to place dense-graded asphalt mixture. A light tack coat of asphalt material is first applied on the existing AC on which the RMP is to be placed. After the mixture has been placed with a standard asphalt paver, the mixture is not compacted but is rolled to seat or smooth the surface. This is accomplished with a (3-metric ton (3-ton) maximum) tandem steel-wheel roller once the freshly placed open-graded asphalt layer has cooled to 71 degrees C (160 degrees F). Only use a vibratory roller of this size when it is operated in the static mode, in other words the vibratory mode of vibration is turned off. One pass of the roller is usually sufficient for seating. With another single pass, the same or a similar-sized roller is used as a finishing roller to remove roller marks once the asphalt layer has cooled to 38 degrees C (100 degrees F).

7-5.2 Cement Slurry Grout.

7-5.2.1 Mixing and Transport.

The slurry grout is mixed in either a batch plant, portable mixer, or in a ready-mix truck. The cross polymer resin is added to the mixture after all other ingredients have been mixed thoroughly. Generally, add the cross polymer resin to the grout mixture at the batch plant if the haul distance is less than 30 minutes. If the haul distance is greater than 30 minutes, add the cross polymer resin to the grout mixture at the job site. When using ready-mix trucks for transporting slurry grout, mix the grout mixture thoroughly at the job site immediately before application for a minimum of 10 minutes. Thorough mixing is best accomplished by rotating the mixing drum at the maximum allowable revolutions per minute. The final control on the acceptability of the mixing process is the mixing of a consistent grout that meets the viscosity requirements.

7-5.2.2 Placement.

7-5.2.2.1 Application of Grout.

Ensure the surface temperature of the bituminous mixture is less than 38 degrees C (100 degrees F) before the application of grout. On hot days, this requires the use of a fog spray of water to reduce the temperature immediately prior to grouting. Do not use excessive amounts of water, which causes ponding. Test each batch of grout at the job site immediately before placement and use in the finished product only if the batch meets the viscosity requirements listed in Table 7-5. The cement grout is poured over the bituminous mixture from the ready-mix truck by means of a pivoting delivery chute and then spread around with the hand squeegees. Ensure the application of the cement grout is sufficient to fill the internal voids of the open-graded bituminous mixture. 10 to 13 kilograms (22 to 28 pounds) of mixed slurry grout fills 0.8 square meter (1 square yard) for each 25 millimeters (1 inch) of thickness of open-graded asphalt mixture with 25 to 35 percent VTM. Begin the grouting operation at the lowest side of the sloped cross-section and proceed from the low side to the high side. Note that slopes up to 2 percent are considered the practical limit for RMP. Sections with slopes up to 5 percent have been placed, but excess handwork and grout overruns are expected at slopes greater than 2 percent. Place the slurry grout in successive paving lanes with a maximum width of 6 meters (20 feet). The use of 50-millimeter (2-inch) by 100-millimeter (4-inch) strips of lumber as wooden battens separating each of the grouting lanes and the RMP from adjacent pavements facilitates an orderly grouting operation. Secure the wooden battens to the surface of the bituminous mixture before grout application to help prevent excessive grout runoff and to prevent overworking the grouting crew. Ensure the grouting operation is in the same direction as the paving operation for the open-graded bituminous mixture. Use the small, 3-metric ton (3-ton) maximum tandem steel-wheel roller (vibratory mode) passing over the grout-covered bituminous mixture to promote full penetration of the slurry grout into the void spaces. Once the open-graded layer is fully saturated with grout, all excess grout is removed by squeegeeing. This process exposes the rough surface of the open-graded material and improve skid resistance.

7-5.2.2.2 Joints.

Make the formation of all joints between successive lanes of RMP in such a manner as to ensure a continuous bond between the paving lanes. Remove the wooden battens as soon as the grout has been applied to the surrounding area and the area underneath them vibrated or reworked with additional grout and hand brooms to assure full penetration and smoothness in these joint areas. There are no time restrictions for placing successive lanes of grout to create joints. Ensure all RMP joints have the same texture, density, and smoothness as other sections of the course. Saw cut the joints between the RMP and any surrounding pavement surfaced with PCC to the full depth of the RMP thickness and filled with a joint sealant material meeting project specifications. Curing.

Curing of a new RMP surface is accomplished with a light coating of a white-pigmented, membrane-forming curing compound. Apply the curing compound to the finished pavement surface while the surface is still damp but without excessive moisture on the surface, normally within 2 hours of the completed slurry grout application. Apply curing compound with a pressurized spraying machine, using one or two coats with a total application rate of 4.5 square meters per liter (183.4 square feet per gallon).

7-5.2.3 Covering Pavement Surface.

7-5.2.3.1 Prior to Grouting.

Protect the pavement and its appurtenances prior to grouting against contamination from mud, dirt, windblown debris, waterborne material, or any other contamination that enters the void spaces of the open-graded asphalt mixture before grout application. Protection against contamination by keeping the construction site clean and free of such contaminants and by covering the pavement prior to grouting with a protective material such as rolled polyethylene sheeting. The sheeting is mounted on either the paver or a separate movable bridge from which it is unrolled without dragging over the pavement surface.

7-5.2.3.2 After Grouting.

Protect the pavement and its appurtenances against both public traffic and traffic caused by the contractor’s employees and agents for a period of 14 to 21 days. This time period depends on the environmental conditions during curing, with 14 days required for warm and dry weather curing and 21 days required for cool and damp weather curing. To properly protect the pavement against the effects of rain before the pavement is sufficiently hardened (the first 24 to 48 hours), materials for the protection of the edges and surfaces of the unhardened RMP are required to be available, at all times,. Use the same protective materials and method of application as described in paragraph 7-5.2.3.1. When rain appears imminent, stop all paving operations, and cover the surface of the hardened RMP with protective covering.

APPENDIX B BEST PRACTICES

B-1 SUMMARY OF DESIGN METHODS FOR SLURRY SEALS

B-1.1 INTRODUCTION

The design method for determining the emulsion requirement consists of determining the surface area of the job aggregate and calculating the amount of asphalt required to coat the surface area with a film thickness of 8 microns (3.15×10^{-4} inch). The absorption characteristics of the aggregate are determined using the CKE test. The total asphalt is the asphalt required for coating the aggregate plus the required due to aggregate absorption.

The water required for a given mixture is determined by a cone test as described in ASTM D3910. Water is added to a slurry mixture until a flow of 25.4 millimeters (1 inch) is obtained on a reference plate. Ensure the consistency of the mixture when the 25.4-millimeter (1-inch) flow is obtained is such that there is no segregation in the mixture. Portland cement or hydrated lime is added to aid in overcoming the segregation; the cone test serves as an aid for determining the amount of Portland cement or hydrated lime required in the mixture.

B-1.2 SURFACE AREA DESIGN METHOD

The surface area design method includes three considerations: the calculation of the amount of asphalt required to coat the surface area of the job aggregate, the absorption characteristics of the aggregate, and the total asphalt content.

B-1.2.1 Surface Area Asphalt Calculation

The surface area of the job aggregate is determined by multiplying the percent of aggregate passing a given sieve by a surface area factor based on the sieve size. The surface area of the aggregate is determined for each particle size (group) and then summed to obtain the total surface area. The surface area units are given in square meters per kilogram (feet per pound) of aggregate. The surface area factors are shown in Table B-1. The total surface area (SA) is then corrected to obtain a corrected surface area (CSA): $CSA = SA \times 2.65 / ASG$, where ASG is the apparent specific gravity of the aggregate. When the surface area and the desired bitumen film thickness are known, the volume of asphalt required and thus the percent by weight of asphalt required is obtained. Equation B-1 is the equation for calculation of the percent asphalt by weight to provide a desired film thickness:

$$SAA = \begin{array}{c} \text{Metric: } CSA \times t \times 0.99941 \times SG_A \\ \text{U.S. Customary: } CSA \times t \times 0.02047 \times SG_A \end{array}$$

Where:

SAA = *asphalt content to cover surface area of aggregate, t micrometers thick, percent of dry aggregate weight*

CSA = *corrected surface area, square meters per kilogram (feet per pound) of dry aggregate*

T = *asphalt film thickness, micrometers*

SGA = *specific gravity of the asphalt*

0.99941 (0.02047) = *conversion coefficient for the units of the equation*

If the specific gravity of the asphalt is not known, the asphalt required to coat the aggregate is calculated by assuming SG_A = 1.0. The error that results from assuming SG_A = 1.0 does not greatly affect the final design requirements.

Table B-1 Factors Used in Calculating Surface Area of Slurry Seal Aggregate

Sieve Size	Surface Area Factors	
	Square Meters per Kilogram of Aggregate	Square Feet per Pound of Aggregate
9.5 mm (3/8 in.)	0.4	2
4.75 mm (No. 4)	0.4	2
2.36 mm (No. 8)	0.8	4
1.18 mm (No. 16)	1.6	8
600 µm (No. 30)	2.9	14
300 µm (No. 50)	6.1	30
150 µm (No. 100)	12.2	60
75 µm (No. 200)	32.8	160

B-1.2.2 Aggregate Absorption

The absorption requirements of the aggregate are determined by using the CKE described in ASTM D5148. In this test, 100 grams (0.22 pounds) of 4.75-millimeter (No. 4) material is centrifuged in the presence of kerosene for 2 minutes. The amount of kerosene retained by the aggregate is assumed to be the amount of asphalt that the aggregate absorbs. The kerosene absorbed (KA) by the aggregate is converted to a percentage of the dry weight of the aggregate.

B-1.2.3 Total Asphalt Content

The total asphalt requirement is obtained by adding the percent asphalt required for the film thickness and the percent asphalt required for absorption. All percentages are based on the dry weight of the aggregate. The total is obtained using equations B-2 and B-3:

$$AR = SAA + KA$$

$$AR = \begin{array}{r} \text{Metric:}\ \ (CSA \times t \times 0.99941 \times SG_A) + KA \\ \text{U.S. Customary:}\ \ (CSA \times t \times 0.02047 \times SG_A) + KA \end{array}$$

Where:

AR = *total asphalt required, percent of dry aggregate weight*

KA = *kerosene absorbed, percent of dry aggregate weight*

The required percentage of emulsion is calculated by dividing the total asphalt required for the aggregate by the percentage of asphalt residue in the emulsion. A sample calculation for determining the asphalt content is presented in section B-1.4.

B-1.3 CONE TEST

The cone test is used to determine the amount of water required to form a workable mixture as described in ASTM D3910. This test uses the sand absorption cone described in ASTM C128. The cone is placed over a base plate. The base plate has concentric circles inscribed in diameters that are equal to the large end of the cone and increase proportionally outward. The radius of each circle increases in 12.7-millimeter (1/2-inch) increments. The cone is loosely filled with a slurry mixture, struck off, and then removed to allow the slurry mixture to “flow” over the base plate. A mixture with a flow of 25.4 millimeters (1 inch) is considered to contain the right amount of water for field workability. Mixtures that do not flow 25.4 millimeters (1 inch) require additional water to obtain the desired flow. If the flow cannot be obtained without segregation of the mixture, the addition of 0.5 to 4 percent Portland cement or hydrated lime helps to reduce the segregation. Flows greater than 25.4 millimeters (1 inch) indicate excess water or segregation.

If Portland cement or hydrated lime is added to reduce segregation and its addition has not been included in the design gradation, correct the total bitumen content of the mixture to include the effects of the Portland cement or hydrated lime. As a rule, increase the asphalt content by 0.6 percent for every percent of additional Portland cement or hydrated lime added to the mixture.

B-1.4 SAMPLE CALCULATION OF ASPHALT REQUIREMENTS FOR A SLURRY SEAL AGGREGATE

B-1.4.1 Surface Area Calculation

The ASG equals 2.96, and the aggregate gradation includes 2 percent Portland cement.

Table B-2 Surface Area Calculation

Sieve Size	Percent Passing	Surface Area Factor square meters per kilogram (square feet per pound) of Aggregate	Surface Area square meters per kilogram (square feet per pound) of Aggregate
9.5 mm (3/8 in.)	100	0.00409 (0.02)	0.409 (2.00)
4.75 mm (No. 4)	99.5	0.00409 (0.02)	0.407 (1.99)
2.36 mm (No. 8)	95.6	0.00819 (0.04)	0.783 (3.82)
1.18 mm (No. 16)	77.8	0.01639 (0.08)	1.275 (6.22)
600 μm (No. 30)	52.0	0.02867 (0.14)	1.491 (7.28)
300 μm (No. 50)	24.5	0.06144 (0.30)	1.505 (7.35)
150 μm (No. 100)	10.7	0.12289 (0.60)	1.315 (6.42)
75 μm (No. 200	6.4	0.32771 (1.60)	2.097 (10.24)
		Total SA	**9.282 (45.32)**

The corrected SA (CSA) = SA×2.65/2.96 = 8.310 square meters per kilogram (40.57 square feet per pound) of aggregate.

B-1.4.2 Kerosene Absorption Calculation

The aggregate gradation includes 2 percent Portland cement.

Table B-3 Kerosene Absorption Calculation

Cup No. (a)	Tare Weight Grams (b)	Sample Weight Grams (c)	Weight before Centrifuging Grams (d = b+c)	Weight after Centrifuging Grams (e)	KA Percent (f = e - d)
1	215.3	100.0	315.3	321.0	5.7
2	215.9	100.0	315.9	321.6	5.7
				Average KA	**5.7**

B-1.4.3 Total Asphalt Requirements

These factors are involved in calculating the asphalt contents:

- Asphalt = SS-lh asphalt emulsion
- Design film thickness (t) = 8 micrometers
- Apparent specific gravity of aggregate (ASG) = 2.96
- Specific gravity of asphalt (SG_A) = 1.028
- Kerosene absorption (KA) = 5.7 percent
- Corrected surface area (CSA) =
- Metric: 8.310 square meters per kilogram of aggregate
- U.S. Customary: 40.57 square feet per pound of aggregate
- Total asphalt required (AR) =
- Metric: $(CSA \times t \times SG_A \times 0.99941) + KA$
- U.S. Customary: $(CSA \times t \times SG_A \times 0.02047) + KA$
- Metric: (8.310×8×1.028×0.99941)+5.7 = 6.83+5.7 = 12.53 percent.
- U.S. Customary: (40.57×8×1.028×0.02047)+5.7 = 6.83+5.7 =
- 12.53 percent
- AR = 12.53 percent of dry aggregate weight
- Residue asphalt content in emulsion = 63 percent by weight
- Emulsion required = $\dfrac{AR \times 100}{\text{Residue asphalt content in emulsion}}$
- Emulsion required = $\dfrac{12.53 \times 100}{63}$ = 19.9 percent of dry aggregate weight, that is, 19.9 kilograms of emulsion is required for every 100 kilograms of dry aggregate, or in inch-pound units, 19.9 pounds of emulsion is required for every 100 pounds of dry aggregate

B-2 POTENTIAL VENDORS

A list of potential vendors is summarized in Table B-1 to assist in the procurement of products. It is not intended to be a complete listing of vendors as there are numerous large and small companies that provide a wide range of materials for dust abatement. Inclusion on this list does not represent endorsement of any kind. The list is provided to assist the soldiers, sailors, marines, and airmen working in the field. Complete a small test section prior to using each product to evaluate the effectiveness and determine the placement details.

VFA	voids filled with asphalt
VMA	voids in mineral aggregate
VTM	voids in total mix
WES	Waterways Experiment Station (USACE ERDC)
WMA	warm mix asphalt
WTAT	wet track abrasion test

C-2 DEFINITION OF TERMS

Common terms related to AC pavements are not defined here since they are found in flexible pavement references, primarily in ASTM D8. The terms defined for this UFC have definitions that have not been universally accepted or that have limited usage.

asphalt base course: A minimum of one course of asphalt mixture placed on a subbase or subgrade to serve as a base course. This mixture is called a black base. An asphalt base course is covered with an intermediate course and surface course.

coarse aggregate: The aggregate retained on the 4.75-millimeter (No. 4) sieve as described in ASTM E11.

cold-mix recycling: Involves reclaiming all of the existing bituminous pavement by breaking it to a maximum particle size of 4 centimeters (1½ inch), mixing it with virgin materials, if needed, and reusing the mixture as a pavement material. Cold-mix recycling material is used to surface secondary roads, if a seal coat is applied, and as a base course for high-quality pavements.

components of a compacted bituminous mixture: A given volume of compacted bituminous concrete consists of air, bitumen, and aggregate.

fine aggregate: Aggregate passing the 4.75-millimeter (No. 4) sieve and retained on the 75 μm (No. 200) sieve, often referred to as sand. Natural sand (fine aggregate) is that material found naturally and not manufactured by crushing.

flow: The deformation, measured in 25 hundredths-of-a-millimeter (hundredths-of-an-inch), that occurs in a compacted specimen of a paving mixture at the point at which maximum load begins to decrease when the specimen is subjected to the Marshall stability test.

hot-mix recycling: Process that involves removing the existing HMA, crushing it, and mixing it in a hot-mix plant with new aggregate, asphalt, and recycling agent, when required. The recycled HMA is designed for use in all types of pavements. Crushed PCC has also been used as aggregate for hot recycled mixtures.

intermediate course: That portion of a pavement placed on the base course to serve as a leveling or transition layer between the base and surface courses. Intermediate courses are called leveling or binder courses.

Marshall stability value: The maximum load in newtons (pounds) that is applied to a specimen of AC paving mixture when tested in the Marshall apparatus.

mastic asphalt: Mastic asphalt is an HMA mixture of fine aggregate and asphalt cement forming a mixture free of voids.

micro-surfacing: Micro-surfacing is the process of applying a latex-modified asphalt emulsion slurry to an existing pavement surface. The slurry is mixed and applied similarly to asphalt slurry seals, except for the specially-designed mixing and constant agitation application equipment required by the latex modifier. Micro-surfacing applications contain larger aggregate particles than conventional asphalt slurry seals. Micro-surfacing is used to fill ruts or for re-establishing skid resistance. Curing is normally completed in 1 to several hours depending on weather conditions.

mineral filler: Mineral aggregate particles passing a 75 micrometer (No. 200) sieve or commercially available materials such as lime or cement.

optimum asphalt content: The asphalt content of a paving mixture determined by the Marshall or gyratory methods of design that satisfies the applicable pavement mix design criteria.

percent VFA: Percentage of the VMA in the compacted aggregate mass that is filled with asphalt.

$$VFA = \frac{V_{bitumen}}{V_{air} + V_{bitumen}} \times 100$$

percent VMA: Percentage of the compacted bituminous mixture not occupied by the aggregate. The percentage of VTM plus the percentage of asphalt cement by total volume is equal to VMA.

$$VMA = \frac{V_{air} + V_{bitumen}}{V_{total}} \times 100$$

percent VTM: Percentage of the compacted AC mixture not occupied by the aggregate or asphalt cement.

$$VTM = \frac{V_{air}}{V_{total}} \times 100$$

porous friction course (PFC): An open-graded, free-draining asphalt paving mixture that is placed on an existing pavement to minimize hydroplaning and to improve skid resistance in wet weather. The course is placed in a layer usually varying from 20 to 25 millimeters (3/4 to 1-inch) in thickness. PFC paving mixtures are produced in asphalt hot-mix plants and placed with conventional asphalt paving machines.

resin-modified pavement (RMP): A composite pavement surfacing that uses a unique combination of HMA and PCC materials in the same layer. The RMP material is described as an open-graded AC mixture containing 25 to 35 percent voids that are filled with a resin-modified Portland cement grout. An RMP layer is 5 centimeters (2 inches) thick and has a surface appearance similar to a rough-textured PCC.

stone matrix asphalt (SMA): SMA, which is also referred to as stone mastic asphalt, is a mixture of aggregate, mineral filler, polymer-modified asphalt cement, and a mineral or cellulose fiber. SMA is designed to prevent rutting and abrasion under high loads or high tire pressures.

surface course: The top course of an AC pavement. The surface course is referred to as the wearing course by many pavement engineers.

surface recycling: Repaving, heater-planing-scarifying, cold milling, and rejuvenating are methods of surface recycling that are used to increase skid resistance, decrease permeability to air and water, and improve properties of the asphalt binder. Depending on the process used, surface recycling modifies from 5 to 50 millimeters (1/4 to 2 inches) of the pavement surface. Surface recycling does not increase the strength of the pavement. The cost to scarify and rejuvenate pavement is the same as the cost of an additional 25 millimeters (1 inch) of overlay, but the benefits of the scarification and rejuvenation usually exceed the benefits of the additional 25 millimeters (1 inch) of overlay.

warm-mix asphalt: Asphalt mixture that has been treated through additives or foaming to allow the mixture to be mixed, placed, and compacted at lower temperatures than HMA.

This Page Intentionally Left Blank

FOREWORD

The Unified Facilities Criteria (UFC) system is prescribed by MIL-STD 3007 and provides planning, design, construction, sustainment, restoration, and modernization criteria, and applies to the Military Departments, the Defense Agencies, and the DoD Field Activities in accordance with USD (AT&L) Memorandum dated 29 May 2002. UFC will be used for all DoD projects and work for other customers where appropriate. All construction outside of the United States, its territories, and possessions is also governed by Status of Forces Agreements (SOFA), Host Nation Funded Construction Agreements (HNFA), and in some instances, Bilateral Infrastructure Agreements (BIA). Therefore, the acquisition team must ensure compliance with the most stringent of the UFC, the SOFA, the HNFA, and the BIA, as applicable.

UFC are living documents and will be periodically reviewed, updated, and made available to users as part of the Military Department's responsibility for providing technical criteria for military construction. Headquarters, U.S. Army Corps of Engineers (HQUSACE), Naval Facilities Engineering Systems Command (NAVFAC), and Air Force Civil Engineer Center (AFCEC) are responsible for administration of the UFC system. Technical content of UFC is the responsibility of the cognizant DoD working group. Defense Agencies should contact the respective DoD Working Group for document interpretation and improvements. Recommended changes with supporting rationale may be sent to the respective DoD working group by submitting a Criteria Change Request (CCR) via the Internet site listed below.

UFC are effective upon issuance and are distributed only in electronic media from the following source:

- Whole Building Design Guide website https://www.wbdg.org/ffc/dod.

Refer to UFC 1-200-01, *DoD Building Code*, for implementation of new issuances on projects.

CHAPTER 1 INTRODUCTION

1-1 REISSUES AND CANCELS.

This document replaces UFC 3-250-04, 16 January 2004.

1-2 PURPOSE AND SCOPE.

This UFC provides guidance for preparing drawings and specifications for roads and airfields to construct rigid pavements using portland cement concrete (PCC) materials. It provides useful information for military and civilian design engineers, laboratory personnel, and project managers concerning mix design, materials, production, and placement of concrete mixtures. This UFC documents the standard practice for rigid airfield pavement construction and follows the chapter outline of Innovative Pavement Research Foundation Report IPRF-01-G-002-1, *Best Practices for Airport Portland Cement Concrete Construction (Rigid Airport Pavement)*, April 2003. This UFC provides supplementary clarification, requirements, and specific guidance for DoD concrete pavements. If there is conflicting guidance, DoD standard practice for military airfields takes precedence over IPRF guidance. This standard practice document aids in the use, interpretation, and implementation of Unified Facility Guide Specifications (UFGS) for DoD concrete pavement construction efforts and aids in resolving field construction problems. The requirements in this UFC produce a pavement of quality sufficient to support all DOD and allies' aircraft and missions.

This UFC prescribes materials, mix design procedures, and construction practices for concrete pavements. This UFC includes discussion of the advantages and disadvantages of techniques, practices, or materials when several choices exist. This includes possible methods and materials to mitigate or eliminate distresses or premature failures. This UFC is specifically tailored for military airfields and other heavy-duty pavements. It may be used for PCC road pavements, but airfield pavement guidance and requirements are generally much more stringent than for road pavements. Commercial construction practices and material quality permissible in civilian roadway construction do not suffice to meet the demands placed on military airfields.

1-3 APPLICABILITY.

The requirements of this UFC should be used for all DoD-owned or -funded organizational airfield pavements, heavy-duty roads, and hardstands. State specification requirements may only be substituted for nonorganizational parking, roads, streets, and driveways where the design index is less than 5. This UFC applies to all DOD military engineering and construction units, Title II on DOD construction efforts, as well as civilian design and construction personnel and companies working on DoD-owned or -funded airfield and other heavy duty pavement construction or repair.

1-4 GENERAL BUILDING REQUIREMENTS.

Comply with UFC 1-200-01, *DoD Building Code*. UFC 1-200-01 provides applicability of model building codes and government-unique criteria for typical design disciplines and building systems, as well as for accessibility, antiterrorism, security, high-performance and sustainability requirements, and safety. Use this UFC in addition to UFC 1-200-01 and the UFCs and government criteria referenced therein.

1-5 ROLLER COMPACTED CONCRETE PAVEMENT.

Appendix E contains information regarding the construction of roller-compacted concrete pavement (RCCP). RCCP is prohibited for airfield pavement use unless approved by the USACE TSC or appropriate Tri-Service Pavements Discipline Working Group (TSPDWG) Service representative.

1-6 GLOSSARY.

Appendix F contains acronyms, abbreviations, and terms.

1-7 REFERENCES.

Appendix G contains a list of references used in this document. The publication date of the code or standard is not included in this document. Unless otherwise specified, the most recent edition of the referenced publication applies.

CHAPTER 2 CONSIDERATION OF DESIGN ISSUES

2-1 INTRODUCTION.

The factors affecting long-term concrete pavement performance are broadly divided into the following categories:

- Adequate design of pavement structure
- Use of quality materials
- Use of proper construction procedures
- Timely maintenance and repair

The pavement designer controls several parameters and details that greatly impact pavement construction. These will be discussed individually in the following paragraphs. When there is a conflict between design requirements and field conditions, any modifications to the design to accommodate field conditions should be reviewed by the original designer to ensure the modifications comply with the original design intent.

2-2 DESIGN CONSIDERATIONS.

Design procedures for airfield pavements are described in the UFC 3-260-02, *Pavement Design for Airfields*. Design procedures for other concrete pavements are described in UFC 3-250-01, *Pavement Design for Roads and Parking Areas*.

2-2.1 Pavement Foundation.

Provide a firm foundation to support concrete construction activities, such as slipform pavers, forms, concrete delivery truck traffic, and other heavy vehicles or equipment. Designers will consider the anticipated field soil support and moisture conditions during construction and select base courses to support concrete placement activities. UFC 3-260-02 mandates use of base courses on pumping susceptible subgrade soils, which generally include the silts and clays that are the most troublesome during construction. However, the designer may include a base course to ensure a viable construction platform for soils such as those classified as SM, SC, GC, or SP by the Unified Soil Classification System (ASTM D2487). These may not be stable under construction traffic or during wet construction conditions.

A designer assesses the characteristics of the subgrade soil at a project location to determine whether a base course is required to support construction activities. Extend base courses far enough beyond the edge of the pavement to accommodate construction activities such as slipform paver tracks or provide space to place and anchor forms. Only use stabilized bases on airfields when there is a specific need, such as lack of suitable local base material, all-weather construction platform, or other structural requirements. Verify that designers working on design-build contracts are aware of this difference at initial design meetings.

2-2.2 Concrete Strength.

Traditionally, calculating the design strength for pavement thickness equates to the ASTM C78/CRD-C 16 flexural strength at 90 days. While modern concrete mixtures can achieve very high strength, this can introduce adverse setting and handling characteristics or shrinkage. Therefore, specify no flexural strength less than 600 psi (4136 kPa) or greater than 700 psi (4826 kPa) for military airfields without prior approval from the TSPDWG. Specifying a 90-day strength allowed designers to take advantage of strength gains between 28 and 90 days before allowing traffic or for minimal traffic. Most modern portland cement chemistry and grinding produce very modest strength increases between 28 and 90 days; however, concretes that use supplemental cementitious materials such as fly ash and ground-granulated blast furnace slag can gain substantial strength after 28 days.

Projects often require reopening pavement to traffic early. A designer balances the desired strength, the time to achieve this strength, and other factors such as durability, against specific project requirements. For pavement that must open early to traffic, the designer should calculate the effect of the limited early age traffic on the total pavement life to select reasonable strengths before allowing traffic. Simply requiring the normal 90-day strength at some very early age can generate a concrete mixture possessing troublesome working characteristics.

2-2.3 Pavement Dimensions.

Concrete pavements for any application are normally jointed plain concrete pavements. Only reinforce odd-shaped slabs or for special circumstances or applications, such as continuously reinforced concrete. Airport concrete pavements are typically designed on the basis of mixed aircraft loadings to minimize maintenance service for multiple decades. The pavements are designed on the basis of expected aircraft repetitions over the design period. For many airfield pavements, the concrete thickness may range from 400 to 500 mm (16 to 20 in.) and transverse joint spacing may range from 4.6 to 6.2 m (15 to 20 ft). Typical longitudinal joint spacing can also range from 4.6 to 6.2 m (15 to 20 ft).

Current practice uses dowel bars for load transfer in all longitudinal construction joints. For concrete pavements subjected to only light aircraft loads, slab thickness may range from 125 to 300 mm (5 to 12 in.) and transverse and longitudinal joint spacing may range from 2.4 to 4.6 m (8 to 15 ft). Slab dimensions in design manuals are set to minimize curling stresses from non-load-associated factors. Failure to adhere to these limits leads to unwanted cracking due to the combined effect of curling stresses and load-related flexural stresses. For these reasons, common practice limits the maximum slab size to 6.1 m (20 ft) as research shows that slab joint spacing equal to or greater than 7.6 m (25 ft) increases the risk of uncontrolled cracking.

2-2.4 Legacy Slabs.

On older airfield pavements with 7.6 m (25 ft) slabs, strict adherence to this policy may create mismatched slab joints. Where joint patterns of abutting pavement facilities do not match, partial reinforcement of slabs may be necessary. Using reinforcement at mismatched joints in such junctures is based upon the type of joint between the two pavement sections. Designers should develop repair projects with a cost-effective joint pattern that minimizes and mitigates mismatch between larger slabs and smaller slabs by incorporating appropriate protective measures, such as expansion joints or reinforcing. See further discussion in UFC 3-260-02.

2-3 DESIGN PROCESS.

The terms “base” and “subbase” often designate the layer directly under the concrete slab. In this UFC, the layer immediately below the slab is called the base. The layer between the base and the subgrade is called the subbase. The overall process of designing a concrete pavement involves the following steps.

2-3.1 Soil Investigation.

Soil borings determine the properties of the subsurface strata and depth to groundwater. Soil samples are obtained for soil classification and laboratory testing (see UFC 3-260-02).

2-3.2 Evaluate Subgrade Support at Design Grade.

The information from the soil investigation indicates the subgrade conditions at and below the design grade.

2-3.3 Design Pavement Section.

After determining the appropriate base type (i.e., stabilized or non-stabilized) and thickness, use the appropriate design procedure to calculate the required PCC pavement thickness.

2-3.4 Select Jointing Plan.

Develop appropriate longitudinal and transverse joint details based on the calculated slab dimensions. Proper construction details are required for joints and transition slabs that tie-in to existing pavements.

2-3.5 Develop Plans and Specifications.

Further develop the design details into complete plans and specifications.

2-3.6 Critical Design Features.

Critical design features that influence long-term concrete pavement performance include:

- Subgrade support uniformity and stability
- Base and subbase uniformity (type and thickness), including drainage

- PCC pavement layer thickness
- PCC properties, as specified
- Uniformity (ability of concrete to produce consistent properties)
- Workability (ability of concrete to be placed, consolidated and finished)
- Strength (ability of concrete to support traffic & environmental conditions)
- Durability (ability of concrete to provide long-term service)
- Jointing details
- Slab dimensions
- Load transfer at joints
- Joint sealing provisions

2-3.7 Construction Variability.

Throughout the design process, recognize that variability in the properties of key design elements significantly affects pavement performance. While some variability is unavoidable, excessive variability during construction induces random pavement performance and higher contractor costs. Make effective use of quality management plans to control construction variability. For each project, the design engineer establishes the acceptable parameters for each design variable. Construction work must meet or exceed the specified quality. Typically, when several marginal features are incorporated into a pavement structure through a design deficiency, poor construction techniques, or a combination thereof, premature failure results or it performs poorly throughout its service life.

2-4 CRITICAL CONSTRUCTION OPERATIONS.

Examples of critical construction operation include the following.

2-4.1 Grading.

Grading is important. Proper grading facilitates drainage and placement of successive layers. Grading issues are discussed in Chapters 4, 5, and 6.

2-4.2 Jointing.

Jointing controls slab cracking, which minimizes the potential for random cracking. Random cracking is a maintenance concern and can reduce the load capacity of pavement. Shallow joint sawing and late sawing can induce random cracking. If dowel bars are misaligned or bonded to the concrete, joints do not function and adjacent slab panels can develop random cracking. Joint sawing, load transfer, and joint sealing practices are discussed in Chapter 9.

2-4.3 Subgrade, Subbase, and Base Quality.

If the compaction of the subgrade, subbase, and base is compromised, the pavement may deflect excessively under aircraft loading and develop corner cracking. Subgrade, subbase, and base construction practices are presented in Chapters 4 and 5, respectively.

2-4.4 PCC Strength.

Low-strength concrete results in early fatigue cracking of the pavement. Concrete flexural strength at 28 days for airfield paving is typically 4,100 to 5,200 kPa (600 to 750 psi). For fast-track construction, these strength levels may be required earlier. Concrete practices, including strength requirements, are discussed in Chapters 6 and 7.

2-4.5 Concrete Durability.

Concrete that is not durable (a result of poor or reactive materials, a poor air-void system, or due to over-finishing) deteriorates prematurely. Concrete durability issues are discussed in Chapters 7 and 8.

2-4.6 Concrete Curing.

Improperly cured concrete can deteriorate prematurely and generate early age spalling. Chapter 8 discusses concrete curing practices.

2-4.7 Concrete Finishability.

Concrete that is over-finished or requires excessive manipulation to provide an acceptable finish deteriorates prematurely. Poorly finished concrete may also generate poor surface conditions. See Chapter 8.

2-4.8 Paver Operation.

Paver operations significantly impact pavement smoothness and in-place concrete quality. Chapter 8 discusses paver operation practices.

CHAPTER 3 PRE-CONSTRUCTION ACTIVITIES

3-1 CONSTRUCTION SPECIFICATION ISSUES.

Pavement construction specifications provide guidance and establish minimum requirements that, when adhered to, facilitate building a quality pavement. The acceptable level of quality for a rigid airfield pavement comprises desirable surface characteristics and a surface free from foreign object generators (FOG) for the service life of the pavement. FOGs result from distresses in the concrete pavement. A FOG that results in foreign object damage (FOD) is a very critical item for airfield concrete pavements. However, good design features, well-developed plans and specifications, and quality construction can minimize or eliminate FOG (and FOD) development.

As a result, it is important that construction specifications clearly define the requirements that promote long-term performance of concrete pavement and exclude arbitrary requirements. The UFGSs are detailed and cover all aspects of concrete paving, including materials and mixture design issues and required construction techniques and inspection requirements. It is important for the specifier and contractor to review military specifications in detail prior to construction.

3-2 PLANNING CONSTRUCTION LOGISTICS.

A successful construction project plans all logistical support in advance and pays attention to the smallest details, including the following:

- Ensuring readiness of all operations, including grade control
- Concrete plant set-up and traffic flow
- Concrete plant capacity and production rate
- Haul road availability and serviceability
- Security and site access requirements
- Availability of crews
- Availability of equipment and materials
- Construction and airfield traffic management
- Concrete placement needs (rate of placement)
- In-pavement structures
- Acquisition of in-pavement electrical items (affects fast track construction)
- Inspection and testing requirements
- Subcontractor readiness – crew and equipment availability
- Project phasing, if any
- On-site testing laboratory
- Other needs related specifically to fast-track paving

Include all parties involved in a construction project in the communication network. Regardless of project size, pavement construction is a team effort that includes operators and users.

3-3 EARLY PAVEMENT TRAFFICKING.

The UFGSs define when a concrete pavement may open to construction traffic and the design aircraft or vehicle traffic. Do not open pavement to aircraft or other design traffic for at least 14 days or longer, depending upon the loading, concrete mixture, and curing conditions. The requirement to allow equipment to operate on the pavement edges is for test specimens molded and cured in accordance with ASTM C31/CRD-C 11, attaining a minimum flexural strength of 400 psi (2.8 MPa) when tested in accordance with ASTM C78/CRD-C 16. Absent strength testing, use a 14-day aging requirement. Also, complete seven days of curing before allowing hauling equipment to use new concrete, and seal or otherwise protect all joints. Consider the following additional factors regarding construction traffic.

a. Develop specific criteria for typical construction equipment for different concrete pavement thicknesses and for edge and interior loading. For example, for large military facilities with concrete pavement thickness of 16 in. (400 mm) or greater, construction traffic may induce flexural stresses in the range of 100 to 150 psi (700 to 1,000 kPa). However, similar construction equipment may induce higher stresses on thinner pavements that are 12 in. (300 mm) or less in thickness.

b. Consider trade-offs between a higher strength requirement and extra thickness for critical areas that require fast track construction. Develop alternate designs for fast-track areas; for example, a thicker slab and cement-stabilized base without higher concrete strength versus use of an asphalt-treated base or a granular base and higher strength concrete.

Another consideration for early age strength levels is drilling to install dowel bars along the longitudinal joint face of pilot lanes. Drilling is typically not initiated until the concrete attains sufficient strength to reduce/eliminate micro-cracking and excess spalling around the drilled holes.

3-4 PRE-BID MEETINGS.

Pre-bid meetings allow the owner to review project requirements with contractors interested in bidding on a project. Although pre-bid meetings primarily tend to review administrative and contractual matters, it is important to highlight modifications of guide specifications implemented in the plans and specifications. Also address critical material supply and availability issues, the schedule, and specific acceptance testing requirements. It is good practice for contractors to attend pre-bid meetings. Distribute meeting minutes to all potential bidders (those requesting bid documents) whether they attend or not. Paving-related discussion items include:

- Owner and contractor organizational hierarchy
- Value engineering issues

- Project overview
- Phasing plan
- Scheduling criteria, including which areas are accessible and when
- Scheduling milestones, with incentives and disincentives
- Expected and unexpected delay resolution
- Alternate bid items
- Restrictions on site access and working hours
- Plant and staging area locations
- Paving sequence for cross-taxiway areas
- Access and egress locations, haul road locations, and construction traffic control
- QA, acceptance testing, and QC requirements
- Water, phone, and power connection locations
- Issuance of design and specification changes
- Provisions for protection of stabilized layers from freeze conditions
- Fast-track changes; thicker slab and stiffer base versus higher concrete strength
- Early age cracking, joint spalling, and edge slump
- Establish acceptability criteria
- Guidelines for corrective measures
- Dowel misalignment testing and resolutions
- Test strip construction requirements and acceptance criteria

3-5 PRE-AWARD MEETINGS.

Some agencies hold a pre-award meeting with the selected contractor. As part of these meetings, the contracting officer may perform an on-site survey of the contractor's facilities or previous projects. The survey helps to verify the data and representations submitted with the bid documents and determine if the contractor understands and has overall capabilities to adequately meet the contract requirements. A pre-award meeting is also an opportunity for the contracting officer and contractor to review the contract line items. Based on the discussions with the contracting officer, the contractor has an opportunity to withdraw the bid if it is determined that the bid may have included erroneous pricing.

3-6 PRE-CONSTRUCTION MEETINGS.

The contracting officer will host pre-construction meetings to review specific project requirements and project planning with the contractor. Review the following items:

- Issue resolution hierarchy – Appendix A
- Construction logistics – Appendix A
- Installation and airfield access and movement – Appendix A
- Security clearance requirements – Appendix A
- Checklist of critical material supply and availability issues – Appendix A
- Project specifications – Appendix A
- Approval of materials – Appendices A and B
- Schedule – Appendix A
- Inspection and testing requirements – Appendices A, B, and C
- Quality management (or contractor quality control) plan – Appendices A and B

Discuss concrete pavement-related items during the pre-construction meetings as a separate agenda. A concrete paving pre-construction meeting is the last opportunity to discuss concrete paving process issues before equipment starts moving. If items are discussed up front before construction begins, the parties can review potential problems and create solutions that work for everyone. Distribute meeting minutes to all parties. Pavement-related discussion items are listed in Appendix A. For projects involving more than 42,000 m^2 (50,000 yd^2) of concrete paving, conduct a half-day concrete pavement construction workshop using this UFC along with project-specific plans and specifications. Attendees at this workshop can include key staff from the contractor's field crew and the testing and inspection crews. Workshops ensure that all involved parties have the same understanding of project requirements and are committed to a successful project.

DoD installations or units can fund and schedule the USACE Transportation Systems Center (TSC) to conduct on-site airfield paving workshops and post-award teleconferences, provide on-site technical support during construction, review PCC mix designs, hot mix asphalt (HMA) job mix formulas (JMF), and warm mix asphalt (WMA) JMF. A list of services and required fees are described in USACE ER 1110-34-1, *Transportation Systems Mandatory Center of Expertise*.

3-7 QUALIFYING CONSTRUCTION MATERIALS.

In some localities, the state Department of Transportation (DOT) has information on materials approved for concrete pavement construction. Evaluate state DOT records for performance history and certification. State DOT certifications together with other documentation can facilitate the material approval review process. If current independent testing certificates cannot be obtained through material suppliers, DoD installations, DoD units, designers, or construction contractors may contract with third-party commercial laboratories accredited to perform the required materials testing. DoD installations, DoD units, designers, or construction contractors may alternatively contract with the U.S. Army Engineering Research and Development Center, (ATTN: CEERDC-GM-C), 3909 Halls Ferry Road, Vicksburg, Mississippi, 39180-6199, to qualify a cement or pozzolan for use in DoD pavement construction on a reimbursable basis. Prior to bid solicitation, the design engineer should address material availability and cost. If alternate materials are proposed in lieu of those specified, the contractor must ensure fulfillment of the specification testing requirements. Testing requirements for concrete aggregates may have long lead times and scheduling conflicts can arise if materials are not pre-qualified in a timely manner. Lead times for aggregate testing are discussed later in this chapter.

3-7.1 Evaluation of Local Aggregates.

The coarse and fine aggregates must meet the requirements of ASTM C33/CRD-C 133. However, for airfield and heavy-duty pavement additional restrictions and requirements exist. The fineness modulus of the fine aggregate, the limits on deleterious materials, the sample size, and order of testing differ from ASTM C33/CRD-C 133. Limits on deleterious materials are an order of magnitude lower than those in ASTM C33/CRD-C 133 for DoD airfields; thus, larger samples are required. Some key items follow.

a. The largest maximum size consistent with the requirements for placing the concrete will produce the most economical concrete with the least tendency to crack due to thermal effects or autogenous, plastic, or drying shrinkage.

b. The minimum nominal maximum aggregate (NMA) size is 38 mm (1.5 inch). For airfield and other heavy-duty pavements, the combined gradation must have a minimum of 10 percent mass retained on the 25mm (1 inch) sieve or must be a combination of #4, #67, and fine aggregate.

c. In areas where D-cracking in pavements is a known problem, use a smaller nominal maximum aggregate size or import aggregate from outside the area.

d. Aggregates for roads generally need to meet the requirements and contain no more than the specified percentages of deleterious materials listed in ASTM C33/CRD-C 133. For DoD airfield pavements, limits on deleterious materials are an order of magnitude lower than those in ASTM C33 (see Tables 3-1 and 3-2). Furthermore, the sample size and test sequence must meet additional requirements.

3-7.1.1 Airfield Coarse Aggregate Deleterious Materials Testing Sequence:

The minimum test sample size of the coarse aggregate is 90 kg (200 pounds) for the 19 mm (3/4 inch) and larger maximum size and 12 kg (25 pounds) for the 4.75 to 19 mm (No. 4 to 3/4 inch) coarse aggregate.

1. Step 1: Wash each full sample of coarse aggregate for material finer than the 0.075 mm (No. 200) sieve. Discard material finer than the 0.075 mm (No. 200) sieve.

2. Step 2: Test remaining full sample for clay lumps and friable particles and remove.
3. Step 3. Test remaining full sample for chert and cherty stone with SSD density of less than 2.40 specific gravity. Remove lightweight chert and cherty stone. Retain other materials less than 2.40 specific gravity for Step 4.
4. Step 4: Test the materials less than 2.40 specific gravity from Step 3 for lightweight particles (Sp. GR. 2.0) and remove. Restore other materials less than 2.40 specific gravity to the sample.
5. Step 5: Test remaining sample for clay-ironstone, shale, claystone, mudstone, siltstone, shaly and argillaceous limestone, and remove.
6. Step 6: Test a minimum of one-fifth of the remaining full sample for other soft particles.

3-7.1.2 Airfield Fine Aggregate Deleterious Materials Testing Sequence:

The minimum test sample size for fine aggregate is 5 kg (10 pounds). The fineness modulus must not be less than 2.50 nor more than 3.40.

1. Step 1: Wash each full sample of fine aggregate for material finer than the 0.075 mm (No. 200) sieve. Discard material finer than the 0.075 mm (No. 200) sieve.
2. Step 2: Test remaining full sample for clay lumps and friable particles and remove.
3. Step 3. Test remaining full sample for lightweight particles (Sp. GR.2.0).

Table 3-1 Categorization of Weather Severity

Weather Severity	Air Freezing Index, Coldest year in 30[1]	Average Precipitation for any Single Month During the Freezing Period
Moderate	500 or less	Any amount
Moderate[2]	501 or more	Less than 25 mm (1 in.)
Severe	501 or more	25 mm (1 in.) or more

[1] Calculated as described in UFC 3-260-02. See ASTM C33/CRD-C 133 for a simplified map of CONUS weather severity.

[2] In poorly drained areas, the weather should be considered severe even though the other criteria indicate a rating of moderate.

Table 3-2 Deleterious Material Limits in Airfield Aggregates - Percent Mass

Material	Coarse Severe Weather	Coarse Moderate Weather	Fine Aggregate All Weather
Clay lumps and friable particles (ASTM C142)	0.2	0.2	1.0
Shale[1] (ASTM C295/CRD-C 127)	0.1	0.2	-
Material finer than 0.075 mm (No. 200 sieve) [2] (ASTM C117)	0.5	0.5	3.0
Lightweight particles[3] (ASTM C123)	0.2	0.2	0.5
Clay ironstone[4] (ASTM C295)	0.1	0.5	-
Chert and cherty stone (SG less than 2.40 – SSD)[5] (ASTM C295/CRD-C 127)	0.1	0.5	-
Claystone, mudstone, and siltstone[6] (ASTM C295/CRD-C 127)	0.1	0.1	-
Shaly and argillaceous limestone[7], (ASTM C295/CRD-C 127)	0.2	0.2	-
Other soft particles (CRD-C 130)	1.0	1.0	-
Total of all deleterious substances, exclusive of material finer than 0.075 mm (No. 200) sieve	1.0	2.0	-
Total for fine aggregate including material finer than 0.075 mm (No. 200) sieve	-	-	3.0

[1] Shale is defined as a fine-grained, thinly laminated or fissile sedimentary rock. It is commonly composed of clay or silt or both. It has been indurated by compaction or by cementation, but not so much as to have become slate.

[2] Limit for material finer than 0.075 mm (No.200 sieve) will be increased to 1.5 percent for crushed aggregates if the fine material consists of crusher dust that is essentially free from clay or shale.

[3] The separation medium will have a density of 2.0 mg/m^3 (SG of 2.0). This limit does not apply to coarse aggregate manufactured from blast-furnace slag unless contamination is evident.

[4] Clay ironstone is defined as an impure variety of iron carbonate, iron oxide, hydrous iron oxide, or combinations thereof, commonly mixed with clay, silt, or sand. It commonly occurs as dull, earthy particles, homogeneous concretionary masses, or hard-shell particles with soft interiors. Other names commonly used for clay ironstone are “chocolate bars” and limonite concretions.

[5] Chert is defined as a rock composed of quartz, chalcedony, or opal, or any mixture of these forms of silica. It is variable in color. The texture is so fine that the individual mineral grains are too small to be distinguished by the unaided eye. Its hardness is such that it scratches glass but is not scratched by a knife blade. It may contain

impurities such as clay, carbonates, iron oxides, and other minerals. Other names commonly applied to varieties of chert are flint, jasper, agate, onyx, hornstone, porcellanite, novaculite, sard, carnelian, plasma, bloodstone, touchstone, chrysoprase, heliotrope, and petrified wood. Cherty stone is defined as any type of rock (generally limestone) that contains chert as lenses and nodules, or irregular masses partially or completely replacing the original stone.

[6] Claystone, mudstone, or siltstone is defined as a massive fine-grained sedimentary rock that consists predominantly of indurated clay or silt without laminations or fissility. It may be indurated either by compaction or cementation.

[7] Shaly limestone is defined as limestone in which shale occurs as one or more thin beds or laminae. These laminae may be regular or very irregular and may be spaced from a few inches down to minute fractions of an inch. Argillaceous limestone is defined as a limestone in which clay minerals occur disseminated in the stone in the amount of 10 to 50 percent by weight of the rock. When these make up from 50 to 90 percent, the rock is known as calcareous (or dolomitic) shale (or claystone, mudstone, or siltstone).

3-7.2 Alkali-Silica Reactivity.

Alkali-silica reaction is a deleterious chemical reaction between the reactive silica constituents in the aggregates and alkali in the cement. The product of this reaction can produce significant expansion and cracking of the concrete. The methodology to determine the susceptibility of aggregate to alkali-silica reactivity (ASR) and the effectiveness of mitigation measures is based on the Portland Cement Association's *Guide Specification for Concrete Subject to Alkali-Silica Reactions* (1998). However, for airfield pavements, the DOD doubles the immersion time of the test to 28 days versus the typical 14 days for roads and sets the expansion limit to 0.08 percent in lieu of 0.1 percent for roads. DoD requires these alterations to reduce the risk of false negative results and ensure deleterious expansion from slowly reactive materials is detected prior to incorporation into DoD airfield pavements.

3-7.3 Service History (Field Performance).

Performance history is a source of information on the susceptibility of an aggregate to ASR. When evaluating a service history as an indicator of the susceptibility of an aggregate to ASR, document the following (if this information cannot be affirmed and documented, the service history may be insufficient to evaluate the aggregate):

- The current supply of the aggregate is representative of that used in the existing historical placements.
- The existing historical placements are exposed to the same severity of exposure condition as the proposed placement.
- The existing historical placements have been exposed to this severity condition for at least 15 years.

- The existing historical placements have the same cement content with the same alkali content of the cement and the water/cementitious material (w/cm) ratio of the concrete equal to or greater than proposed concrete mix placement.
- The existing historical placements have the same pozzolans in both class and content as well as total equivalent alkali content and SiO_2 + Al_2O_3 + Fe_2O_3 content.

3-7.4 Laboratory Evaluation.

In the absence of an adequate history of field performance or for airfield or other heavy-duty paving, test both fine and coarse aggregates as follows.

3-7.4.1 ASTM C1260/CRD-C 174.

For roads, results per this test that yields a mean 14-day mortar bar expansion less than or equal to 0.10 percent contains acceptable aggregate and may be used for concrete production. When the mean 14-day expansion is greater than 0.10 percent, the aggregate is suspect and additional testing is warranted before the aggregate is approved for used. For military airfield and heavy-duty paving projects, expansion is limited 0.08 percent after 28 days of submersion for aggregate to be acceptable without mitigation.

3-7.4.2 ASTM C295/CRD-C 127.

This test supplements the results of ASTM C1260/CRD-C 174. This test identifies and quantifies the reactive mineral constituents in the aggregate. Reactive constituents include strained or microcrystalline quartz, chert, opal, and natural volcanic glass in volcanic rocks.

3-7.4.3 ASTM C1293/CRD-C 175.

This is an optional test to verify results of ASTM C1260/CRD-C 174. An aggregate that produces a mean expansion at one year exceeding 0.04 percent is considered potentially reactive. Although the time required for this test generally makes it impractical to use for a specific job, some aggregate suppliers can provide test results specific to their aggregates. The suppliers must demonstrate that the test results represent the aggregate currently being produced from their quarry.

3-7.4.4 ASTM C1567.

While similar to ASTM C1260/CRD-C 174, this test includes supplementary cementitious materials and is used to determine the proportioning of these supplementary cementitious materials to mitigate ASR. Furthermore, the limits and test length for airfield paving are 0.08 percent after 28 days of submersion for the mitigation to be acceptable.

3-7.4.5 CRD-C 662.

If evaluating lithium nitrate as a means to mitigate ASR expansion, with or without supplementary cementitious materials (SCM), test in accordance with CRD-C 662.

3-8 MITIGATION MEASURES.

For roads, if the aggregate demonstrates potential reactivity by ASTM C295/CRD-C 127, ASTM C1260/CRD-C 174, ASTM C1293/CRD-C 175, or by previous field performance, it may be used if an appropriate mitigation measure is effective. Specify and test several combinations of cementitious materials to allow the contractor as much flexibility as possible to meet the other requirements of the project. For military airfield construction, any combination that produces a mean 28-day expansion of 0.08 percent or less when tested according to ASTM C1567 is considered an acceptable method of controlling expansion due to ASR. The cement used for testing must be the same type and brand used on the project. Possible mitigation measures include incorporating a supplementary cementitious material. These materials include low-calcium Class F fly ash (calcium oxide [CaO] content less than 8 percent), slag, silica fume, or natural pozzolan in combination with portland cement.

3-8.1 D-Cracking.

D-cracking describes the distress in concrete that results from the disintegration of coarse aggregates after they become saturated and are subjected to repeated cycles of freezing and thawing. For pavements subject to freezing conditions in service, reject or beneficiate aggregate susceptible to D cracking to remove particles of susceptible size; generally, these are larger particles. Most rock types associated with D-cracking are of sedimentary origin. If the performance history of a proposed aggregate is unknown and the pavement is subject to numerous cycles of freezing during a season, test the aggregate using ASTM C 666/CRD-C 20 (either Procedure A or Procedure B). This method tests the durability of concrete under cycles of freezing and thawing in conditions likely to saturate the concrete. Modifications for testing aggregate for D-cracking include increasing the number of cycles to 350 and calculating the durability index from the expansion of the specimens.

3-8.2 Lead Time Required for Aggregate Testing.

Table 3-3 gives the time required for testing of ASR and freeze-thaw (D-cracking). Typically, about 60 days’ lead-time is available from contract award to start of work, so aggregate acceptance must be done within that time or before award. Design engineers must specify ASTM C1260/CRD-C 174 if ASR testing is required. Design engineers must emphasize the test time requirements if aggregate qualification tests are needed. ASTM C1260/CRD-C 174 can test the effectiveness of mitigation measures, as described in this UFC. Test several combinations of cementitious materials simultaneously to save time and allow flexibility to meet other job requirements.

Table 3-3 Testing Time Required

Test Method (ASTM)	Time for Test Result
C1260/CRD-C 174	16 days
C1293/CRD-C 175	1 year for potential aggregate reactivity; 2 years to test effectiveness of mitigation measures
C666/CRD-C 20	2 to 3 months

3-9 AVAILABILITY/CERTIFICATION OF CEMENTITIOUS MATERIALS.

3-9.1 Cementitious Materials.

Secure cement supplies to ensure supply during peak construction season. If the cement source is changed, conduct additional mix design and compatibility testing. Problematic combinations often include cements with relatively low sulfate contents or with sulfates available only in forms that are not readily soluble. While such cements may perform satisfactorily alone, they may be prone to early stiffening if used with water-reducing admixtures containing lignosulfonates or triethanolamine. In hot weather, these effects are more pronounced. Mixture designs should be pre-qualified using different cementitious materials in the event a substitution is necessary, alternate mix design data is available, and new materials can be accommodated without delay.

3-9.2 Portland Cement.

The various types and requirements of cement are given in ASTM C150/CRD-C 201. The cement types are presented in Table 3-4. ASTM C150/CRD-C 201 also specifies optional chemical requirements, such as limits on the maximum alkali content, and optional physical requirements, such as heat of hydration. Specify these requirements judiciously, if at all, since they often increase the cost or limit the available options. Frequently there are equally acceptable or even preferable alternatives. For example, deleterious expansions due to ASR may be controlled as well or better by a combination of cement with Class F fly ash or slag instead of low-alkali cement. Generally, do not specify a maximum limit on the alkali content of the cement. This may not be sufficient to control deleterious expansions. In some cases, higher alkali content may be desirable to increase the rate of hydration during cool weather or when supplementary cementitious materials are used. Sulfate resistance may be obtained with sufficient quantities of slag or an appropriate fly ash as well as (or better than) a Type II or Type V cement. Heat of hydration may be reduced using a combination of slag, Class F fly ash, and natural pozzolan with Portland cement. If the cement is used alone (that is, without supplementary cementitious materials), specify the optional requirement for false set; however, evaluate the setting characteristics for the concrete.

Table 3-4 Types and Uses of Portland Cements

Designation	Application
Type I	Most widely available; used when other special properties are not required.
Type II	For general use, especially when moderate sulfate resistance or heat of hydration is required. Some cements meeting requirements for both I and II are designated Type I/II.
Type III	Used for high early strength.
Type IV	Used when low heat of hydration is required.
Type V	Used when high sulfate resistance is required.

3-9.3 Blended Cement.

The types and requirements of blended cements are given in ASTM C595/CRD-C 203. The types of blended cements are listed in Table 3 5. All cements designated Type I under ASTM C595/CRD-C 203 have comparable strength requirements at early ages as do those specified by ASTM C150/CRD-C 201 for Type I cement. However, the actual strengths at early ages are generally lower because slag and pozzolans included in blended cements react more slowly than cement alone. Type IL (10) and IL (15) cements contain up to 10 or 15 percent limestone ground with the cement clinker. This material provides similar performance to Type I cement but can be slightly more porous. It also has a lower embodied carbon content than similarly produced Type I cement.

Table 3-5 Types of Blended Cements

Designation	Composition
Type IL (10) (15)	Contains 10 to 15 percent ground limestone
Type IS	Contains 25 to 70 percent blast furnace slag
Type P and Type IP	These contain 15 to 40 percent pozzolan (fly ash or natural pozzolan). Type P is used when higher early strengths are not needed.
Type I (PM)	Contains less than 15 percent pozzolan.
Type I (SM)	Contains less than 25 percent slag.
Type I (PM) and Type I (SM)	Should not be used when the special properties of pozzolan or slag are desired, as they don’t contain enough of these materials.
Type S	Contains at least 70 percent slag

3-9.4 Hydraulic Cement.

The various types of hydraulic cements are given in ASTM C1157/CRD-C 271. The types of hydraulic cements are given in Table 3-6.

Table 3-6 Types of Hydraulic Cements

Designation	Use
Type GU	For general use
Type HE	For high early strength
Type MS	For moderate sulfate resistance
Type HS	For high sulfate resistance
Type MH	For moderate heat of hydration
Type LH	For low heat of hydration

3-9.5 Supplementary Cementitious Materials.

Supplementary cementitious materials offer the potential for improved performance of concrete and reduced cost. They provide benefits more economically and sometimes more effectively than the appropriate choice of ASTM C150/CRD-C 201 cement. The benefits include:

- Control of expansions due to ASR
- Reduced permeability
- Sulfate resistance
- Reduced heat of hydration

3-9.5.1 Pozzolans.

ASTM C618/CRD-C 255 defines pozzolans as “siliceous or siliceous and aluminous materials which in themselves possess little or no cementitious value but will, in finely divided form, and in the presence of moisture, chemically react with calcium hydroxide at ordinary temperatures to form compounds possessing cementitious properties.” Fly ashes and natural pozzolans must meet the requirements of ASTM C618/CRD-C 255. Class F fly ash with $SiO_2 + Al_2O_3 + Fe_2O_3 > 70$ percent, CaO content less than 8 percent, and loss of ignition not exceeding 3 percent is the preferred choice for controlling ASR and provides sulfate resistance. Class C fly ash is not permitted for concrete pavement.

3-9.5.2 Dosage.

Typical dosages for Class F fly ash are generally between 15 percent and 35 percent by mass of cementitious materials. Evaluate sources to determine actual chemical composition to establish typical usage rates. For treatments below 25 percent replacement, the SiO_2 + Al_2O_3 + Fe_2O_3 content must be greater than 70 percent. At 15 percent replacement, the SiO_2 + Al_2O_3 + Fe_2O_3 content must be greater than 90 percent.

3-9.5.3 Weather Effects.

In cool weather, concrete with Class F fly ash may not gain strength quickly enough to allow joint sawing before shrinkage cracks form.

3-9.5.4 Alkali-Silica Reactivity.

If fly ash is used to control expansions due to ASR, a lower CaO content is more effective. Ideally, the CaO content should be less than 8 percent. Test the fly ash to verify effectiveness and dosage requirements. Only use Class F fly ash with a total equivalent alkali content less than 4 percent when mitigating ASR potential in DoD airfield pavement. Only use Class F fly ash with a loss on ignition not exceeding 3 percent when mitigating ASR potential in concrete using air entraining admixtures in DoD airfield pavement.

3-9.5.5 Mixture Property Control.

Natural pozzolans are available either as components of Type IP cement or as additives. They can be effective in controlling expansions due to ASR and in reducing heat of hydration.

3-9.5.6 Slags.

Finely ground granulated blast furnace (GGBF) slag must meet the requirements of ASTM C989/CRD-C 205. Table 3-7 lists the three grades of GGBF slag. The three grades of GGBF slag are based on their activity index. Typical dosage of slag is between 25 percent and 50 percent of cementitious materials. For airfields, the minimum dose is 40 percent and the maximum is 50 percent. Note that concrete strength at early ages (up to 28 days) trends lower than slag-cement combinations, particularly at low temperatures or at high slag percentages. Establish the desired concrete properties while considering the importance of early strengths; the curing temperatures; and the properties of the slag, cement, and other concrete materials.

Table 3-7 Grades of GGBF Slag

Designation	Properties
Grade 80	Least reactive, not normally used for airfield pavements
Grade 100	Moderately reactive
Grade 120	Most reactive, through finer grinding. Difficult to obtain in some locations in U.S. and Canada

3-10 CERTIFICATION OF ADMIXTURES AND CURING COMPOUNDS.

3-10.1 Admixtures.

3-10.1.1 General.

Chemical admixtures are ingredients commonly used in paving concrete to obtain or enhance specific properties of concrete. For concrete with multiple admixtures, purchase the admixtures from the same manufacturer. The large manufacturers test their own admixtures for incompatibility and other interactions and can provide helpful advice for avoiding undesirable reactions. Not all admixtures work well in all applications. For example, the low slumps typical of paving concrete make certain air-entraining admixtures less effective. The contractor should seek the advice of the manufacturer on applying and using admixtures. Obtain batching requirements, mixing procedures, and recommended dosages from the manufacturer. Use trial batches to determine exact dosages for the particular concrete mixture design. Placement temperature affects the required dosages of chemical admixtures. Develop trial batches accordingly. Never use admixtures to compensate for marginal concrete mixtures. The specifier and the contractor must consider if adjustments to the concrete mixture design are preferable to admixtures. As an example, obtain the effects of accelerating and retarding admixtures by adjusting the quantity and composition of the cementitious materials in the mix. Blend admixtures separately into the concrete. Do not place admixtures directly on dry aggregate or on dry cement as they can be absorbed and are not available to readily mix with the concrete. Consult the manufacturer for information about potential interactions between admixtures. In higher dosages, some water reducers may retard setting or strength gain. Chemical admixtures must meet the requirements of ASTM C260/CRD-C 13 or ASTM C494/CRD-C 87.
ASTM C260/CRD-C 13 specifies the requirements for air-entraining admixtures. The types of admixtures specified by ASTM C494/CRD-C 87 are given in Table 3 8.

Table 3-8 Types of Admixtures

Designation	Use
Type A	Water-reducing admixtures
Type B	Retarding admixtures
Type C	Accelerating admixtures
Type D	Water-reducing and retarding admixtures
Type E	Water-reducing and accelerating admixtures
Type F	Water-reducing and high range admixtures
Type G	Water-reducing, high range, and retarding admixtures

3-10.1.2 Air-Entraining Admixtures.

Air-entraining admixtures entrain a system of finely divided air bubbles in the cement paste. They are an essential protection for concrete exposed to freezing as they provide outlets for freezing water to expand and not disrupt the internal structure of the concrete. Air-entraining admixtures can also improve the workability of fresh concrete. They reduce water demand, bleeding, and segregation. Select an admixture appropriate for pavement use; some admixtures are used only in concretes with higher slump allowances than typical for airfield pavements. Higher air content in concrete reduces its strength. If the air content of the production concrete is higher than specified in the approved mix design, it may reduce the strength of in-place concrete and strength samples. Typically, a 1 percent increase in air results in a 5 percent loss in compressive strength.

3-10.1.3 Accelerating Admixtures.

Accelerating admixtures are classified as Type C and Type E by ASTM C494/CRD-C 87. They accelerate the setting and early strength gain of concrete. Typically, they are used only in cold weather or in repairs when the reduction of an hour or two in the setting time is important. They are also used when some increase in the early-age strength is needed. If any of these properties are needed over the course of the job, it is preferable to design the concrete accordingly rather than rely on accelerating admixtures. Accelerating admixtures primarily affect the setting time, heat evolution, and strength development. The strength at later ages may decrease, and in aggressive environments the durability may be adversely affected. Alternate means of obtaining early strength development include:

- Use of Type III cement
- Higher cement contents
- Heating the water or aggregates
- Improving curing and protection
- Some combination of the above

3-10.1.4 Retarding Admixtures.

Retarding admixtures delay the initial and final setting times; however, they do not reduce the rate of slump loss. They affect the rate of strength gain for as little as one or two days, or as long as seven days, depending on the dosage. They may be used in hot weather when long haul times are unavoidable or to prevent the formation of cold joints. Changes in temperature may require adjustments in admixture dosage to maintain the desired setting time. In hot weather, the dosage may be increased to the point where excessive retardation occurs. In some cases, this results in cracking of the pavement because the concrete begins to crack due to drying before gaining sufficient strength to saw the joints.

3-10.1.5 Water-Reducing Admixtures.

Water-reducing admixtures, as defined in ASTM C494/CRD-C 87 as Types A, D, and E, are used in concrete pavement applications. Some Type A water-reducing admixtures act as Type D (water-reducing and retarding) admixtures at higher dosages. High amounts of water-reducing admixtures may lead to excessive retardation. The rate of slump loss is increased when using water-reducing admixtures. Some water-reducing admixtures enhance the effectiveness of air-entraining admixtures so a lower dosage achieves the required air content. High-range water reducers are typically not used in pavement concrete. Types A, D, and E can be used to:

- Reduce the water/cement ratio at a given workability.
- Increase the workability for a given water content.
- Reduce the water and cement contents for a given workability.

3-10.2 Curing Compounds.

Curing compounds (liquid membrane-forming compounds) need to conform to the requirements of ASTM C309/CRD-C 304 and CRD-C 300, as applicable. ASTM C156/CRD-C 306 specifies a method for determining the efficiency of curing compounds, waterproof paper, and plastic sheeting. Pigmented curing compounds are recommended because they make it easy to verify proper application. For concrete placement on sunny days and in hot weather, the selected curing compound should contain a white pigment to reflect the sun's heat. Properly applied curing compounds must have the following properties:

- Maintain the relative humidity of the concrete surface above 80 percent for seven days
- Be uniform and easily maintained in a thoroughly mixed solution
- Not sag, run off peaks, or collect in grooves
- Form a tough film to withstand early construction traffic

3-11 QUALITY CONTROL/QUALITY ASSURANCE REQUIREMENTS.

The development of specifications for contractor quality control/quality assurance (CQC/QA) is discussed in this section. The implementation of specific project CQC/QA requirements is discussed in Chapter 10.

3-11.1 Basic CQC/QA Definitions.

3-11.1.1 Contractor Quality Control (CQC).

CQC, also called process control, refers to the contractor's roles and responsibilities. The goal of the CQC program is to provide testing, monitoring, and reporting of information to adequately document that the contractor is meeting the project specifications and to allow the contractor to make timely adjustments to the construction process. The contractor needs to develop a written CQC plan that is available for review and approved by the Contracting Officer.

3-11.1.2 Quality Assurance (QA).

QA consists of all actions necessary to provide a reasonable level of confidence that the final product will meet the intent of the government from a serviceability and maintenance perspective. QA refers to the government's roles and responsibilities. The goal of the QA program is to verify that the results from the contractor's CQC plan are truly representative of the actual material being placed and that the contractor is "doing the right things." The government will develop a written QA plan and distribute it to all project personnel, including the contractor.

3-11.1.3 Acceptance Testing.

Acceptance testing describes the QA tests conducted to determine the degree of compliance with contract requirements and is linked to pay items. Acceptance testing can be part of the QA or CQC plan or both. For example, CQC may be responsible for fabricating and field curing concrete strength samples, but QA is responsible for transporting, laboratory curing, and testing. Clearly define all acceptance testing procedures and responsibilities prior to starting any work.

3-11.2 General Issues.

Important quality-related concrete pavement construction items include:

- Testing crew training/certification (typically ACI certification)
- Testing laboratory certification (as per ASTM C1077/CRD-C 553)
- Plant certification
- Plant operator certification
- Test equipment calibration: flexural strength test machine calibration and other laboratory testing equipment
- Role of QA/acceptance or verification/resolution of conflicts between QA and QC test results
- Use of control charts by contractors
- Development of a CQC plan
- Management of CQC data
- Timely review and processing of CQC data
- Ability of construction team to make decisions quickly with changing project conditions

3-11.3 CQC Plan.

One of the most important activities of a concrete pavement construction project is the contractor's development of a comprehensive CQC plan. The contractor must implement and adhere to the CQC plan throughout the course of the construction project. Meetings between the CQC and QA representatives prior to construction help resolve conflicts and identify gaps in the inspection process. The components of a good CQC plan include:

1. Introduction
    - Project description

- Key contact information (contractor, owner, and owner's representative)
- Contract plans and specifications highlights

2. Purpose of CQC
3. Organization chart (Clearly delineate the chain of responsibility from top management.)
    - CQC roles (testing laboratory, contractor)
    - Project personnel
4. Duties and responsibilities
    - QC manager
    - QA or acceptance testing administrator, as applicable
    - Project engineers
    - Technicians/inspectors
5. Inspections (paving related) (Include tests required and frequency and acceptance criteria.)
    - Material inspections
    - Excavation and embankment inspection
    - Concrete paving inspection
    - Demolition of existing pavement
6. QC test schedules/testing plans
    - Report submittals
7. Deficiencies reporting
8. Conflict resolution
9. Changes to the CQC/supplemental items
10. Placement agreement form
11. Appendices (as needed)

3-11.4 Review of CQC Plan.

Write the CQC plan clearly to minimize any misunderstanding. Review the plan for ambiguity with respect to sampling locations, number of tests, test procedures, special provisions, and acceptance limits. Make copies of all test procedures cited in the plan readily available at the project site or at the project test facility. The management of each organization must fully support the CQC process. Without management support, urgent deadlines and outside pressures can dominate project activities and CQC testing and inspection will suffer. An inspection and testing checklist is provided in Appendix B. The following are items to review in CQC plans:

- Are all required tests discussed?
- Are proper standards for each test referenced?
- Are testing requirements clearly defined and understood?
- Are all procedures clearly defined?
- What items are tested?
- What actions are taken when test results are unacceptable or outside of project action or suspension limits?
- What are the documentation procedures and timelines?
- How and to whom are the test results reported?
- How are nonconforming test results handled?
- Does the paving plan address hot and cold weather construction activities?
- If nighttime construction is anticipated, does the plan properly address the procedures for use and placement of portable light plants?
- Does the plan provide the chain of command for decision making?

3-11.5 CQC Versus QA Testing Responsibilities.

Contractors and inspectors must be aware of testing requirements and how test results are used. QA testing is used for acceptance and pay adjustments while the contractor's test results are used for process control. This can create conflicting situations. Minimize the potential for conflicts between QA and QC through timely communications. Once the CQC and QA plans are created, reviewed, and approved, the contractor and the inspection teams will meet to review and resolve any potential conflicts or gaps in the plans. For example, the CQC plan may assume that the owner is making flexural strength samples for opening to traffic while the QA plan assumes it is the responsibility of the contractor. Or the QC plan may call out storage of traffic samples at the paving location and the QA plan defines storage in the laboratory. An often-overlooked part of any construction project is CQC data management. Data management includes items necessary to document the construction process. These items include test results and procedures, consignment forms, laboratory control charts, and requests for information. Track any missing information and resolve as soon as possible. Missing items are difficult to locate if the project team waits until the end of the project. In addition to the types of documents submitted, the schedule for submission and the review process must be determined before construction begins.

3-12 TEST SECTION CONSTRUCTION.

Test sections are mandatory for all design-build paving projects, all airfield paving projects, and for other paving projects where the pavement thickness is 250 mm (10 in.) or greater and constructed using slipform paving. The designer and the using agency decide where the test section will be constructed. Use the test section to evaluate the concrete batching, transporting, placement, finishing, and curing processes. The specification clearly identifies the objectives for test section construction and establishes the construction monitoring and acceptance plan requirements. Develop the acceptance plan in accordance with project requirements. Clearly define test section dimensions and construction location. The designer and using agency must decide whether to place the test section near the project site or allow its use as part of the final pavement, provided it is placed at an outer edge location. Both the contractor and the government must have senior representatives present during the test section placement as this event establishes the acceptable and unacceptable procedures. The government must give the contractor timely notification of acceptance or a clear explanation of what is rejected.

3-12.1 Test Section Details.

Consider including the following construction details in the test section.

- Pave at the paving width anticipated for the project.
- Allow sufficient length (typically 122 m [400 ft]) for the contractor to demonstrate their paving operation.
- Place in conditions anticipated during pavement construction.
- Use the same equipment and concrete haulers as used during construction.
- Include blockouts to evaluate paving processes where light cans and embedded steel are located.
- Include at least one construction header to evaluate starting and ending.
- Include tie-down (mooring point) and ground point if the paving project includes them.
- For large projects, test strip construction should also include hand placement.

3-12.2 Test Evaluation Items.

Construct test sections using the same procedures as for production paving. The following paragraphs contain the items to evaluate during test section placement.

3-12.2.1 Pre-Paving Preparation and Inspection Activities.

Accomplish the following activities prior to starting paving operations.

- Base condition (grade and surface)
- Grade controls (stringline setup, paver track-line)
- Joint locations
- Dowel bar baskets, embedded steel, and tie bars, if used

- Blockouts
- Concrete aggregate (for gradation and moisture content)
- Equipment for transporting, placing, consolidating, finishing, texturing, and curing
- Vibrators on pavers (for frequency and amplitude).

3-12.2.2 Batch Plant Operations.

Evaluate the following batch plant charging and concrete mixing processes prior to the start of paving operations.

3-12.2.2.1 Plant Production Rate.

Batching through the plant at expected production rates will evaluate whether additional loaders are required and stockpile management plans are acceptable. Establish and approve mixing times based on plant uniformity testing.

3-12.2.2.2 Concrete Uniformity.

If difficulties in mixing or concrete uniformity are encountered, changes to the plant, changes in the mixing process, changes to the concrete mixture designs, or additional plant uniformity testing should be considered. Difficulties in concrete mixing at the design w/cm ratio, non-uniform concrete between the front and rear of the drum during discharge, and excessive loss in slump may indicate the following possible problems:

- Materials not sequenced properly into the drum
- Too large a batch size relative to drum capacity
- Inadequate mixing times
- Liquid admixture incompatibility with cement or supplementary cementitious materials
- Sensitivity to initial concrete temperature
- Sensitivity to stockpile moisture changes

3-12.2.3 Concrete Delivery.

Evaluate the following concrete delivery processes before starting paving operations.

a. The time between the addition of water and depositing concrete on grade must be checked to verify that the concrete can be batched, transported, and dumped on grade within specified time limits.

b. Additional concrete haulers are required if the paver stops and waits for concrete delivery.

c. Compare concrete material batch quantities with the approved mixture design quantities.

d. Deliver concrete using the same equipment as used in production (agitator, open-end dump trucks, as well as other material-handling vehicles and equipment).

3-12.2.4 Concrete Placement.

Evaluate the following concrete placement operations before starting paving operations.

a. Concrete dumped from trucks, chuted from agitator trucks, or spread using belt spreaders should not drop more than 1.5 m (5 ft).

b. Concrete dumped on grade or placed in front of the paver using belt placers or spreaders must be examined for aggregate segregation. If the concrete appears segregated, uniformity testing on coarse aggregate content must be conducted.

c. Significant differences in aggregate content between samples of concrete from the same truck indicate that concrete transport or dumping processes may need to be modified.

d. When concrete is dumped in front of the paver or spreader and dowel baskets are placed during slipforming, observe the alignment procedures to ensure the baskets are being properly located and installed.

3-12.2.5 Quality Assurance/Quality Control.

Evaluate the following concrete sampling and QA/QC operations before starting paving operations. Address deficiencies noted concerning acceptance, QA and QC, concrete sampling, transporting, beam fabrication, initial and final curing procedures, and subsequent testing, and implement corrective action.

a. Sample concrete in front of the paver and test for slump, air content, initial concrete temperature, and plastic unit weight in accordance with the project requirements. Check concrete air content behind the paver. Document ambient air temperatures.

b. Properly transport concrete samples for beam or cylinder if concrete beams are fabricated and initially cured at a central location. Fabricate extra samples for testing at different ages. Early-age strength tests can verify strength gain relative to the mixture design and establish relative opening times for construction equipment.

c. Fabricate beams and cylinders at intervals more frequently than the sublot limits. This provides a better indication of variability due to any minor changes in batch quantities and changes throughout the day.

3-12.2.6 Consolidation and Finishing.

Evaluate the following concrete consolidation and finishing operations before starting paving operations.

a. Difficulties in placing, consolidation, maintaining a smooth pavement, maintaining a tolerable edge slump, closing the surface and edges, and surface tearing indicate problems with concrete, concrete mixture design, or the paver operation.

b. Adjust the vibrator frequency, spacing, and elevation if problems with consolidation are encountered. Supplementary vibrators may be necessary at longitudinal construction joints if excessive entrapped air voids or honeycombing are observed along vertical edges.

c. If problems in consolidation are attributed to the concrete, conduct slump tests at the plant to establish slump loss. There may be an incompatibility problem between cement, liquid admixtures, and supplementary cementitious materials if concrete exhibits a high slump loss (generally considered greater than 25 mm [1 in.]). Verify aggregate moisture monitoring.

d. Dowel bar inserters are prohibited on DoD airfield projects.

e. Verify pavement thickness by probing or by stretching piano wire across string line pins and using a ruler.

f. Transfer transverse joint stations from the base or sides of forms to the pavement surface as references for joint sawcutting.

g. Observe paving at blockouts for movement of the blockout from the planned position. Check embedded steel behind the paver to ensure the steel is properly secured to the base and is not disturbed by paver vibrators.

h. Examine the surface directly behind the paver screed or the tube float to ensure the surface is not tearing. Surface tearing is associated with excessive concrete slump loss, excessive concrete slump, a poorly adjusted paving machine, or excessive paver speed. Closing tearing cracks during finishing operations may not prevent them from reflecting to the surface.

i. Examine the surface behind the paver screed or tube float to ensure it is closed. Difficulty in closing the surface is indicative of one or more of the following:

- Premature concrete stiffening (possible admixture incompatibility)
- Insufficient paste/mortar content
- Vibrator frequencies set too high
- Vibrator elevations set too low
- Paving speed too high
- Inadequate mortar quantities maintained in the grout box

j. Measure edge slump at frequent intervals. Increasing the coarse aggregate content, decreasing the water content, or decreasing the mortar content can reduce edge slump. Paver side form batter can sometimes be adjusted to compensate for edge slump. Reducing paver speed may also help reduce edge slump.

k. Examine the concrete, after finishing but prior to any texture operations, with a straight edge. The surface must be closed. Avoid adding water to aid in the finishing operation. If additional water is required during hot weather, a minimal amount of water addition is tolerable only if applied in a fine mist. An excess of surface laitance after finishing is indicative of excessive finishing or excessive water application. Finishing efforts need to be just enough to provide a smooth closed surface. An excessive amount of finishing leads to a non-durable concrete surface.

3-12.2.7 Texturing.

The method of texturing must be inspected for uniformity in appearance. If burlap is used, it must be wet enough to provide a rough surface texture without exposing or rolling any coarse aggregates. Ponding of laitance or the depositing of thick films of water is indicative of the burlap being excessively wet.

3-12.2.8 Curing.

Consider the following concrete curing operations before starting paving operations.

a. Establish curing compound coverage rates prior to test strip construction. The coverage rate depends on the surface texture applied.

b. The application of curing compound must be uniform along the pavement surface and vertical edges.

c. A non-uniform application is indicative of spray nozzles set too low, clogged nozzles, cure rig speed set too fast, insufficient mixing of curing compound, or an insufficient number of passes.

3-12.2.9 Sawcutting.

Consider the following concrete sawcutting operations before paving.

a. Periodically monitor the temperature of fresh concrete if maturity meters, infrared guns, or surface thermometers are used to establish sawcutting times. Sample temperatures approximately every 20 minutes until joints are ready.

b. If the maturity meter technique is used to establish sawcutting times, insert thermocouples into the plastic concrete as soon as possible after texturing. Thermocouples are inserted into the pavement per the manufacturer’s instructions. To obtain representative temperatures, the thermocouples should be positioned at least 0.6 m (2 ft) inward from pavement edges.

c. Allow sawcut operators to initiate cutting when concrete is slightly too green to calibrate temperature or maturity measurements.

d. Cut several meters (feet) to allow a visual rating or quantify joint raveling. Repeat this process until representatives for the owner, contractor, and inspector agree that sawcuts meet project requirements.

e. Document conditions of sawcuts and photograph to avoid future disputes over excessive raveling. Document the maturity and temperature when “acceptable” sawcuts can be made for production paving.

f. Check sawcut depths for each saw used on the test strip. Carry transverse sawcuts through the longitudinal free edges or as close to forms as possible.

3-12.2.10 Test Section Acceptance.

After test strip construction, perform a final inspection of the pavement. Items to inspect include:

- Condition of the surface and slipformed edges
- Texture and curing compound coverage
- Headers and sawcut joints
- Blockout areas (light can penetrations or other utilities)
- Edge slump and profile (straight edge or profile testing)
- Cores (for thickness and assessing consolidation and segregation).

See ASTM D6938, *Standard Test Method for In-Place Density and Water Content of Soil and Soil-Aggregate by Nuclear Methods (Shallow Depth).*

3-12.2.11 Adjustments to Quality Control/Quality Assurance Operations.

Document and discuss any deficiencies noted during test section construction or post-construction inspection and testing techniques. Hold meetings between the contracting officer and the contractor to review the test section results. Agree on actions to address and resolve deficiencies before commencing production pavement construction. Consider making any necessary changes in the CQC plan and operations.

CHAPTER 4 SUBGRADE PREPARATION

4-1 INTRODUCTION.

The subgrade provides the foundation for the entire pavement system. Uniformity and stability of the subgrade affect the long-term performance of the pavement and the construction process. Subgrade stability is needed to provide adequate support of the pavement section and to provide an acceptable construction platform. Pavement design begins with identification of the pavement foundation. Construction begins with foundation preparation. Important elements of subgrade preparation include evaluating subgrade stability, subgrade modification to improve stability, and evaluating surface tolerances. A geotechnical engineer experienced in subgrade preparation can address issues with:

- Variability of soil condition
- Soil with low bearing strength, ≤ 96 kPa (1 ton/square foot [tsf])
- Organic soil
- Swelling/expansive soil
- Frost-susceptible soil

Implement all measures within the limits of construction to control water pollution, soil erosion, and siltation as shown on the plans or required by applicable permit. Follow all pertinent local, state, and federal laws.

4-2 GRADING AND COMPACTING SUBGRADE.

4-2.1 Grading.

4-2.1.1 Pre-Grading Activities.

Mass grading is the first phase of subgrade preparation. It removes high points and fills low areas to achieve the desired finish elevation. The cut/fill items are typically addressed in the design phase of the project. Construction staking is the second phase of pre-grading. It is a good practice for the owner/engineer to perform an independent verification of the staking accuracy. Automated grading equipment using global positioning is commonly used to establish the grade. If these systems are employed, it is a good practice to periodically verify the results through the use of conventional surveying. Important items to consider include the following.

a. Fill material is usually obtained from cut operations. Use the geotechnical report to evaluate the potential of this material for engineered fill.

b. If the in-place material is not of sufficient quantity or has unacceptable material properties, identify alternate borrow areas to source fill material.

c. It is incumbent upon the contractor to inform themselves regarding local subgrade conditions related to pre-grading and other construction activities.

4-2.1.2 Removal of Unsuitable Subgrade.

When preparing the grade, unsuitable soil can be encountered. Materials such as peat, organic silt, silt, and soil with high organic content are classified as unsuitable. To deal with these materials consider the following actions:

- Remove and replace with soil similar to the surrounding subgrade.
- Remove and replace with granular material.
- Alter the properties through compaction or stabilization.

4-2.1.3 Protection of Grade.

During grading operations, protect the grade by performing two essential activities, as follows.

1. Provide temporary drainage: trenches, drains or ditches necessary to divert or intercept surface water. If water ponds on the subgrade, the material softens and is damaged by construction traffic. This results in delays and the need for repairs.
2. Implement procedures to manage site traffic over the grade. Do not use channelized traffic patterns over one portion of the grade. Make sure the traffic is distributed over the grade.

4-2.1.4 Grading Operations.

Grading operations for a concrete pavement may require an embankment.

a. The embankment is constructed by placing material in successive horizontal layers for the full width of the cross-section.

b. Most specifications include a maximum loose depth of fill placement. Using thicker fill layers requires a contractor to demonstrate to the engineer that the thicker fill layer can be compacted to the specified density.

c. During construction of the embankment, hauling equipment needs to travel evenly over the entire width of the embankment. If equipment travel is channelized, permanent deformation and shear failure can occur.

d. In the construction of embankments, begin layer placement at the deepest portion of the fill. As placement progresses, construct layers approximately parallel to the finished pavement grade line.

e. In areas where subgrade transitions occur, mix the subgrade materials by disc at the boundary of the transition zone. Perform subgrade mixing over a distance of about 30 m (100 ft) along the transition zone (15 m [50 ft] on either side of the transition). This practice reduces the potential for differential settlement or frost heave.

4-2.2 Compaction.

4-2.2.1 Compaction Requirements.

Subgrade compaction is essential to building a stable work platform. Due to the weight of construction equipment, it is good practice to compact all subgrade materials to 95 percent of the maximum density using the modified Proctor test (ASTM D1557/CRD-C 162); this helps provide a stable working platform. Field density control is a full-time function. This allows observation of the material as it is placed. If the material appears to change, one-point field Proctor tests are used to check the maximum density. Typical compaction requirements are as follows.

a. Use the modified Proctor test (ASTM D1557/CRD-C 162) to determine the maximum density for pavements trafficked by aircraft/vehicles greater than 27,215 kg (60,000 lb) in weight. Use the standard Proctor test (ASTM D698/CRD-C 653) for lighter aircraft/vehicles.

b. Cohesive soil use in fill sections: When a cohesive soil (plasticity index [PI] greater than 5 or a liquid limit [LL] greater than 25) is used, compact the entire fill to 90 percent maximum density.

c. Cohesive soils in cut sections: Compact the top 150 mm (6 in.) to 90 percent maximum density.

d. Cohesionless soil use in fill sections: When a cohesionless soil (PI equal to or less than 5 and a LL equal to or less than 25) is used, compact the top 150 mm (6 in.) of fill to 100 percent maximum density, with layers below compacted to 95 percent maximum density.

e. Cohesionless soil use in cut sections: Compact the top 150 mm (6 in.) to 100 percent maximum density and compact the next 450 mm (18 in.) to 95 percent maximum density.

f. If the natural subgrade exhibits densities equal to or greater than the specified densities, no compaction is required other than that required for a smooth surface, usually with only surface rolling.

4-2.2.2 Moisture Control.

Moisture control is essential to obtain a stable subgrade. Adhering to the following requirements promotes maximum soil density.

a. Specifications for compaction usually require the moisture content in the subgrade to be within ± 2 percent of optimum moisture content before rolling to obtain the prescribed compaction.

b. For expansive soils, moisture content must be 1 to 3 percent above optimum before compaction to reduce swell potential.

c. For fine-grained soils that do not exhibit swelling properties, keep the moisture content at 1 to 2 percent below optimum.

d. Cohesive soils compacted wet of optimum can become unstable under construction traffic even when the target density is achieved.

4-2.2.3 Moisture Compaction Relationships.

Moisture density curves of typical soils can provide insight into field performance. In Figure 4-1, the shape of the curve suggests that clayey sand soil is moisture sensitive. A small change in moisture content results in compaction difficulty. Additional compaction-related items to consider include the following.

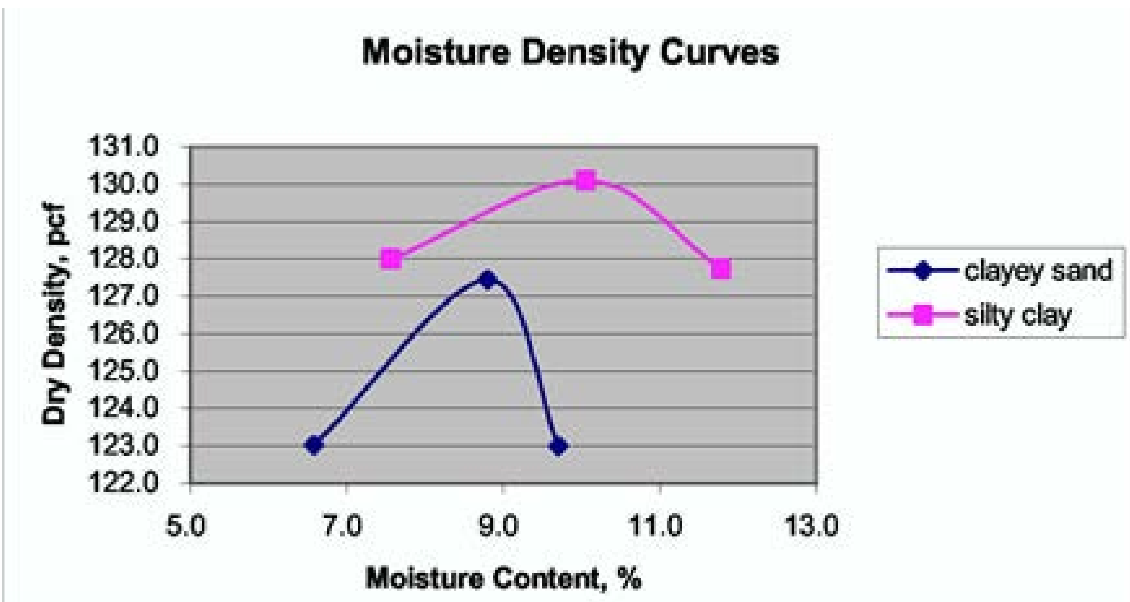
a. Use sheepsfoot rollers for cohesive soil. The pads must penetrate 70 percent of the lift thickness.

b. Discing of cohesive soil is necessary to control moisture.

c. Use static steel drum rollers to smooth the surface of the grade after compaction.

d. Use vibratory steel drum rollers for cohesionless soil. If the water table is close to the surface or if subgrade soils are saturated, use vibration with caution.

Figure 4-1 Typical Moisture-Density Curves.



4-2.2.4 Nuclear Density Gauge.

Nuclear density testing can check the density of the compacted soil. Calibrate gauges to local materials. If problems achieving density are encountered, use the following troubleshooting techniques:

- Perform additional moisture density testing to ensure the proper maximum density value is used to control field compaction.
- Use a sand cone or volume measure to perform the density tests.

- Use traditional methods to determine moisture content.
- Probe the subgrade to determine if soft layers are present below the problem area.

4-3 SUBGRADE STABILIZATION.

Subgrades are often stabilized for one of the following reasons: (a) to improve low strength soil, (b) reduce swelling potential, and (c) improve construction conditions. Unsuitable subgrade conditions can delay construction work due to the time required to implement appropriate measures. Having a stabilized subgrade facilitates staying on schedule. This is important on construction projects that require timely pavement opening to traffic. Find details on stabilization in UFC 3-250-11, *Soil Stabilization and Modification for Pavements*. If the site contains fine-grained soils, prepare a contingency plan for stabilization if unsuitable soils are encountered in localized pockets. Usually, fine-grained soils with unconfined compressive strengths of 190 kPa (2 tsf) or less present stability problems. For localized areas, consider the following procedures:

- Remove soft or disturbed material and replace with subgrade material from adjacent areas. This method works for surficial disturbance.
- Remove soft or disturbed material and replace with crushed stone. If the layer has a unconfined compressive strength less than or equal to 96 kPa [1 tsf]), use geotextile fabric to prevent intrusion of the subgrade into the stone layer.
- Place a geogrid over the soft area. Place and compact 250 mm (10 in.) of crushed stone on top of the geogrid to distribute the load to the subgrade.

4-4 ACCEPTANCE OF GRADE.

For unstabilized materials, consider scarifying, cutting, or filling areas to adjust the grade, if needed. With stabilized materials, filling in thin lifts is not possible. Therefore, with stabilized materials, construct the grade high and trim to final grade. For large projects, consider the use of an autograder or trimmer to minimize grade problems. Use the following criteria to accept a finished grade:

- Surface deviation: Maximum deviation of 10 mm (3/8 in.) (based on 3.6 m [12 ft] straightedge)
- Surface elevation: Maximum deviation of ±13 mm (0.5 in.)

4-4.1 Protection of Grade.

Once the grade is accepted, implement a traffic control plan. Heavy construction trucks traveling on the prepared surface can damage the grade. Enforce traffic management if logistics require use of the prepared grade by construction equipment. Smooth and re-compact all ruts or rough places that develop in a completed subgrade prior to placing the subbase.

4-5 ADVERSE WEATHER CONDITIONS

4-5.1 Drainage.

Implement provisions for drainage at each stage during the subgrade preparation. Maintain a positive slope to assure drainage. When the subgrade moisture content is above optimum, consider discing and drying to reduce the moisture content. If rain is expected after the subgrade is prepared for compaction, seal the subgrade surface using a rubber-tired or steel drum roller. If this is not done in time, serious problems can develop due to excess moisture in the subgrade.

4-5.2 Freezing Temperatures.

If a subgrade is subject to freezing, scarify the surface of the subgrade to a depth of at least 150 mm (6 in.) and re-compact. If the grade preparation was halted for winter, scarify the exposed subgrade surface to a depth of at least 150 mm (6 in.) and recompact prior to continuing grading the following spring.

4-5.3 Troubleshooting Guide.

Table 4-2 lists various subgrade problems, probable causes, and corrections.

Table 4-1 Troubleshooting Guide for Subgrades

Problem	Probable Cause	Corrective Action
Surface appears loose	• Low density	• Check moisture content and density • Re-condition to optimum moisture and re-compact area
Depressions or excessive movement under roller	• High moisture content • Weak layer under surface	• Check moisture content and re-condition to optimum moisture if high • Probe grade with DCP to find weak layer • Stabilize area
Surface varies from coarse to fine	• Segregation of imported material • Change of material	• Perform sieve analysis to check gradation • Mix surface and re-compact

CHAPTER 5 BASE AND SUBASE CONSTRUCTION

5-1 INTRODUCTION.

The layer immediately below the pavement surface is the base course. The term subbase designates layer(s) below the base and above the subgrade.

5-2 SUBGRADE PROTECTION.

Subbase and base course granular layers left exposed over a winter in a wet-freeze region can cause softening of the subgrade. Cover these layers with the pavement. If this is not possible, use caution when resuming construction. Construction traffic can make a subgrade unstable.

5-3 SUBBASE COURSE.

Subbase materials are generally granular materials that are natural material or crushed. Their stability in CBR values ranges from 20 to 100. These materials are generally used as subgrade protection layers (frost protection) or to provide drainage above the subgrade. In frost areas, limit the percent of the material less than 0.075 mm (passing the No. 200 sieve) to 3 percent. Important elements for subbase placement include the following.

a. Start placement along the centerline or high point to maintain drainage during construction.

b. Perform placement using automated equipment or a stone box on a bulldozer.

c. Develop moisture density relationships in the laboratory using the modified Proctor test (ASTM D1557/CRD-C 162) for aircraft/vehicle traffic greater than 27,215 kg (60,000 lb) in weight. Use the standard Proctor test (ASTM D698/CRD-C 653) for lighter aircraft/vehicles. Moisture control is critical to achieving compaction. It is the best practice to keep material within 1 percent of the optimum moisture. For free-draining subbase materials, consider a lower moisture content to avoid adding excess water to the subgrade during compaction of the subbase.

d. Layer thickness must be three to four times the largest aggregate size. A layer thickness close to the largest aggregate size adversely affects density, grading, and smoothness.

e. Prior to subbase placement, evaluate the subgrade for stability. Repair any soft areas.

f. Implement traffic management in front of placement to eliminate potential problems.

g. Nuclear gauges are permitted to monitor subbase density.

h. Verify density values using one-point tests at the delivered moisture content. Perform one-point tests twice a day.

i. The grade tolerance for subbase is 13 mm (0.5 in.) using a 4.8-m (16 ft) straightedge.

- Laser auto-graders or auto-trimmers are recommended on larger projects.
- For projects where automated equipment cannot be justified, it may be necessary to relax the surface tolerances.

j. Once the subbase layer is placed, protect the surface.

- Provide drainage so water does not pond on the surface.
- If dry conditions prevail, watering may be necessary.

k. Rolling can be accomplished with vibratory drum rollers. If compaction is difficult, use rubber tire rollers, as the kneading action of wheels aids in compaction.

5-4 BASE COURSE.

A good base course is important to avoid or minimize construction difficulties. Base course materials are similar to subbase materials, but are usually of higher quality in terms of crushed aggregate content, deleterious material, and gradation. The requirements for bases under rigid concrete pavement are less restrictive than for flexible pavements. Therefore, the designer must select the correct requirements and guide specifications for concrete pavements. The requirements for proof rolling of the completed base course are given in UFC 3-260-02. The critical elements for placement of a base course are the same as those described for subbase materials. In addition, consider the following items.

a. Check the underlying course (subgrade or subbase) before placing and spreading the base course. Correct and compact any ruts and soft or yielding areas (due to improper drainage conditions, hauling, or any other cause) to the required density before placing the base.

b. Do not place the base if the underlying course is wet, muddy, or frozen.

c. Suspend work on the base course during freezing temperatures or if the base material contains frozen material.

d. Use vibratory rollers, rubber tire rollers, and static wheel rollers for compaction of base material. With some material, the vibratory roller may be used alone to obtain compaction and a smooth, even surface.

e. Grade tolerance for base layers is 10 mm (3/8 in.) across a 4.8 m (16 ft) distance. Automated placement methods are usually required to attain the tight tolerances.

5-5 CHEMICALLY STABILIZED BASE COURSES.

DoD does not require stabilized base courses under concrete pavements. The need for stabilization is determined on a project-by-project basis. There are several types of stabilized bases. Cement stabilization is the most commonly used stabilizer, although asphalt cement, lime, or other materials are also used. The properties and qualities of a cement stabilized material depend upon the amount of cement added. The strength and stiffness of the stabilized layer will increase with increasing amounts of cement. The stiffness of stabilized base layers has an impact on the performance of concrete pavements. They affect the curling/warping behavior of a slab and they increase the restraint on the slab during the initial curing period. With higher amounts of cement, the stiffness of a lean concrete base can be extremely high. The result is an increased potential for random cracking, reflective cracking, or cracking due to unsupported edges of the pavement slabs. However, a well-designed and -constructed stabilized base increases the fatigue life and improves the constructability of a concrete pavement. Details are available in UFC 3-250-11.

5-5.1 Material Cautions.

Lean porous concretes such as cement treated base (CTB) courses are more susceptible to sulfate attack than pavement concretes. During the design phase of the project, consider investigating possible detrimental effects on the CTB caused by sulfates present in the soil, groundwater, or aggregates. Cover a CTB layer with the pavement layer before winter or a freezing event. If a CTB layer must remain exposed, it must first attain its design strength. Before construction resumes in the spring, check the grade.

5-5.2 Strength.

The primary issue with lean concrete is the strength of the mixture. If the compressive strength is greater than 10 MPa (1,500 psi), the flexural strength is greater than 2.5 MPa (350 psi), or the amount of material passing the 0.075 mm (No. 200) sieve is 15 percent or less, the material is a lean concrete rather than stabilized material. Restrict traffic on lean concrete until attaining a compressive strength of 2,400 kPa (350 psi).

5-5.3 Reflective Cracking.

As the maximum compressive strength achieved in the lean concrete increases, the potential for cracking, and therefore reflective cracking, increases. One method to counteract cracking is to design joints in the layer. The design of the jointing pattern in the lean concrete must match the joint pattern of the pavement or reflective cracking may occur. Take care to align the joints when placing the concrete pavement. Another method of preventing reflective cracking is by applying a double application of wax-based curing compound to the surface of the lean concrete. The double application reduces the potential for bonding between the lean concrete and the pavement and minimizes the potential for random cracking in the pavement.

5-6 DRAINAGE LAYERS.

By default, rigid pavement designs incorporate a drainage layer unless the existing subgrade is highly permeable. Normally, place the concrete pavement directly on the drainage layer. Drainage layers may be open-graded materials, either unstabilized or stabilized, with subgrade or asphalt cement, open-graded with a finer choke stone surface, or a rapid-graining material that limits fines but includes some sand-sized fraction to provide better stability under traffic. Construction on unstabilized open-graded materials may require special equipment and operations. Consequently, requirements for drainage layers must be clear in the project plans and specifications so the contractor can prepare a realistic bid. The common practice is to use cement or asphalt stabilized drainage layers. Match the porosity of the drainage layer to the anticipated needs for the quick evacuation of water. The design balances the need for stability against the need for porosity, with stability taking precedence. Drainage layers can increase restraint forces, resulting in early cracking. The use of unstabilized open-graded aggregate drainage layer is not recommended for pavements used by wide-body aircraft. These layers do not provide the necessary stability and construction-related problems (rutting due to construction traffic) are common. If an unstabilized open graded layer is necessary, place it deeper in the pavement structure to reduce stresses on the layer. The thickness of the drainage layer is typically 100 to 150 mm (4 to 6 in.) in thickness with no individual layer less than 75 mm (3 in.) in thickness.

5-7 CONSTRUCTION ISSUES.

Stabilized bases provide rigid paving platforms and uniform pavement support. However, they also have the potential to increase slab warping, curling, and frictional restraint forces on the concrete slab. This shortens the window of joint sawing opportunity and increases the potential for random cracking in the pavement. The designer must consider these issues in the joint layout and construction specifications of a concrete pavement on top of a stabilized base course. For cement stabilized materials, an application of a double coat of wax-based curing membrane or a geotextile will reduce restraint. If the surface is trimmed after curing, apply another coat of curing membrane. As the strength of a cement stabilized layer is increased, reduce the joint spacing of the pavement and saw cut joints as soon as possible.

5-8 TROUBLESHOOTING GUIDE.

Table 5-1 provides a list of various stabilized base problems, the probable causes, and suggested corrective actions.

Table 5-1 Troubleshooting Guide for Stabilized Base Courses

Problem	Probable Cause	Corrective Action
Granular base and subbase: surface appears loose	• Low density • Layer (lift) too thick for compaction • Insufficient rolling	• Check moisture content and density. • Re-condition to optimum moisture and re-compact area.
Granular base and subbase: depressions or excessive movement under roller	• High moisture content • Weak layer under base or subbase	• Check moisture content and re-condition to optimum moisture if high. • Probe grade with DCP to find weak layer. Stabilize area.
Bird baths on finished grade	• Improper grade control	• Perform grade survey and correct deficient areas

CHAPTER 6 CONCRETE PAVING PREPARATION

6-1 INTRODUCTION.

This chapter discusses pre-paving construction items, including grade control and acceptance, concrete plant operation inspection, and paving equipment inspection. Addressing these items early on may help avoid problems associated with concrete quality, pavement thickness, and concrete placement and finishing operations. The following critical elements should be in place before production paving starts.

- Check all equipment in the paving train to assure it is operational.
- Verify that an acceptable length of grade is available for concrete paving.
- Check that approved test reports are available for all materials in storage at the job site and the plant site.
- Verify that backup testing equipment is available. Develop extra equipment backup plans.
- Verify that all necessary concrete placement tools are available, such as hand tools, straight edges, hand floats, edgers, and hand vibrators.
- Verify that extra vibrators and joint-sawing equipment are available in case the original equipment breaks down during construction.
- Verify that radio/telephone communication with the plant is operational.
- Verify that equipment is available to water the grade, if necessary.
- Monitor the string line regularly and re-tension as necessary.
- Verify that the day’s work header is in place (needed or just saw off excess).
- Develop an extreme weather management plan.
- Check the weather forecast for each day of paving.
- Make sure a sufficient length of plastic covering is available in case of sudden and unexpected rain.
- Verify positive drainage within the plant site.

6-2 GRADE ACCEPTANCE.

The grade is accepted after the base layer is placed, trimmed, leveled, and compacted. Proper base grade ensures that nominal pavement thickness is achieved and final profiles and elevations are consistent with contract documents. The following are grade issues to check.

a. Check elevation tolerances for each pavement layer. Elevations and tolerances are shown on plans for the compacted subgrade, stabilized and non-stabilized layers, and top of pavement.

b. Consider the following items prior to paving:

- Effect of grade on as-placed concrete volume; materials cost impact if final grade is low.
- Effect of grade on pavement thickness variability. If final grade is variable, it will affect thickness determined through core sampling. Minimize concrete thickness variability as it may affect payment for thickness.
- Remove loose debris on the base before paving.

c. Proper base grade control is critical, as it affects drainage during construction and the service life of the pavement.

6-3 CONCRETE PLANT OPERATION.

Concrete is a manufactured product, whose quality and uniformity are sensitive to quality control variation during manufacture. A plant must be in good condition, operate reliably, and produce acceptable concrete uniformly from batch to batch.

6-3.1 Quality and Uniformity.

Concrete quality and uniformity are greatly affected by aggregate segregation and varying moisture content of the aggregates. Batch plants and equipment must meet ASTM C94/CRD-C 31. Key items listed in ASTM C94/CRD-C 31 for batch plants are as follows.

- Separate aggregate bins for each size coarse aggregate with a capability of shutting off material with precision.
- Controls to monitor aggregate quantities during hopper charging.
- Scales accurate to ± 0.2 percent tested within each quarter of the total scale capacity. Adequate standard test weights for checking scale accuracy should be available.
- Cement and water added to an accuracy of ± 1 percent of the required total mass.
- Aggregate added to an accuracy of ± 2 percent of the required total mass.
- Admixture added to an accuracy of ± 3 percent of the required total mass.

6-3.2 Pre-production Inspection.

The engineer should inspect the concrete plant before the start of paving using the National Ready Mixed Concrete Association (NRMCA) checklist in *Certification of Ready Mixed Concrete Production Facilities*. Inspect plants before the start (or re-start) of each paving project and when uniformity or strength problems are encountered during production. The concrete plant inspection should include the following:

- Check foundations of stockpiles for proper separation and adequate drainage.
- Check bins for adequate partitions to prevent intermingling of aggregates.

- Check scales with test weights throughout range to be used.
- Check scales for seals by approved agency.
- Check water meter for accuracy.
- Check for leakage of lines.
- Check capacity of boilers and chillers if their use is anticipated.
- Check admixture dispensers for accuracy.
- Check mixers for hardened concrete around blades.
- Inspect concrete hauling units for cleanliness.
- Check to ensure all concrete-making materials have been certified and approved for use.
- Observe stockpiling operations; verify that segregation and contamination will not occur.
- Observe charging of the bins; verify that segregation and contamination will not occur
- Review aggregate moisture tests.
- Observe batching operations at start and periodically during production.
- Check scales for zeroing.
- Check to ensure proper batch weights are set on the scales

6-3.3 Traffic Flow.

Optimize the traffic flow at the plant. Consider the following:

- Delivery of raw materials.
- Delivery of concrete to the paver.
- CQC/QA-related traffic operations and testing personnel safety.
- Operation of equipment for managing the aggregate stockpiles.
- Plant safety requirements.

6-3.4 Managing the Aggregate Stockpile.

Develop and implement stockpile management procedures. Procedures must address construction of stockpile storage pads, keeping loader buckets off the floor, truck unloading, maximum stockpile heights, bin charging, quality control sampling, water sprinkling, aggregate washing, and aggregate moistures. The following are key items related to aggregate stockpile management.

a. Handle and store aggregates in a way that minimizes segregation and degradation and prevents contamination by deleterious substances.

b. Closely monitor and maintain aggregate stockpiles to keep moisture content at or above saturated surface dry condition. This is particularly important for absorptive aggregates used during hot weather.

c. If aggregate moisture varies throughout the day, increase the frequency for determining moisture content. Moisture content variability increases when loaders retrieve aggregates from one area of the stockpile or if water-sprinkling of stockpiles is not uniform.

d. The water added at the mixer must be adjusted for the moisture of the aggregate. In hot weather, use of chilled water may be considered.

e. Limit the aggregate drop height when building up a stockpile. Build stockpiles up in layers of uniform thickness. When removing aggregate from a pile (with a front-end loader), remove the material vertically from bottom to top so that each load contains a portion of each layer.

f. Stockpiles should be separated from one another. If there is not enough space between them to keep size fractions separate, use a wall.

g. Bulldozers should not be allowed on stockpiles because they break down the aggregate and segregate the particle sizes.

h. Proper stockpile management reduces the likelihood of aggregate contamination. Contamination generally occurs when clay and mud are tracked with trucks unloading aggregates. Aggregate contamination can also occur if aggregates are not unloaded onto belt placers but stockpiled by end loaders. Stabilize haul roads and dump area to minimize aggregate contamination from trucks. Aggregate contamination may also occur if loaders charging aggregate bins scrape the bottom of the pile.

i. Visually examine stockpiles for segregation. If apparent, perform gradation testing from representative areas of the stockpile to verify segregation. Reject segregated material.

6-3.5 Concrete Uniformity Testing.

Conduct concrete uniformity testing before the start of paving. Uniformity testing establishes minimum mixing times. Truck mixers must meet ASTM C94/CRD-C 31. Uniformity tests compare differences in concrete sampled at approximately 15 percent and 85 percent drum discharge. Differences between concrete discharged at 15 percent and 85 percent should be less than the maximum allowable differences stated in ASTM C94 for five of six tests. Test batch (stationary) plants in accordance with CRD-C 55. This test method differs from ASTM C94 in that it requires three samples from an individual batch. Minimum mixing times for production are established by the concrete uniformity tests. The six tests required for each method are:

1. Density (unit weight)
2. Air content
3. Slump

4. Coarse aggregate content
5. Air-free mortar unit weight
6. Seven-day concrete compressive strength

6-4 PAVING EQUIPMENT ISSUES.

Check the paving equipment for the following:

a. Check availability of required pieces of equipment. For example, the number of trucks hauling concrete will affect slipform production rates. In the event of mechanical breakdown, extra equipment (such as concrete saws) should be onsite.

b. Ensure equipment is in proper working order. The equipment requiring inspection include concrete haulers, concrete placers, concrete spreaders, slipform pavers, curing/texture rigs, and sawcutting equipment.

c. Inspect slipform pavers to ensure they achieve proper consolidation through vibration. Check vibrator frequency and amplitude prior to paving. Spud vibrators under no load must have a frequency of no less than 135 Hz (8000 vibrations per minute) and an amplitude of 0.75 mm (0.03 in.), as determined in CRD-C 521. Tube vibrators under no load must have a frequency of no less than 80 Hz (5000 vibrations per minute) and an amplitude of 0.75 mm (0.03 in.). Establish vibrator elevations that do not interfere with pre-placed dowel baskets.

d. Check curing application equipment to ensure a uniform and proper application of curing compound.

e. Blades for joint sawing must be suitable for the aggregate type used in the mix.

6-5 STRINGLINE ISSUES.

The accuracy of the elevations and offset distances for grade reference points is important to the final smoothness of the pavement surface. These elevations and offsets provide the basis for establishing the stringline. The stringline provides an accurate reference for elevation and alignment control of the grade trimming, subbase/base placement, and concrete paving train. The final product reflects any error in the stringline. Setting up the stringline takes careful planning. The interval between stakes is important, particularly on vertical curves. On tangent sections, a maximum staking interval of 7.6 m (25 ft) will usually result in a good product. A tighter interval is necessary to produce smooth pavements on vertical curves and is based on the rate of change of curvature.

6-5.1 Stringline Aids.

The following aid in establishing a proper stringline:

- Use rigid stakes

- Use quality line
- Avoid knots and splices
- Prevent perceptible sagging
- Eyeball for staking errors and irregularities
- Monitor, protect, and maintain line
- Adjust stake spacing to fit conditions

6-5.2 Stringline Type.

Stringline materials and their properties and behaviors are listed:

- Braided nylon (polyester, Kevlar, polyethylene) line
    - Typically, 3 mm (1/8 in.) diameter braided string
    - Lightweight, but good pull strength
    - Does not crimp like wire
    - Does not result in hand injury (cuts)
    - Develops a sag
    - Has a stretch over time
    - Requires frequent monitoring
- Aircraft cable
    - Typically, 2.5 mm (3/32 in.) galvanized cable
    - Splicing not as simple as nylon string
    - Less sag
    - Less affected by weather (humidity)
    - Less stretching over time

CHAPTER 7 CONCRETE MIXTURE

7-1 INTRODUCTION.

Concrete mixture design considerations are discussed in this chapter. The quality of concrete is usually defined in terms of workability, strength, and durability. Strength requirements are often mistakenly emphasized above quality requirements because concrete strength is an important component of the pay schedule. It is preferable to optimize all three aspects of concrete quality. Specific information on concrete mixture design is in TSPWG M 3-250-04.97-05, *Proportioning Concrete Mixtures with Graded Aggregates for Rigid Airfield Pavements*.

7-2 CONCRETE HIGHLIGHTS. `

Concrete is a two-component mixture: aggregates and paste. In this mixture, the aggregate particles are completely coated with the paste. The paste consists of cementitious materials and water and incorporates entrapped air or purposely entrained air. Aggregates make up about 60 percent to 75 percent of the total volume of concrete. The quality of the concrete depends on the quality of the aggregates and paste and the bond between the two. The quality of the paste is significantly influenced by the amount of water used. Typically, less water improves the quality of the concrete. A maximum w/cm ratio is typically specified to avoid excess water and ensure good quality paste is achieved. Cleanliness of the aggregates also influences paste/aggregate bond and the quality of the concrete. The properties of freshly mixed (plastic) concrete are changed by adding chemical admixtures to the concrete, usually in liquid form, during batching. Chemical admixtures are commonly used to improve or control the following attributes:

- Workability
- Entrained air
- Water demand
- Setting time
- Other properties

7-3 CONCRETE MIXTURE REQUIREMENTS.

A 90-day flexural strength is specified for airfield and heavy-duty pavement design purposes. However, this can be reduced to 28 days if required and approved by the Service-specific TSPDWG representative. A 28-day flexural strength may be specified for roads. Compressive strength testing can be used for field acceptance of strength provided correlations between compression and flexural tests have been developed. Project-specific correlations are developed during the concrete mix design phase. Seven-day compressive strength testing is performed for QC and 14-day testing is performed for QA. Requirements are established for aggregates (coarse and fine), cementitious materials, admixtures, concrete mixture design, and concrete acceptance. The following are a few of the required attributes for concrete used for airfield and heavy-duty pavement:

- Maximum design flexural strength cannot exceed 650 psi (4.5 MPa) at 90 days. Actual field measured strength may be higher.
- Minimum cement content of 280 kg/m^3 (470 lb/yd^3) and 310 kg/m^3 (517 lb/yd^3), if pozzolan is used.
- Maximum w/cm ratio of 0.45. For severe sulfate exposure areas, the practice is to limit the w/cm ratio to 0.40.
- Maximum slump for fixed-form concrete is 50 mm (2 in.). Adjust slump for slipform concrete as needed to meet tolerances for smoothness, joint face deformation, and edge slump.
- Air content is based on exposure condition and the maximum aggregate size.
- Fine aggregate fineness modulus between 2.5 and 3.4.

7-4 LABORATORY MIXTURE DESIGN PROCESS.

The following is a discussion of the procedure for proportioning concrete mixtures adapted from the Portland Cement Association (PCA) mixture design procedure.

a. Obtain required information (for example gradation, absorption, specific gravity) for the materials to be used.

b. Identify project requirements for maximum w/cm ratio, nominal air content, slump, sulfate resistance, and strength.

c. Choose slump. For slipform paving, it must be in the 13 to 38 mm (0.5 to 1.5 in.) range to minimize edge slump.

d. Choose maximum size of aggregate. Use the largest size of aggregate that is economically available and can be placed and consolidated.

e. Estimate mixing water and air content.

f. Select w/cm ratio. Determine the w/cm ratio needed to meet the requirements for strength and durability. It may need to be lower to resist sulfate attack.

g. Calculate cementitious materials content. Estimate the proportions of the various cementitious materials used according to the properties desired.

h. Estimate coarse and fine aggregate contents.

i. Adjust for aggregate moisture condition.

j. Conduct trial batches. These will determine the exact proportions of desired properties to obtain as well as the admixture dosages required. The admixture dosages may require adjustment to achieve the required air content and slump when the laboratory batch is scaled up to the sized field batch.

7-5 MIXTURE DESIGN ISSUES.

Mixture design procedures typically do not directly address concrete workability. They do, however, indirectly attempt to define workability in terms of the slump test. The slump test is not a true indicator of concrete workability, especially for slipform concrete. The contractor must recognize that in addition to designing the mixture to meet the requirements of strength, slump, and air, the mixture must be designed to ensure workability for the given mixture characteristics, the project paving equipment, and expected ambient conditions at time of paving. Mixture design requirements do not address the issue of aggregate gradation. There may be conflicting requirements related to allowable fine aggregate gradation in terms of material passing the 0.3 and 0.15 mm (No. 50 and No. 100) sieves and also with respect to the fineness modulus. The contractor must review these requirements at the time of the concrete mixture design phase. ASTM C33/CRD-C 133 provides guidance.

7-5.1 Mix Design Guides.

The following are general guidelines to use when developing a mix design.

a. Develop mixes with different w/cm ratios to establish sensitivity of flexural strength with a slight change in w/cm ratio (establish a 3-point curve).

b. Monitor slump loss during trial batching. Excessive slump loss (25 mm [1 in.] in 15 minutes) may indicate false setting or a material incompatibility problem.

c. Conduct early-age strength tests (at 3, 7, and 14 days) to evaluate potential problems for 28 days.

d. Monitor a well-insulated concrete cylinder temperature during the first 12 hours. A temperature increase of less than 10 °F (Δ5.5 °C) may indicate a retardation due to material incompatibility.

e. Concrete for hot weather placement should contain less cement and more supplementary cementitious materials, preferably Class F fly ash, calcined clay, or slag. Trial batches for hot-weather concreting also must include the use of retarders to verify the dosages and their effects on setting time.

f. Concrete for cold weather placement must contain more cement and less of the slow-reacting supplementary cementitious materials (Class F fly ash, slag). If these materials are required for other purposes, such as control of ASR, the early strength can be obtained by increasing the total cementitious materials content using Type III cement, using warm water, or reducing the w/cm ratio. Trial batches for cold-weather placement must include accelerating admixtures to verify the dosages and their effects on setting time.

g. Trial batches must be tested for the range of temperatures anticipated over the project duration.

7-6 CONCRETE MIXTURE DESIGN ISSUES.

The best concrete mixture design results in a concrete with the following characteristics:

- Easily mixed, placed, consolidated, and finished under the job conditions.
- Attains the required compressive or flexural strength at the desired time.
- Will be durable in the service environment. The durability concerns often outweigh the limitations imposed by the strength requirements.

7-6.1 Workability.

Workability is an essential characteristic of concrete. Workability is the ease of placing, consolidating, and finishing freshly placed concrete without segregation. Workability is also typically and erroneously specified in terms of slump measurement. However, because of the many factors that affect today's concrete, slump is not considered an adequate measure of workability and the contractor should not rely on the slump measurement alone to assess the workability of the project concrete.

7-6.1.1 Factors Affecting Workability.

The concrete mix design process should not focus solely on meeting the strength and slump requirements; achieving acceptable workability is equally critical. Workability-related factors include the following:

- Segregation during transport and placement
- Ease of consolidation that will result in a well-distributed concrete matrix
- Well-formed slipformed edges with little or no edge slump
- Minimum hand-finishing required behind the paver to manipulate the surface for tightness and smoothness

7-6.1.2 Mixture Components Affecting Workability.

Obtaining the desirable workability for a given mix requires consideration of the following items:

- Aggregate: size, grading, particle shape, water demand, variability
- Cement: cement content, water demand
- Fly ash (if used): effect on initial set, water demand, effect on finishing
- Slag cements and GGBF slag: effect on finishing and saw cutting
- Water: total water demand
- Admixtures: air-entrained concrete exhibits better workability; water reducers reduce water demand while improving workability

7-6.2 Strength.

The pavement designer establishes the strength requirement for the concrete that meets the intent of the design. The strength requirement may be in terms of flexural strength or compressive strength at ages of 14, 28, or 90 days. The standard deviation for the strength needs to be established to provide guidance on the target strength levels to be achieved during the mixture design phase. The concrete also needs to be produced uniformly from batch to batch to keep the lot standard deviation as small as possible. A higher standard deviation for a lot may result in a reduction in the strength-related pay factor. Mixture designs must also be developed for hand-placed (fixed-form) areas. These mixtures have workability requirements different from mechanically placed mixes. However, the strength and durability requirements must be the same as the production concrete.

7-6.2.1 Weather Conditions.

For hot or cold weather placements, the heat of hydration is a concern. Trial batches must verify that the proposed mixes will achieve the desired strengths for cold weather placements and not generate excessive heat in hot-weather placements. Refer to paragraphs 8-16 and 8-17, respectively, for details on the specific concerns that must be addressed for hot and cold weather job conditions.

7-6.2.2 Fast Track Concrete.

The following list contains considerations and requirements for placement and use of fast-track concrete.

a. Although fast track paving does not necessarily mean high early-strength concrete, there are many situations when fast track concrete or high early-strength concrete may be specified or is necessary.

b. Fast track concrete is best suited for bridging the areas incorporating cross taxiways or high traffic volume apron areas.

c. The production of high early-strength concrete can be achieved using normal locally available concrete-making ingredients and conventional construction methods.

d. Typically, a conventional high early-strength concrete mix incorporates higher cement factor, optimized w/cm ratio, uniform aggregate gradation, and admixtures as needed. A Type III cement may also be considered.

e. There are no specific or unique mix designs for achieving high early-strength concrete. A wide range of mixes can be designed to meet project needs.

f. High early-strength concrete can be produced using proprietary cements and admixtures.

g. When high early-strength concrete is specified, the early age strength requirement is typically defined in terms of compressive strength, as follows:

- About 5 to 7 MPa (750 to 1,000 psi) in about four to six hours.
- About 14 to 21 MPa (2,000 to 3,000 psi) in about 24 hours.

h. There may still be a requirement to meet a specified flexural strength at 14, 28, or 90 days.

7-6.3 Sulfate Resistance.

The potential for severe sulfate attack exists when concrete is exposed to water-soluble sulfate (SO_4) in soil or water (as determined by CRD-C 403 and ASTM D516/CRD-C 408) in excess of 0.20 percent or 1,500 parts per million. The potential for moderate sulfate attack exists for sulfate contents in excess of 0.10 percent or 150 parts per million. If the soils or groundwater contain sulfates, the cementitious material(s) must be appropriately resistant to sulfate attack and the w/cm ratio needs to be reduced appropriately. Also, as previously discussed, use of pozzolans or slags should be considered. For sulfate resistance, the main consideration is the tricalcium aluminate (C_3A) content of the cement. A supplementary cementitious material with high CaO and aluminum oxide (Al_2O_3) contents, however, may effectively add to the C_3A content of the system, making it more vulnerable to sulfate attack. For DoD construction, test for durability per ASTM C88. The maximum limit of sulfate soundness loss is 12 percent after five cycles, or for magnesium sulfate, 18 percent after five cycles

7-6.4 Air Entrainment.

Concrete subject to freezing must contain a well-distributed system of finely divided air voids to protect it from frost damage. While the specifications typically provide a required volume of air as measured by ASTM C231/CRD-C 41 (pressure method) or ASTM C173/CRD-C 8 (volumetric method), these methods do not distinguish between a good air void system and a poor one. Consider the following items.

a. Produce trial batches to determine the correct dosage of the admixture for the conditions, including temperature, expected on the job site.

b. Typical air content requirements for pavements range from 5 percent to 7 percent, depending on exposure.

c. The volume of air required for frost protection increases with decreasing aggregate size because of the corresponding increase in paste content.

d. All other factors being equal, an increase in air content results in a decrease in concrete strength.

e. Test the air-void system parameters on the hardened concrete according to ASTM C457/CRD-C 42.

- An air-void spacing factor of 0.20 mm (0.008 in.) or less is necessary
- For concretes containing supplementary cementitious materials, an air void spacing factor of 0.15 mm (0.006 in.) or less is necessary.

f. Allow the trial batch concrete to sit for a length of time representative of the haul time and then measure at the end of that period to ensure that testing accounts for loss of air. When concrete is delivered to the site in non-agitating trucks, the loss of air can range from 1 to 2 percentage points.

g. In a no-freeze environment, if air is entrained solely to facilitate workability, the minimum air contents required for frost damage protection do not apply.

h. Typical slipform paving operations reduce air content by 1 to 2 percent during consolidation.

7-7 BLENDED CEMENT/SUPPLEMENTARY CEMENTITIOUS MATERIAL.

The judicious use of supplementary cementitious materials, either as components of blended cements or added at the mixer, can greatly enhance the properties of the concrete. Key issues related to the use of cementitious materials and blended cements are summarized below.

a. Class C fly ash is not permitted for paving concrete.

b. Slags contain sufficient calcium to have some cementitious properties of their own. The potential for early stiffening in the presence of certain water reducers and in hot weather can be verified as follows:

- Test the concrete by making trial batches at the highest temperature anticipated.
- Verify that slump loss is not rapid for the conditions of the job and that setting times are acceptable.
- If the concrete loses slump rapidly, consider reducing the dosage of fly ash, using a different fly ash, using a different cement, or using a different water reducer.

c. Class F fly ash and natural pozzolans react with water and calcium hydroxide from the hydration of subgrade cement to form calcium silicate hydrate.

d. The reactivity of the cementitious materials and the rate of strength gain of concrete containing them can vary significantly, depending on their chemical and mineralogical composition and on their firmness.

e. Purely pozzolanic Class F fly ash and natural pozzolans tend to produce a lower heat of hydration and lower strengths at early ages than subgrade cement.

f. Slag generally lowers the heat of hydration and the early-age strength.

g. Most supplementary cementitious materials increase the strengths at later ages.

h. Appropriate supplementary cementitious materials, appropriately used, can provide the following benefits:

- Reduce the tendency for thermal cracking by reducing the heat of hydration.
- Increase the strength (particularly at later ages).
- Reduce concrete permeability and diffusivity.
- Control expansions due to ASR and increase resistance to sulfate attack.

i. For a particular application, some supplementary cementitious materials are better than others, and some may be completely inappropriate.

j. Natural pozzolans can provide excellent performance, somewhat like Class F fly ashes.

k. If the aggregate selected is susceptible to ASR, consider incorporating a Class F fly ash to control it. The CaO content of the Class F fly ash should be less than 8 percent. Test the combination of aggregate, cement, and fly ash to determine the quantity of fly ash required.

l. Class F fly ash is considered to the most effective supplementary cementitious material for control of heat of hydration, control of ASR, and resistance to sulfate attack.

m. Some supplementary cementitious materials make things worse. Therefore, test each combination of cementitious materials, aggregates, and admixture.

n. Blended cements containing Class F fly ash, slag, calcined clay, or silica fume may also be used for control of heat of hydration, control of ASR, and resistance to sulfate attack.

o. If the available blended cement does not meet the requirements for control of ASR or sulfate resistance, incorporate additional supplementary cementitious material of the same or different kind at the mixer as necessary.

p. Ternary mixtures that contain three cementitious materials may offer the best alternative in some applications. For example, a Type IS cement may not be sufficient on its own for the required sulfate resistance, but the addition of either slag or Class F fly ash at the mixer can improve its performance.

7-8 MATERIALS INCOMPATIBILITY.

Some concretes exhibit undesirable characteristics because of incompatibility among different concrete materials. These undesirable characteristics include: (a) early loss of workability (early stiffening), (b) delayed set (retardation), (c) early-age cracking due to excessive autogenous and drying shrinkage of concrete, and (d) lack of proper air-void system. These incompatibility-related problems affect construction productivity and long-term concrete performance. As concrete mixtures become more complex with the use of supplementary cementitious materials and combinations of chemical admixtures, the likelihood of incompatibility among components increases. The problem is compounded because:

- Factors that result in incompatibility among various cementitious materials and admixtures are not well known.
- Material incompatibility may be induced by temperature changes. Therefore, test trial batches at the extremes of temperature anticipated at the project site.

7-8.1 Early Stiffening.

Early stiffening occurs when there are insufficient sulfates in solution at the right time to control the hydration of the aluminates. The early stiffening leads to loss of workability, as indicated by loss of slump. Workability loss leads to difficulties in concrete placement and consolidation. The tendency to early stiffening may be attributed not only to the individual cementitious materials, but also to interactions among the various cementitious materials and the chemical admixtures and ambient temperatures.

7-8.2 Retarded Concrete.

Although retarded concrete is not a common phenomenon, from time to time some paving projects experience concrete setting problems. At these projects, setting may be delayed by a few hours to more than 12 hours. A consequence of this problem is the inability to perform joint sawing in a timely manner, leading to uncontrolled cracking.

7-8.3 Shrinkage.

Premature cracking in concrete can be caused by a host of factors. Shrinkage can occur in the fresh (plastic) or hardened concrete. Plastic shrinkage cracking results as water rapidly evaporates from the surface of the fresh concrete. Cracking may also occur somewhat later in the life of the pavement due to excessive autogenous and drying shrinkage.

7-8.4 Air Void System.

Problems related to the use of certain air-entraining agents include:

- Accumulations of air voids around the aggregate particles, leading to strength loss
- A poor-quality air void system in the hardened concrete that affects long-term freeze-thaw durability

7-8.5 Reducing Incompatibility.

It is advisable to have hot and cool weather mixture designs in locations where seasonal differences in temperature are usually significant. Other steps to minimize incompatibility problems include the following.

- All admixtures used on a project must be from the same manufacturer to ensure compatibility among them. Do not exceed the recommended dosages.
- Ensure all cementitious materials meet project specifications and the requirements of appropriate ASTM/CRD standards.

7-9 AGGREGATE REQUIREMENTS.

7-9.1 Aggregate Grading.

The grading of the aggregate can have a substantial effect on the properties of the concrete mixture. The grading of the fine aggregate fraction is also important; too little fines make the concrete difficult to extrude and finish as well as more prone to bleeding; excess fines increase the water demand of the concrete and the required dosage of air-entraining admixture.

7-9.1.1 Well-graded Aggregate.

Concrete mixtures produced with a well-graded aggregate combination tend to:

- Reduce the need for water
- Provide and maintain adequate workability
- Require minimal finishing
- Consolidate without segregation
- Enhance strength and long-term performance

7-9.1.2 Gap-graded Aggregate.

Concrete mixtures produced with a gap-graded aggregate combination tend to:

- Segregate easily
- Contain more fines
- Require more water
- Increase their susceptibility to shrinkage
- Limit long-term performance

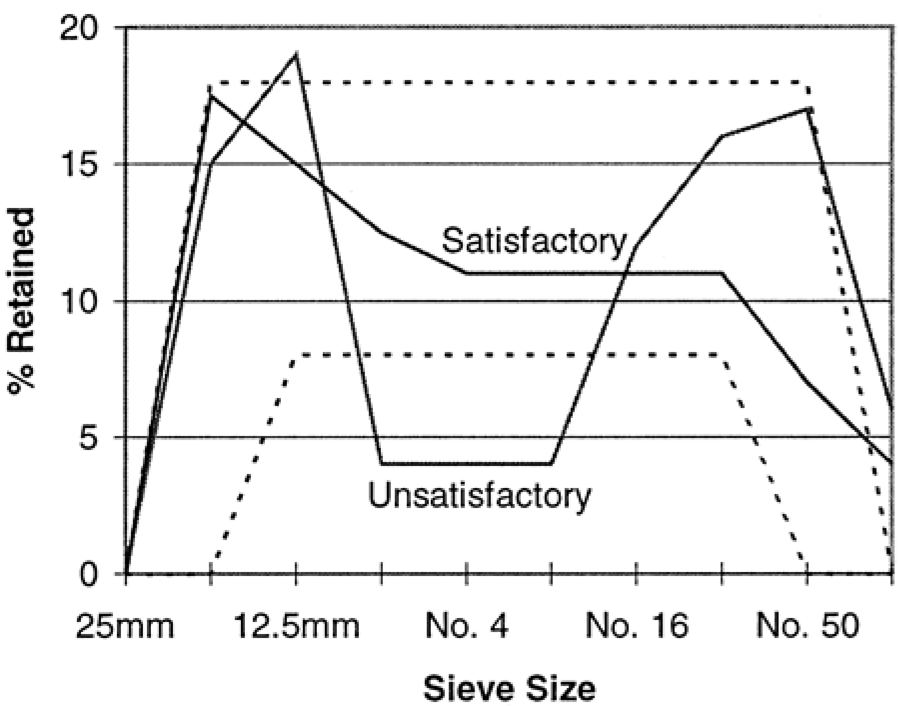
7-9.1.3 Combined Aggregate Grading.

Proportion the concrete mixture so the requirements for workability and finishability are met. Also, proportion the mixture as a well-graded combined aggregate such that the minimum requirements for air content and the water cementitious ratio are met.

7-9.1.4 Percent Combined Aggregate Retained Graph.

Grading reports should include the following sieve sizes: sieves used for the analysis include 50 mm, 37.5 mm, 25 mm, 19 mm, 12.5 mm, 9.5 mm, 4.75 mm, 2.36 mm, 1.18 mm, 0.6 mm, 0.3 mm, and 0.15 mm (2 in., 1 1/2 in., 1 in., 3/4 in., 1/2 in., 3/8 in., No. 4, No. 8, No. 16, No 30, No. 50, and No. 100, respectively). Plot the selected proportions for the combined gradation on a graph as the percentage retained for each reporting sieve size (y axis) versus the considered sieve size (x axis). The plot of the graph should be a line showing a relatively smooth transition between coarse and fine aggregate. The maximum and minimum percent retained limits, represented by the dotted lines in Figure 7 1, are a guide and the plot should not have no significant valleys or peaks between the 9.5 mm (3/8 in.) sieve size and the finest reporting sieve size. An example of the percent aggregate retained graph, including a satisfactory and unsatisfactory combined aggregate gradation plot, is shown in Figure 7-1.

Figure 7-1 Percent Combined Aggregate Retained



7-9.1.5 Coarseness Factor / Workability Factor.

Use the combined aggregate grading to calculate a coarseness factor and a workability factor. Determine the coarseness factor for a particular combined aggregate gradation by dividing the amount retained above the 9.5 mm (3/8 in.) sieve by the amount retained above the 2.36 mm (No. 8) sieve and multiplying the ratio by 100. The workability factor is the percentage of combined aggregate finer than the 2.36 mm (No. 8) sieve. Determine this factor by using the percentage passing the 2.36 mm (No. 8) sieve from the combined aggregate sieve analysis. Increase the workability factor by 2.5 percent for each 56 kg/m^3 (94 lb/yd^3) of cementitious material used in excess of the baseline amount of 335 kg/m^3 (564 lb/yd^3) of cementitious material. Only adjust the workability factor upwards, because 335 kg/m^3 (564 lb/yd^3) is the minimum amount of cementitious material permitted for rigid airfield pavement mix designs. The combined aggregate grading is used to calculate the coarseness factor and the workability factor as follows.

Equation 7-1. Coarseness Factor and Workability Factor

$$Coarseness\ Factor = 100\left(\frac{\%\ retained\ above\ 9.5\ mm\ \left(\frac{3}{8}\ in.\right)\ sieve}{\%\ retained\ above\ 2.36\ mm\ (\#8)\ sieve}\right)$$

$$Workability\ Factor = \%\ passing\ 2.36\ mm\ (\#8)\ sieve + 2.5\% *$$
$$each\ 56\frac{kg}{m3}\left(94\frac{lb}{yd3}\right) of\ cementitious\ material\ above\ 335\ kg/m^3\ \left(564\frac{lbs}{yd^3}\right)\ \ (7-9.1.5.)$$

The coarseness and workability factors are plotted on a chart similar to that shown in Figure 7-2. The coarseness factor should not be greater than 80 nor less than 30. The plot of the workability factor and the coarseness factor is a single point that is to be above the control line and within the workability box, as shown in Figure 7-2. Obtain the following information from an examination of where the aggregate mixture factors plot, as shown in Figure 7-2.

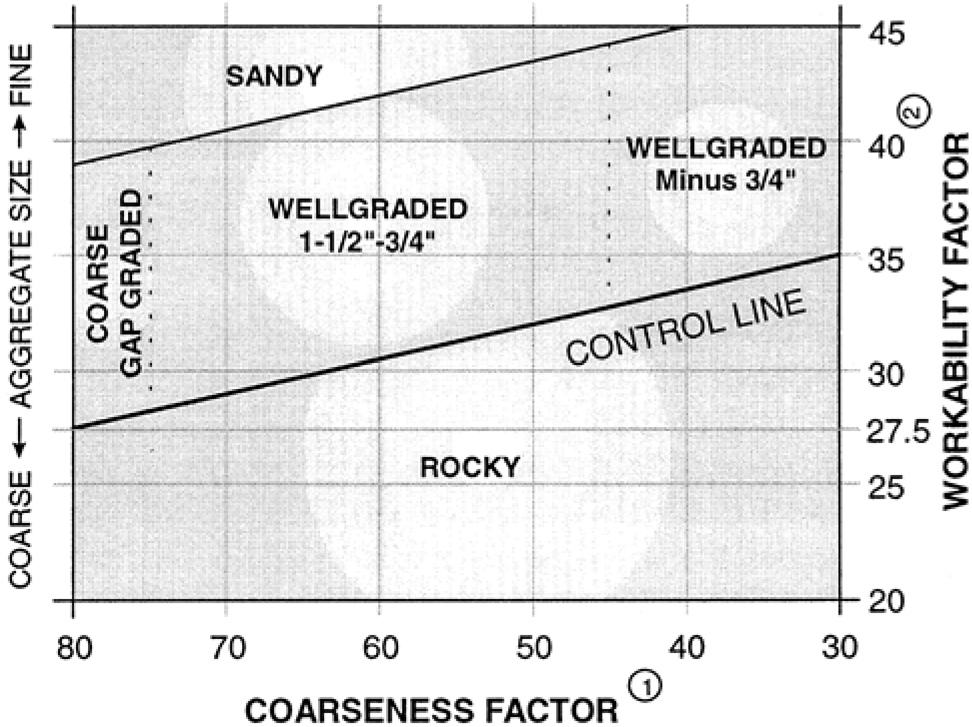
a. Aggregate blends that plot close to the bottom boundary line may tend to have too much coarse aggregate, producing rocky mixtures with inadequate mortar.

b. Aggregate blends above the top boundary line (Area D) will produce sandy mixtures with high amounts of fines requiring higher water content and potential for segregation.

c. Aggregate blends with coarseness factors higher than 75 (Area E) will produce gap-graded mixtures with inadequate workability and high potential for segregation.

d. For aggregate sizes less than 19 mm (0.75 in.), the areas will slide to the right within the given control lines.

Figure 7-2 Aggregate Proportioning Guide



7-9.1.6 Aggregate Proportioning Guide.

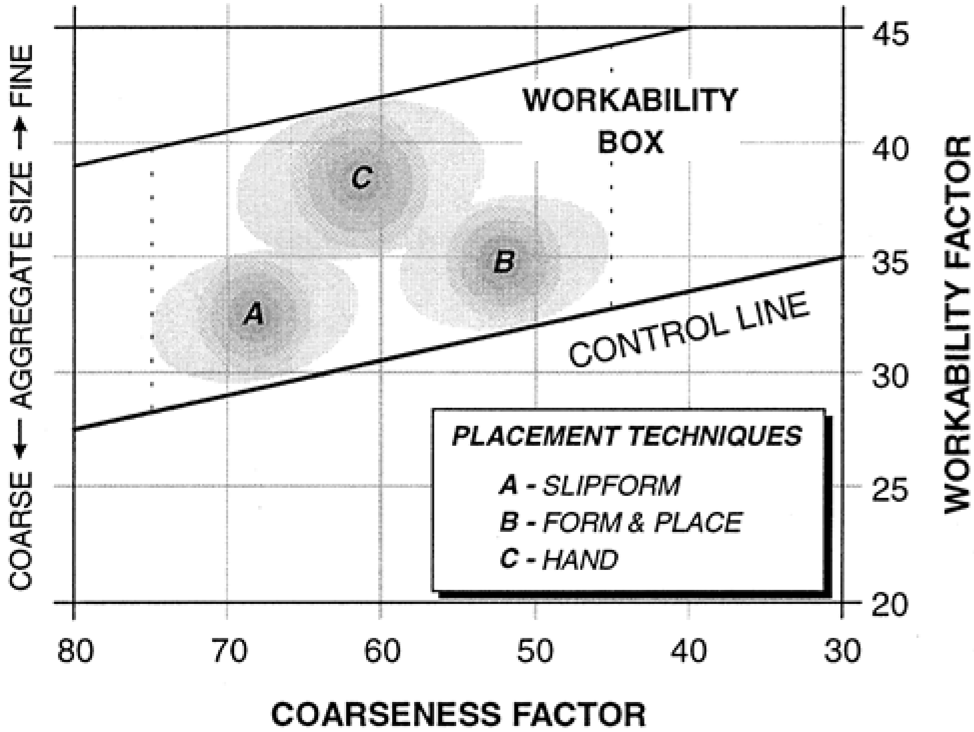
When a combined aggregate grading appears to meet the criteria of the percent retained graphic, then assess the location in the workability box that is best suited to the method of placement. Evaluate the workability factor and coarseness factor, as shown in Figure 7-3, as follows.

a. Aggregate blends that plot at the lower left of the box near the control line (Area A) produce mixtures suitable for slipform paving. However, based on texture and shape, aggregates falling in other regions of the chart can be acceptable for slipform paving.

b. Aggregate blends that fall at the lower right corner of the workability box (Area B) produce mixtures suitable for fixed form paving. This assumes that smaller aggregate sizes are needed to move the coarseness factor to a lower number and increase workability.

c. Aggregate blends that fall at the top of the box (Area C) produce mixtures suitable for hand-placed areas.

Figure 7-3 Workability Box within Aggregate Proportioning Guide



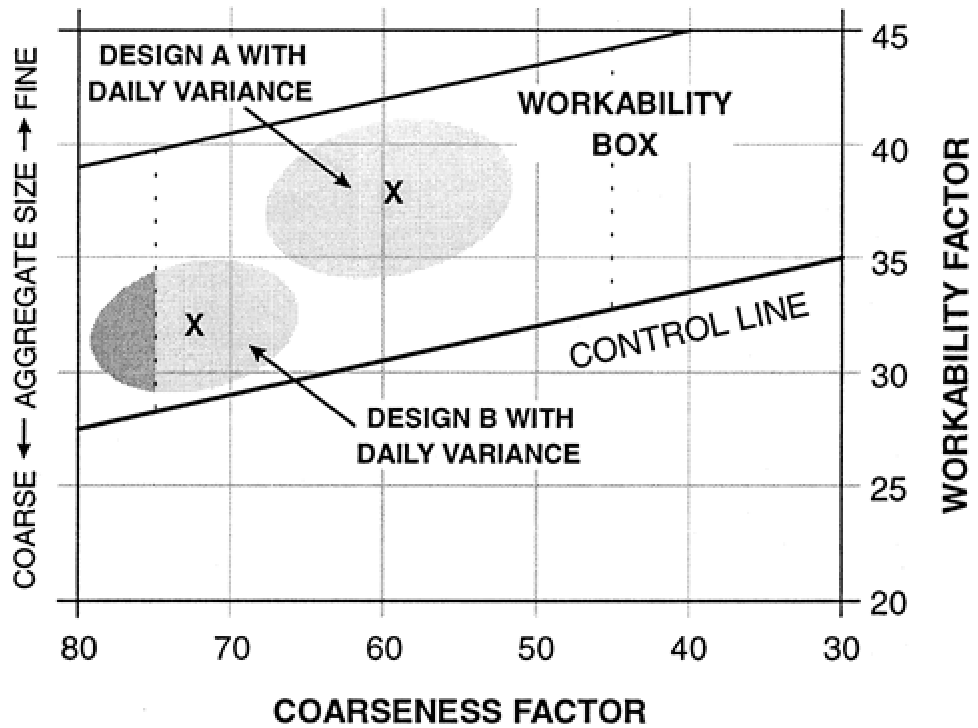
7-9.1.7 Controlling Factors.

The above criteria is not exact because the aggregate proportioning guide for grading does not take other “workability” factors into account. The shape of the fine aggregate particles will affect workability, but this is not reflected in the grading. When using the coarseness/workability chart it is assumed that particles are rounded or cubical shaped. Flat and elongated aggregates typically limit workability and finishing characteristics. Rounded or cubical shaped aggregates typically enhance workability and finishing characteristics. While the entrained air content directly affects workability, it is not considered in the aggregate proportioning guide. Chemical admixtures adjust the workability of the mixture and should not be neglected in the final selection of a concrete mixture for subgrade ability. Use the aggregate proportioning guide as a guide and not as a rule. It is necessary that the person doing the mixture proportioning be familiar with the method of placement and the characteristics of the mixture best suited to that method. In a similar fashion, the person evaluating the mixture proportioning study must balance the data presented and the results of previous paving projects. The final test, for both the contractor and the engineer, are the characteristics and the response of the mixture to the method of placement as observed at a test strip placement.

7-9.1.8 Gradation Variations.

An important consideration in selecting the final design aggregate grading, using the aggregate proportioning guide, is the location of the design grading relative to the expected daily variance of the concrete mixture materials. Changes in coarse, blend, and fine aggregate gradations could place the plot outside of the workability box, as illustrated in Figure 7-4. A normal variance of about 5 percent on the coarseness factor and about 3 percent on the workability factor should be considered in the final selection of an aggregate blend. Therefore, Design A would be a better choice than Design B, considering the daily variance.

Figure 7-4 Daily Variance within Workability Box for Aggregate Proportioning



7-9.1.9 Slag Aggregates.

Properly aged iron ore blast-furnace slag aggregates have a history of good performance. However, control of moisture content is important when slag aggregates are used. Potential problems include variations in workability and consolidation. If slag aggregate moisture is not managed well, the in-place concrete may exhibit honeycombing and poorly formed edges. **Note:** Never use slag from open hearth steel mills as concrete aggregate or for econocrete/lean concrete base because of the expansive nature of the steel slag aggregates.

7-9.1.10 Recycled Concrete Aggregates.

Recycled concrete, or crushed concrete, is a feasible source of aggregates if it meets the project-specific aggregate requirements. Recycled concrete generally has a higher absorption than virgin aggregates and may require more water to achieve the same workability and slump than concrete with virgin aggregates. Recycled aggregate may also require added cement to achieve desired workability. A potential problem with recycled aggregate is that the variability in the properties of the old concrete may affect the properties of the new concrete. Recommend evaluating recycled concrete aggregates by petrographic examination. Identify why the recycled concrete was removed. Do not incorporate problematic recycled concrete into new concrete mix. Recycled concrete cannot contain rebar.

7-10 FIELD ADJUSTMENTS OF CONCRETE MIXTURE DESIGN.

Shortages of cement or other concrete-making ingredients may occur during the construction season. If any changes in type, source, or brand of cementitious material, admixtures, or aggregate source need to be made, trial batches need to be carried out to verify the required properties are retained. Certain minor adjustments to the concrete mixture proportions may be necessary due to changes in the weather and to maintain the required workability and air content. However, if air content is increased or water is added above the design w/cm ratio, the concrete strength may decrease. Adjustments of admixture dosages are acceptable, provided the maximum dosages do not exceed the manufacturer’s maximum recommended dosage. The dosage of air-entraining admixture required to entrain a given volume of air will vary with the temperature of the concrete. If the required dosage was determined in the laboratory at 70 °F (20 °C), it can be decreased by approximately 30 percent for placement temperatures of 40 to 50 °F (4 to 10 °C) and increased by approximately 30 percent for placement temperatures of 100 to 110 °F (40 to 45 °C).

7-10.1 New Mixture Design Implementation.

If a new mixture design is developed because of changes in concrete materials, allow the contractor to proceed with paving once the early-age breaks indicate that the new mixture provides the specified strength at the specified age. It is advisable that the contractor use a higher strength mixture temporarily until all the new mixture strength results are available. Note that concrete strength is not the only criterion for the new mixture to satisfy. Required concrete characteristics include mixing, placing, consolidation, and finishing under the job site conditions. Verify setting times. If pavement construction spans more than one season, it is advisable to develop more than one mixture design.

7-10.2 Differences in Laboratory and Plant Mixing.

Note the following differences between laboratory and plant mixing.

a. Differences in the size of a batch and type of mixer produce different mixing efficiencies. It may be necessary to adjust chemical admixtures dosages to obtain the desired workability and air content.

b. Normal laboratory mixing procedures obscure any tendency of a concrete mixture to false set. A concrete mixture that behaves appropriately in the laboratory may false set when mixed in the batch plant. In the laboratory, test the slump after the initial three minutes of mixing and compare to the slump after final mixing to check the tendency to false set.

c. Temperature can significantly affect workability, water demand, slump loss, air content, and setting. Conduct laboratory mixture designs at the temperature(s) anticipated in the field.

d. Test the slump and air content every 10 to 15 minutes for a sufficient amount of time after initial mixing to simulate the longest anticipated haul time.

e. Long haul times may necessitate an initial air content higher than required at placement to compensate for the loss of air during transit.

f. Avoid mixture designs that are excessively sensitive to elevated placement temperatures, variations in aggregate moisture content, or slight variations in batching.

g. The manufacturer's maximum recommended dosage of water reducer should not be routinely required for acceptable workability in the laboratory, as there is no possibility of increasing the dosage in the field without affecting the setting time.

h. Closely monitor the concrete material properties as well as the fresh concrete properties during the early stages of a job to make quick adjustments if needed.

i. Perform 3-, 7-, and 14-day strength tests using field concrete. If results are not tracking the laboratory 3-, 7-, and 14-day results, then potential problems may exist. Stop the paving operation and redesign the concrete mixture. In this case, only a few days of concrete may potentially be of concern.

j. If plant mixture behavior differs from the laboratory mixture, causes may include:

- Ambient temperature
- Mixing time
- Material differences (laboratory materials are cleaner; different cement characteristics)
- Mixing process differences (drum vs. laboratory mixer)
- Aggregate moisture content
- Material charging differences

k. Hot (fresh from the mill) cement use during peak construction season may result in:

- Tendency to false set
- Admixture demand change; may need more in the field than in a laboratory

7-10.3 TROUBLESHOOTING GUIDE.

Observations and documentation are important tools to isolate and solve construction problems. Look for patterns that appear to connect cause and effect. For example, if everything works well until the weather becomes hot or a new shipment of cement arrives, the most recent change may be a clue to the root cause of the problem. Alternatively, if construction practices are marginal, the last change may simply tip the balance to unacceptable performance. In hot weather or cold weather, certain types of problems predominate. Paragraph 8-20 discusses common problems and possible remedies.

CHAPTER 8 CONCRETE PLACEMENT, FINISHING, TEXTURING, AND CURING

8-1 PAVING EQUIPMENT.

Paver-finishing machines accomplish concrete paving for mainline pavement and large fillets. Handwork areas are those areas too small to use a machine. Heavy and light pavers are used for machine paving. Slipform pavers are heavy machines. Only use light-weight machines, such as bridge deck finishers, clary screeds, truss screeds, or roller screeds if the contractor can show that they can produce satisfactory pavement with this type of equipment.

8-1.1 Slipform Pavers.

Slipform pavers can be used in side form applications by stretching the paver width beyond the forms. Slipform pavers can stretch to 14 or 15 m (45 to 50 ft), depending upon model and available attachments, but most are commonly used at 8 to 11 m (25 to 37.5 ft) width. Slipform pavers are usually used for airfield concrete pavement that is 200 mm (8 in.) or more in thickness. Slipform pavers provide the consolidation required for deep lift concrete pavement. Common elements of the slipform paver include:

- Self-propelled with four tracks
- Generally weigh at least 3,280 kg/m (2,200 Ib/ft) of paving lane width
- Variable-speed hydraulically controlled internal vibrators
- Ability to carry a head of concrete in front of the screed
- Continuous auger or hydraulic plow-pans to distribute concrete in front of the screed
- Finishing attachments

8-1.2 Manual Paving.

Labor-intensive manual paving is typically carried out only for small areas such as fillets.

8-1.3 Differences Between Slipform and Bridge Deck Paving Machines.

The differences between slipform and bridge deck paving machines are summarized below.

a. The bridge deck paver production capacity is significantly less than a slipform paver.

b. The bridge deck paver is most economical when paving lanes wider than 12 m (40 ft) and in geometrically constrained areas. Bridge deck pavers are capable of placing concrete up to 15 m (50 ft) wide.

c. A bridge deck paver is more mobile and maneuverable and may be used when paving constrained areas such as cross-taxiways or restricted aprons area.

d. A major difference between the pavers is the method of consolidation.

- The single vibrator of a bridge deck paver consolidates the concrete by plowing transversely across the truss.
- Combined with the forward travel of the paver, the concrete is plowed in a zigzag pattern.

e. For a constant radius of action with the vibrator, depending on forward speed, the amount of vibration energy and coarse aggregate distribution may not be as uniform as achieved using vibrators that are uniformly spaced and plowing in one direction as on slipform pavers.

- Vibrators on bridge deck pavers may have smaller offset weights that allow higher vibration frequencies than desired. Higher frequencies increase the potential for disrupting the air void system, increasing the potential for durability problems.
- Concrete mixtures are uniquely designed for fixed form paving. Slipform paver concrete mixtures do not work for fixed form paving and vice versa.

8-2 CRITICAL FACTORS FOR CONCRETE PAVING:

The following are critical factors affecting concrete paving.

- A good grade for paving; trimmed and compacted to specification
- Stringline management; monitor and maintain stringline at regular intervals
- Continuous supply of concrete to the paver
- Consistent concrete workability
- Well-maintained paving equipment
- Proper operation of paving equipment
- Controlled density of concrete; just the right level of vibration to consolidate concrete and provide enough fines at surface for a tight finish
- Most importantly, a skilled and dedicated crew

8-3 CONCRETE DELIVERY AT THE SITE.

Before and during concrete delivery, the following should be considered:

a. Inspect the grade for acceptance before depositing concrete. Remove loose debris and repair any base damage.

b. Verify string line elevations.

c. Concrete should be deposited on grade within reasonable time after the addition of mixing water. When placed, there should be time remaining for consolidation, strike-off, and finishing before initial set.

d. When pulling slipform pavers off headers, a slightly higher slump concrete should be used to facilitate hand consolidation and finishing operations.

e. Encourage the use of agitator trucks because they usually provide more uniform concrete placement and minimize concrete segregation.

f. The consistent delivery of concrete is necessary to minimize stopping and starting of the paver. If paving operations are stopped to wait for concrete from the batch plant, use additional trucks or reduce the paver speed.

8-4 CONCRETE PLACEMENT.

Acceptable concrete placement practices include the following.

a. Deposit concrete close to and uniformly in front of the paver or front spreader, taking care to minimize disturbance to the base, embedded steel, dowel bars, and side forms.

b. Place the concrete such that one side of the paving lane is not overloaded with concrete.

c. In formed areas, place the concrete as close as possible to its final position to minimize the potential for concrete segregation.

d. Concrete is either dumped on grade in front of the paver or onto belt placers and side-loading spreaders.

- If dumping on grade, control rate of dumping by controlling the tailgate opening.
- It is poor practice to spread concrete in front of a paver using an end loader.

e. The advantage of dumping directly in front of pavers or spreaders is that concrete head in front of the machine auger is easily maintained.

f. The disadvantages of directly unloading in front of the paver are the following.

- Trucks backing into the paver may disturb the compacted granular base.
- Dowel baskets must be placed just ahead of the paver. Placing dowel baskets just ahead of the paver may not allow time to verify dowel bar alignment or verify that baskets are securely fastened to the base. The safety of laborers fastening baskets in areas between the forward-moving paver and backward-moving dump trucks must be considered.
- When placing baskets just ahead of the paver, a full-time inspector may be required to check dowel bar placement and alignment.
- Stringlines may have to be broken on at least one side of the paver to allow trucks to back in and pull forward away from the paver.

g. When using a belt placer:

- Swing the belt back and forth to maintain a uniform head of concrete in front of the paver
- If the paver is low on concrete, back up placer to place more material where needed

h. When a spreader is used, do not advance more than 7.5 m (25 ft) ahead of the paver and thus allow timely adjustment if the head of concrete at the paver is too low or too high.

i. The paver operator must control the level of concrete in the grout box by raising or lowering the strike-off blade when required.

j. The following may reduce the potential for dowel bar misalignment associated with the forward-moving concrete head in front of the paver or spreader:

- Deposit small amounts of concrete carefully over pre-positioned baskets fastened to the base to minimize the weight associated with the forward-moving head of concrete in front of the paver or spreader.
- Do not dump concrete by trucks directly on basket assemblies.

8-4.1 Concrete Head.

Concrete head must be consistent and of proper height for the paver size and concrete mix. A heavier paver generally produces a smoother concrete pavement since it is less affected by surges of concrete coming into the paver.

8-4.2 Paver Speed.

a. Slow and constant speed of the paver results in smooth pavements.

b. The rate of placement (speed of the paver) should coincide with the capability of the batch plant and the rate of delivery of concrete to the paver.

c. The paver should not be stopped frequently during the paving operation.

d. Generally, the forward speed should be a minimum of 30 m (100 ft) per hour.

8-4.3 Filler Lane Placement.

If pilot lane joints are open wide at the time of filler lane placement, then mortar from the filler lane can seep into the joints and result in small comer breaks/spalls. If pilot lane joint widths are greater than 6 mm (0.25 in.), use backer rod, duct tape, or asphalt mastic to cover the joint openings. Although filler lanes may appear to be reasonably easy to place, the paving contractor must be aware of the potential for cracking within the filler lanes because of restraint from:

- Doweled longitudinal joints

- Friction from pilot lane joint faces
- Possible use of higher slump concrete (More shrinkage potential)
- Shorter window for sawing joints

8-5 EMBEDDED STEEL AND TIE-BAR PLACEMENT.

Use chairs to securely support embedded steel bars or mesh typically used in fillet areas and other odd-shaped panels. Space the chairs close enough to support the steel without sagging. Support tie bars used as embedded steel and positioned around penetrations on chairs within tolerances of the specified elevation. Welded wire fabric must be flat and meet specified elevations within tolerances after fastening to chairs. Supplementary consolidation with spud vibrators is commonly used around wire mesh; therefore, chairs must be strong enough to support the weight of laborers during concrete consolidation. Prior to concrete placement accepted by inspectors, verify the embedded steel bar diameter, length, presence of epoxy coatings, absence of breaks in epoxy, location, elevation, clearance of embedded steel (from other steel or dowel/tie bars at joints), and frequency of chairs.

8-5.1 Tie Bars.

Tie bars are not permitted on airfield pavements. Use tie bars only for road and street projects.

8-5.2 DOWEL BAR INSTALLATION.

During dowel bar installation, consider the following.

a. Dowel bars at transverse contraction joints are pre-positioned using dowel bar baskets secured to the base. Installing these dowels by dowel inserters attached to the paver or by any other means of inserting the dowels into the plastic concrete is not permitted.

b. Dowel bars at longitudinal sawed contraction joints can be pre-positioned using basket assemblies. Dowel bars at longitudinal sawed contraction joints cannot be injected using a dowel bar jammer on airfield or other heavy-duty pavement.

c. Dowel bar inserters are prohibited at longitudinal construction joints due to the high potential for misalignment and undesirable air pockets.

d. Dowel bars at longitudinal construction joints and transverse headers are installed using a drill and epoxy technique. Holes are drilled into vertical edges.

8-5.2.1 Dowel Bar Alignment.

Dowel bar alignment is a critical item and must be checked on a regular basis. Dowel misalignment has a significant effect on pavement performance. Table 8-1 lists the types of dowel bar misalignment and their impact on performance. Figure 8-1 illustrates these types of misalignments. Important dowel installation items are as follows.

8-5.2.1.1 Typical Alignment Specifications.

- 10 mm/m (1/8 in./ft) or less out of alignment in the vertical and horizontal plane
- 15 mm (5/8 in.) or less horizontal or longitudinal translation
- 13 mm (1/2 in.) or less vertical translation

8-5.2.1.2 Basket Assembly Stations.

Verify the assemblies to ensure they are centered at joint locations.

8-5.2.1.3 Dowel Bars at Longitudinal Joints.

Inspect bars to ensure the specified clearance from the ends of transverse joint dowel bars is maintained.

8-5.2.1.4 Reduce Restraint at Slab Corners.

To reduce restraint at slab corners, position dowel bars at longitudinal joints at least 150 mm (6 in.) and preferably 300 mm (12 in.) away from the ends of dowel bars in the transverse joints.

8-5.2.1.5 Dowel Baskets.

Securely fasten baskets to the base.

- Clips are generally adequate when fastening a basket to stabilized base.
- Long stakes are required to securely fasten baskets in granular and open graded bases.

8-5.2.1.6 Longitudinal Dowel Basket Wires.

Crimp wires instead of cutting. Crimping reduces cross-sectional area while maintaining basket stability.

8-5.2.1.7 Verify Dowel Bar Alignment.

Verify alignment by:

- Exposing dowels in plastic concrete
- Coring over dowel bar ends
- Using a magnetic rebar cover meter.
- Nondestructive testing such as GPR.

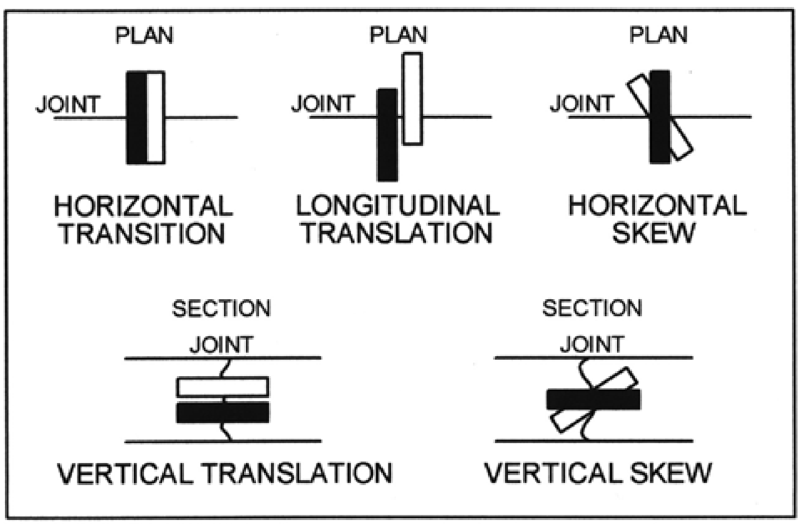
8-5.2.1.8 Prior to Paving.

Inspect dowel bars for breaks in the epoxy coating. Field kits are used to cover exposed dowel bar steel at basket welds and chips in the coating. If a light coat of form release oil or other de-bonding agent is specified, inspect the coverage before concrete placement.

Table 8-1 Types of Dowel Bar Misalignment and Impact on Performance

Type of Misalignment	Effect On		
	Spalling	Cracking	Load Transfer
Horizontal translation	---	---	Yes
Longitudinal translation	---	---	Yes
Vertical translation	Yes	---	Yes
Horizontal skew	Yes	Yes	Yes
Vertical skew	Yes	Yes	Yes

Figure 8-1 Dowel Bar Misalignment Categories



8-5.2.2 Basket Versus Inserted Dowels.

A method specification is typically used for dowel baskets.

- Positive tie-in to subbase is specified.
- Inspection of basket stability and dowel alignment is performed before concrete placement.
- Dowel placement (depth) for first few joints per day may be checked using a covermeter or GPR.

For inserted dowels, prior inspection is not possible.

- As a result, the contractor takes a risk because a check of dowel misalignment is only possible after concrete has hardened.
- The dowel placement (depth) for the first few joints of the day must be inspected using a covermeter.
- Also, there is typically not enough guidance in specifications for inspection of inserted dowels. The contractor should bring up this issue at the pre-bid meeting if the inserted dowel technique is to be used.

8-5.2.3 Dowel Bars at Construction Joints.

Install dowel bars at construction joints using the drill and epoxy grout procedure. Side injected dowel bars are prohibited on airfield pavements. Install dowel bars after the concrete has cured sufficiently to allow:

- The new pavement to support drilling equipment weight.
- Hole drilling without excessive chipping and spalling (> 12.5 mm [0.5 in.]) or beyond the diameter of the grout retention disc. Expect minor chipping.

Important items in the installation process include the following.

a. Use gang drills to simultaneously drill several holes.

b. Slightly over-size holes, about 3 to 6 mm (1/8 to 1/4 in.) larger than the dowel bar diameter.

c. Spot-check the depth of drilled holes to ensure the dowels are nominally inserted halfway into holes.

d. Inject epoxy at the back of the drilled holes and twist the dowel as it is pushed into the hole. Applying epoxy by hand to dowel bars before insertion is a prohibited technique.

e. Grout retention disks may be used to prevent epoxy from flowing out of the holes.

f. Inspect dowel bars to verify adequacy of the epoxy coverage. Proper epoxy grouting is important to ensure the dowels are bearing on a sound interface and voids do not exist. Otherwise, load transfer effectiveness is compromised.

g. Oil the exposed ends of the dowel bars before concrete placement. Do not use grease to coat the exposed ends of dowel bars.

8-6 CONCRETE CONSOLIDATION.

Proper use of internal vibrators is important to properly consolidate the concrete without adversely affecting the concrete strength and durability. Important items related to concrete consolidation are summarized below.

a. Slipform pavers consolidate concrete in the grout box using gang-mounted vibrators.

b. For larger pavers, vibrators are hydraulically driven. Electric or hydraulic vibrators may be used for small slipform pavers.

c. Inadequate consolidation results in lower concrete strength and honeycombing. Inadequate vibration can be due to:

- Poorly functioning or dead vibrator
- Paver speed too high
- A concrete mix with poor workability

d. Over-consolidation can lead to freeze-thaw durability problems if the air void system is adversely altered. Over-consolidation can be due to:

- Excessive vibrator frequency
- Reducing paver forward speed without an adjustment to vibrator frequency
- Concrete mix properties of poor workability

e. Vibrators are generally positioned no more than 100 mm (4 in.) below the finished pavement surface. Setting vibrators too low results in air being trapped under the grout box head, leading to delamination or blistering of the concrete surface.

f. Vibrators are generally positioned at an attitude of 5 to 10 degrees. As the paver moves forward, the angled vibrators plow the concrete.

g. Vibrator spacing is a function of the radius of the zone of influence. The zone of influence and vibration energy input into concrete is a function of paver speed, vibrator rotor force, and frequency (set by equipment operator).

h. Before each day of paving, vibratory frequencies and amplitudes must be checked under no load. Large deviations between vibrators are indicative of poorly functioning vibrators.

8-6.1 Verifying Consolidation.

Examine cores drilled in the test strip or initial stages of placement to ensure that for the paving variables (vibrator depth, attitude angle, frequency under load, spacing, grout box head, and travel speed), the consolidation is acceptable. Examine cores between and in vibrator paths for:

- Evidence of aggregate segregation in vibrator trails
- Excessive entrapped air
- Differences in hardened concrete density

8-6.2 Vibration for Consolidation.

Slipformed vertical edges should not exhibit excessive entrapped air voids. With slipform and fixed-form pavers, supplementary vibrators may need to be positioned close to vertical edges to ensure adequate consolidation. Evaluate the response of the concrete mixture to vibration on the first day of paving or after the test strip construction. Eliminate large pockets of entrapped air (honeycombing) and aggregate segregation by changing the following:

- Vibrator frequency
- Forward travel speed of paver
- Vibrator depth
- Vibrator spacing

Smart vibrator systems that continuously monitor individual vibrator frequencies during paving operations are available. Use of a smart vibrator system is recommended since this allows continuous verification of frequency uniformity. Vibrator frequency in the range of 6,000 to 8,000 vibrations per minute (under load) will usually result in acceptable consolidation for a properly designed mix.

8-7 CONCRETE FINISHING.

Concrete finishing is a critical step in the paving process. Concrete finishing is the hand finishing typically applied to obtain a smooth surface necessary to correct any unevenness behind the paver. Concrete finishing efforts are to be kept to a minimum. Ideally, the correct concrete mixture will result in an acceptable surface finish behind the paver. The concrete surface does not need to be very tight and every small blemish on the surface does not need to be corrected. The following can aid in obtaining a good finish:

- Minimize excessive handwork
- Do not apply water to help finish the surface
- Surface does not need to be excessively smooth or tight
- Too much paste at the surface results from:
    - Too much water applied to the surface
    - Over-vibration (high frequency)
    - Paver speed too slow for vibratory effort
    - Over-finishing
- Important items related to finishing are as follows.
    - The need for concrete finishing is minimized by:
        - Selecting a workable concrete mixture
        - Properly operating the paving equipment
    - Excessive hand finishing will work water to the surface and can affect surface smoothness and concrete durability.
    - Problems closing the surface behind the paver are indicative of:

        - Inadequate volume contained in the grout box or concrete setting up in the grout box
        - Fine to coarse aggregate volume or paste volume too low
        - The finishing pan angle needing adjustment
        - The paver speed being too high
        - Vibrators needing adjustment
    - If water is used to assist with finishing, it needs to be fogged, not sprayed, over the surface and should not be worked into the surface with floats.

8-7.1 Hand Finishing.

Excessive hand finishing or adding mortar and water to the surface of the pavement are indicators of mixtures with an undesirable combined gradation. Continuing these practices produces pavements that are FOD generators, such as scaling and spalling. Adjust mixture proportions and finishing techniques whenever necessary to minimize hand finishing.

8-8 CONCRETE TEXTURING.

Concrete pavements require a surface texture that provides the desired level of skid resistance. The primary functions of surface texture are to provide (a) paths for water to escape from beneath tires and (b) a degree of sharpness at the surface necessary for the tire to break through the residual film that remains after the bulk water leaves. Concrete texturing is the most common technique used to provide concrete with a high skid-resistant pavement surface. However, texturing will not prevent hydroplaning. Texturing is applied while the concrete is still in plastic condition. Texture methods include the following.

8-8.1 Brush or Broom Finish.

- Applied when the water sheen (bleed water) has just disappeared
- Applied transversely across the pavement
- Corrugations should be uniform in appearance and 1.5 mm (1/16 in.) deep
- The textured surface must not exhibit tears and be unduly rough
- Burlap or Astroturf drag finish

Macrotexture of the finished concrete surface should have a mean depth of 1 mm (0.04 in.) when measured by ASTM E965. Burlap drags are the most common texture techniques for airfield pavements.

- The burlap rating should be about 500 gm/m^2 (15 oz/yd^2).
- The trailing edge of burlap must have a heavy buildup of grout to produce the desired longitudinal striations on the surface.

- Operate the drag with the fabric moist and clean, or changed as required to keep clean.
- The corrugations produced by burlap drag must be uniform in appearance and about 1.5 mm (1/16 in.) deep.

8-8.2 Wire Combing (Rigid Steel Wires).

- Use wire combing to provide a deeper texture in the plastic concrete.
- Steel wires are about 100 mm (4 in.) long, 0.8 mm (0.03 in.) thick, and 2 mm (0.08 in.) wide.
- Continuous tracks are approximately 3 mm by 3 mm (1/8 in. by 1/8 in.) and spaced 13 mm (0.5 in.) center to center.
- Brush, broom, or burlap finish is not necessary before providing wire tining.
- Wire combing is not a substitute for grooving. It does not provide for improved surface drainage.

8-8.3 Wire Tining (Flexible Steel Bands).

- Use wire tining to provide a deep texture in the plastic concrete.
- Flexible steel bands are about 130 mm (5 in.) long, approximately 6 mm (0.25 in.) wide and spaced 13 mm (0.5 in.) apart.
- Brush, broom, or burlap finish is not necessary before providing wire combing.
- Wire tining is not a substitute for grooving. It does not provide for improved surface drainage.

8-9 GUIDANCE FOR TEXTURING AND GROOVING.

The designer must select the type of texturing desired. If no guidance is given, the usual default method is burlap drag. For airfield paving projects, do not specify artificial turf, wire comb, or surface grooving textures.

8-9.1 Grooving.

Spring tine grooving is limited to use on roads and streets only. Grooving of airfield pavement must be sawcut. Use either the FAA’s standard or trapezoidal grooving patterns. For the standard groove pattern, grooves are approximately 6 mm by 6 mm (0.25 in. by 0.25 in.) and spaced 37 mm (1.5 in.) center to center for airfield pavements and spaced 50 mm (2 in.) for roads. Trapezoidal grooves are spaced 57 mm (2.25 in.) center to center, 6 mm (0.25 in.) deep, 6 mm (0.25 in.) wide at the bottom, and 12 mm (0.5 in.) wide at the top.

Do not groove within 152 mm (±76 mm) (6 in. [±3 in.]) of the runway centerline, crown, Transverse joints, working cracks or light fixture. Do not groove within 6.1 m (20 ft) of the aircraft arresting system cable. Grooves are not required to cross joints. Do not groove through compression seals. Replace any compression seals cut or otherwise damaged by the grooving operations. Terminate grooves within 1.5 to 3 meters (5 to 10 feet) of the pavement edge to allow for operation of the grooving equipment.

8-10 CONCRETE CURING.

Curing is the maintenance of adequate moisture and temperature regimes in freshly placed concrete for a period of time immediately following finishing. Improper curing can have serious detrimental effects on near-term (plastic shrinkage cracking) and long-term properties of hardened concrete (less durable surface, excessive warping). Four important keys to proper application of a curing material are (a) proper mixing, (b) uniformity of application, (c) timing of application, and (d) yield check (rate of application). Important issues related to proper concrete curing are addressed below.

8-10.1 Timing of Curing Application.

Timing is critical, especially during hot weather. Apply curing compound as soon as free water disappears from the concrete surface after finishing and texturing. When using fly ash and slag, free water may not form.

8-10.2 Curing Compounds Spraying.

Uniform coverage and coverage rates are critical for sprayed curing compounds.

a. Apply spray curing using spray equipment mounted on a self-propelled frame that spans the paving lane.

b. Limit hand spray curing to hand-placed concrete areas.

c. Employ overlapping coverage that provides a two-coat application at a coverage.

d. Uniformity of white-pigmented curing compounds are subject to visual examination, but verify application rates by measuring the volume used for a given area and compare it to the specifications.

e. Apply curing to exposed concrete faces after slipforming or removing forms.

f. Apply curing to joint surfaces immediately after sawing and cleaning.

g. If using moist curing, maintain the entire concrete surface continuously wet for the entire curing period (typically seven days) or until a curing compound is applied.

See additional discussions related to curing for hot and cold weather concrete placement in paragraphs 8.16 and 8.17.

8-11 MINIMIZING EDGE SLUMP.

Detect excessive edge slump while concrete is in the plastic state. Edge slump is considered excessive if more than 15 percent of the joint length for a single slab exhibits edge slump greater than 6 mm (0.15 in.) or if any edge slump exceeds 10 mm (3/8 in.).

Minimize edge slump occurrences because it impacts joint efficiency and performance. The continual correction of excessive edge slump in fresh concrete can lead to unacceptable levels of joint spalling in the finished concrete. If such a problem develops, stop paving and implement measures to correct excessive edge slump. Factors that affect edge slump include:

- Concrete consistency
- Concrete mixture compatibility with placement techniques
- Paver adjustments and operation
- Excessive finishing

The correction of edge slump is discussed in Chapter 11.

8-12 FIXED FORM PAVING.

Fixed form paving is typically used to pave short lengths or isolated areas such as fillets or irregular pavements and employs machine pavers or manual placement. Important considerations include the following.

8-12.1 Steel Forms.

Position forms on the finished base and check top elevations.

8-12.1.1 Granular Base.

a. If grade along the forms is low, place and compact additional base material.

b. If grade along the forms is too high, rework the base to lower the grade.

c. Correcting high spots in granular material only near form edges is poor practice. High spots between the forms will result in a lower concrete thickness away from forms that result in variable thickness.

8-12.1.2 Stabilized Base.

a. If grade along forms is low, shim forms to maintain horizontal alignment during concrete placement. If more than 25 mm (1 in.) shimming is needed, remove and replace the base in low areas to achieve the required base elevation.

b. For high areas in cement treated base, cut down cement-treated open graded and open graded asphalt stabilized bases with a motor grader blade.

c. Grind high areas in lean concrete (econocrete) and asphalt concrete bases to elevation.

d. Lowering base elevations only in the vicinity of forms results in a thin concrete cross-section away from forms that produces variable thickness.

e. Consider a bond breaker layer of broadcast sand or double application of waxed-based curing compound in areas that are ground and thereby reduce the potential for bonding between the base and the concrete.

8-12.2 Set Forms.

Mechanically tamp forms and stake them securely into the base with stakes no more than 900 mm (36 in.) apart.

8-12.3 Check Transition Joints.

Ensure that no significant deviation affects the finished concrete smoothness between forms.

8-12.4 After Forms are Connected.

Check vertical and horizontal alignment.

8-12.5 Damage.

To minimize damage during form-removal operations, spray forms with form release oil not more than four hours before paving.

8-12.6 Spalling.

To prevent corner spalling and damage to concrete, forms are not normally removed earlier than 12 hours after concrete placement; however, remove forms no later than 24 hours. Removing forms later than 24 hours may affect concrete curing of vertical edges adjacent to forms.

8-12.7 Exposed Sides.

Spray exposed sides with curing compound within 30 minutes after form removal. Coat edges at coverage rates used for the pavement surface.

8-13 PAVING AND IN-PAVEMENT STRUCTURES.

8-13.1 Lighting Fixtures.

The most common in-place structures in airfield concrete paving are light cans. Layout in-pavement lighting systems to minimize interference with proposed pavement joints. For conflicts with pavement joints, make use of pavement blockouts to construct in-pavement lighting structures near a joint. Normally, a blockout is required when the centerline of the light base can is within 750 mm (2.5 ft) of a pavement joint. Light cans may be installed using one of the following techniques.

8-13.1.1 Blockouts.

a. Install blockouts at light can locations and place the pavement around the blockouts.

b. Check blockouts elevations for grout box clearance.

c. Place filler material used to stabilize blockouts within 75 mm (3 in.) or less of the finish elevation.

d. After construction, remove any filler material, position light cans, and backfill the blockout area with concrete.

e. Fixed blockouts can restrain slab movement and increase restraint stresses associated with moisture and thermal changes. Use deformed tie bars around diamond-shaped blockouts to hold any restraint cracks tight and reduce the potential for crack spalling. Position tie bars between the upper third and half depth of pavement. Securely tie bars to chairs fastened to the base.

8-13.1.2 Split Cans and Coring.

This technique allows the pavement to be slipformed with pre-placed light cans. Can elevation adjustments can be made after concrete placement. The steps involved are as follows.

1. Position partial can in the base.
2. Pre-place concrete at the base of the partial cans to anchor the cans.
3. Pave the lane.
4. Drill a 100 mm (4 in.) diameter core to determine the exact center of the can.
5. Drill a 360 to 460 mm (14 to 18 in.) hole for the can top section.
6. Complete light can installation.

8-13.1.3 Cookie Cutter.

This technique is similar to the coring method: light cans are anchored in place and paving is placed over them. The steps involved are as follows.

1. After the paving machine passes over a light base, a “cookie cutter” is pressed into the plastic concrete by a worker sitting on a bridge suspended over the pavement.
2. After the concrete sets (sufficiently rigid for the reservoir to retain its shape but plastic enough to allow surface finishing), the cookie cutter is removed, the concrete inside the impression is removed and discarded, and the surrounding surface is hand finished.

8-13.1.4 Implications of Improperly Installed Light Bases.

Benefits to the paving contractor include time and cost savings when light base installation deficiencies are detected before concrete paving. It is relatively cost free to check a light base before paving; it is an expensive proposition to remove a light base after the pavement is placed and finished. The height setting of a light base is the most common cause of a deficient installation. When the light base is set too high, there is no satisfactory mitigation other than to remove and replace. Therefore, checking the height before concrete paving is a critical step.

On some projects, the uniformity of the concrete surface surrounding the light base has been observed to distort to the extent that height tolerances become difficult to establish and high spots block the light beam. The specific cause or causes of this problem are not known and the condition is only detected during inspection after paving is complete. The surface of the concrete around light base locations must be carefully inspected immediately after pavement finishing and during the time that the concrete is plastic.

8-14 OTHER STRUCTURES.

Other in-place structures commonly encountered with airfield pavements include hydrant pits, utility manholes, and drainage structures (trenches). These are typically installed using the blockout method or pre-placed with concrete around the structure. In both cases, embedded steel must be used around the structure for crack control. Additional items to consider for the design and construction of in-place structures include the following.

a. Design details for in-place structures must account for expansion of concrete pavements adjacent to the structure and for moisture infiltration into the structure.

b. Larger in-place structures (such as utility manholes, hydrant pits, or drainage trenches) must be located at least 1.2 m (4 ft) from a transverse or a longitudinal joint to minimize potential for cracking. If it is not feasible to locate a larger structure outside of the 1.2 m (4 ft) dimension, place the structure at the pavement joint along with appropriate load transfer (thickened edge) and concrete slab expansion details.

c. Smaller slab penetrations, such as monitor wells and under-drain cleanouts, can be located closer to the pavement joints, in a similar manner to an in-pavement light fixture (no less than 750 mm [2.5 ft] from the pavement joint.

d. An isolation joint around an in-place structure must be used to accommodate concrete slab expansion. Load transfer between the concrete slab and the adjacent structure must also be accounted for.

e. Trench drain walls must be designed to be stiff enough to resist concrete pavement expansion. Struts in trench drains may be required if concrete expansion movement at the trench drain is anticipated to be high.

8-15 PAVING AT FLEXIBLE PAVEMENT INTERFACES.

Matching elevations is a common problem where concrete and flexible pavement sections abut one another.

8-15.1 Techniques for a Smooth Interface.

a. Sawcut flexible pavement vertically full depth where it abuts new concrete to minimize disturbance to the base layer under the asphalt layer.

b. If the flexible system is sawcut significantly ahead of paving, shore up the vertical face of the flexible pavement system to minimize loss of base associated with unsupported granular layers sloughing.

c. Alternatively, over cut the flexible pavement, pave along the planned flexible pavement interface, and replace the flexible pavement at the over cut. If possible, use a buried concrete slab tied to the concrete pavement along the over cut area.

d. To minimize the potential for faulting at the interface construction joint, compact the base adjacent to forms and along the cut flexible pavement edge using pole tampers and plate compactors.

e. To minimize the hand-finishing effort when matching elevations, start paving at the flexible pavement edge and move the paver away from the edge.

f. Do not allow slipform equipment to track on the unsupported flexible pavement edges.

g. When paving parallel to the flexible pavement, match elevations between the concrete and flexible pavements and manipulate the concrete during finishing. Depending on cross-slope drainage requirements, consider the following:

- Grind the flexible pavement down to the planned concrete elevation.
- Place concrete higher and thin mill or resurface the flexible pavement.
- During compaction of the surface layer of asphalt, do not allow the steel roller to run on the concrete edge.

8-16 HOT-WEATHER CONCRETE PLACEMENT.

ACI defines hot weather as a period longer than three consecutive days exhibiting the following conditions:

- The average daily air temperature is greater than 25 °C (77 °F). The average daily temperature is the mean of the highest and the lowest temperatures occurring during the period from midnight to midnight.
- The air temperature for more than one-half of any 24-hour period is not less than 30 °C (86 °F).

8-16.1 Concrete Mixture.

Only use a concrete mixture for hot weather previously verified as appropriate by using trial batches mixed and cast at temperatures representative of typical hot weather conditions for the site. During hot weather, problems that are likely to occur include:

- Rapid slump loss
- Reduced air contents
- Premature stiffening
- Plastic shrinkage cracking
- Thermal cracking

8-16.2 Hot Weather Concreting.

a. Do not exceed the maximum allowable w/cm ratio or the manufacturer's maximum recommended dosage of any admixture.

b. Retarding admixtures if their performance is verified during trial batches. High dosages of water reducers (even high-range water reducers) can retard setting.

c. Substitute slag, Class F fly ash, or natural pozzolans for part of the cement. These materials hydrate more slowly and generate lower heats of hydration than cement, thus reducing problems with slump loss, premature stiffening, and thermal cracking.

d. Correct air content by increasing the dosage of air-entraining admixture.

e. Early-age thermal cracking may be prevented by ensuring the temperature of the plastic concrete is as low as practical. It should not exceed 32 °C (90 °F).

   - Aggregates may be cooled by sprinkling with water. Corrections for the aggregate moisture are required.
   - Aggregates must be batched in a saturated surface dry condition to avoid absorbing mixture water.

f. Hot cement or fly ash provided by the supplier should not be used.

g. Mixing water may be chilled or chipped ice may be used to substitute for some of the water. Ensure all ice melts during mixing.

h. Mixing and transporting equipment may be painted white or a light color to minimize the heat absorbed from the sun.

i. Concrete placements can be scheduled for nighttime.

j. The base should be moistened before the concrete is placed to keep the temperature down and keep it from absorbing water from the concrete.

k. The concrete should be placed and finished as rapidly as possible and curing compound applied at the earliest possible time. The use of a white curing compound will reflect the sun's heat. If there is any delay in applying the curing compound, use a fog spray or evaporation retardant to keep the surface from drying out.

l. Steps should be taken during hot weather to reduce the rate of evaporation from the concrete. The likelihood of plastic shrinkage cracking increases with the rate of evaporation. Plastic shrinkage cracking results from the loss of moisture from the concrete before initial set. The rate of evaporation is a function of:

- Air temperature
- Concrete temperature
- Relative humidity
- Wind speed

m. Calculate the rate of evaporation using the American Concrete Pavement Association's (ACPA) Evaporation Rate Calculator (http://www.apps.acpa.org/apps/EvaporationCalculator.aspx) or the High PERformance Concrete PAVing (HIPERPAV) software. Current data from an on-site weather station should be used.

n. When the rate of evaporation is predicted to be above 1.0 kg/m^2/hr (0.2 lb/ft^2/hr), provide fog spraying or use an approved evaporation retardant, as appropriate.

o. If conditions of temperature, relative humidity, and wind are too severe to prevent plastic shrinkage cracking or corrective measures are not effective, paving operations must be stopped until weather conditions improve.

p. Refer to ACI 305, *Hot Weather Concreting*, for additional information.

8-17 COLD WEATHER CONCRETE PLACEMENT.

Cold weather is defined by ACI as a period when, for more than three consecutive days, the following conditions exist:

a. The average daily air temperature is less than 4 °C (40 °F). The average daily temperature is the mean of the highest and lowest temperatures occurring during the period from midnight to midnight.

b. The air temperature is not greater than 10 °C (50 °F) for more than one-half of any 24-hour period.

c. When concrete is to be placed in cold weather or at a time of year when cold weather is likely, plans to maintain the concrete at the appropriate temperature must be made well before the temperature is expected to drop below freezing. Consider the following for cold weather concreting.

- Concrete mixture designs developed for placement at cooler temperatures normally have higher cement content than those used in hot weather.

- The use of slag, fly ash, and pozzolans should be reduced or eliminated unless they are required to control ASR or provide some degree of resistance to sulfate attack. In the latter case, the total cementitious materials content may need to be increased or the cement changed to Type III instead of Type I/II.
- The required dosage of air-entraining admixture should be lower than the dose at normal temperatures.
- Because the concrete will take longer to set, there is also some danger of plastic shrinkage cracking, especially if the concrete is much warmer than the ambient air or if the wind is blowing.
- An accelerating admixture conforming to ASTM C494/CRD-C 87 Type C or E may be used, provided its performance has been previously verified by trial batches.
- Do not use admixtures containing added chlorides. Also, do not use calcium chloride.
- Aggregates must be free of ice, snow, and frozen lumps before being placed in the mixer.
- The temperature of the mixed concrete should equal or exceed 10 °C (50 °F).
  - o The mixture water and aggregates may be heated to less than 66 °C (150 °F).
  - o The material must be evenly heated.
- Concrete should not be placed when the temperature of the air at the site or the surfaces on which the concrete is to be placed is less than 4 °C (40 °F).
- Covering and other means of protecting the concrete from freezing must be available before starting placement.
- The concrete temperature should be maintained at 10 °C (50 °F) or above for at least 72 hours after placement and at a temperature above freezing for the remainder of the curing time (when the concrete attains a compressive strength of 20 MPa [3,000 psi]). Corners and edges are the most vulnerable to freezing.
- Completely remove and replace concrete damaged by freezing.
- Concrete placed in cold weather gains strength slowly. Concrete containing supplementary cementitious materials gains strength very slowly.
  - o Sawing of joints to opening to traffic may be delayed.
  - o Verify the in-place strength by a maturity method, temperature-matched curing, nondestructive testing, or tests

of cores from the pavement before opening the pavement to traffic.

- Refer to ACI 306, *Cold Weather Concreting*, for additional information.

8-18 PROTECTING CONCRETE AGAINST RAIN DAMAGE.

The paving team and the inspector must be knowledgeable of procedures to protect fresh concrete in the event of rain. Consider the following.

a. Protective coverings, such as polyethylene sheeting or tarpaulins, must be available onsite at all times.

b. When it starts to rain, batching and placing operations should stop. The fresh concrete must be covered so the rain does not indent the surface or wash away the cement paste.

c. There are two primary consequences of rain during pavement placement:

- Rain can damage the surface by leaving imprints or washing away paste at the surface. Damage is generally minimal once the concrete has achieved final set.
- Rain-induced rapid surface cooling after final set could lead to a more rapid development of thermal restraint stresses. Even if sawcutting is begun in a timely manner, an increase in the potential for early-age uncontrolled cracking exists. Joint sawing is discussed in Chapter 9.

d. Should a rainstorm occur before the curing membrane is effective, the damage is usually limited to the surface.

e. Stiff, low-slump, paving-quality concrete that has been consolidated, struck off, and finished may sustain only minor surface blemishes from light rain.

f. When the rain is light, water will not soak into the concrete and result in an increase in the w/cm ratio.

g. If the concrete was textured prior to the rainfall, the texture may be compromised. This surface blemishing and texture damage, if light, can generally be taken care of by diamond grinding the surface to a depth of about 3 mm (1/8 in.).

h. Any concrete exposed to significant rain while it is loose or unconsolidated must not be used in the pavement as it can absorb water.

i. Once the unprotected pavement surface is exposed to rain there should be no attempt to finish or texture the surface.

j. Removal of extra surface water prior to covering should not be attempted. Water removal operations often increase the erosion of paste at the surface.

k. Adding dry cement or floating dry cement into the surface should not be attempted. Adding cement extends the time the surface is exposed, increasing the potential for additional surface damage. Working dry cement into the surface can also alter the entrained air void system that is required for freezing and thawing protection.

l. As soon as the surface has dried, the curing membrane can be applied. Once the curing period is over, the surface exposed to rain should be diamond-ground to remove the surface blemishes and texture the surface.

m. Any attempt to finish or texture the surface during or after the rain event runs the risk of working water into the surface of the concrete. This will make a minor surface problem into a serious problem.

n. If unconsolidated concrete exposed to rain has been incorporated into the pavement, it must be removed.

o. Use of early entry saws or skip sawing (discussed in Chapter 9) to quickly install joints prior to incoming rain should be considered.

p. Installing joints as quickly as possible reduces the potential for early-age cracking attributed to restraint stresses generated with rapid surface cooling.

q. Once rain has ceased and surface coverings removed, needed joints are sawed as quickly as possible.

r. If a rainstorm catches an unprotected pavement, it is crucial that paving stop. The best precaution to avoid rain damage or random cracking is to quickly cease paving operations. On larger airfield projects, contractors may rely on weather stations at the airfield or subscribe to meteorological weather forecasting services to monitor current weather information.

8-18.1 Assessing Rain Effects.

Consider the following guidelines in assessing rain effects.

8-18.1.1 Mist.

An intermittent light mist may be beneficial, as long as no significant water is added to the unconsolidated concrete in front of the paver or to the concrete surface to be finished.

8-18.1.2 Accumulated Water.

If rain is sufficient to accumulate any water at all on the surface of freshly placed concrete prior to finishing, stop paving and take protective measures.

8-18.1.3 Hard Rain.

If rain is sufficiently hard to mark freshly placed concrete, it is past time to stop paving.

8-19 TESTING RAIN-EXPOSED SURFACE.

Evaluate any rain damage and establish the extent of damage. The rain-damaged concrete must be removed if the surface is determined to be not durable in terms of abrasion, skid resistance (surface texture), or freezing and thawing. Cores can be drilled for petrographic examination to determine if rain has altered the surface hardness or entrained air-void system. Cores should be recovered from the beginning and end of the damaged surfaces. Results from the petrographic examination can establish the limits of and disposition of damaged concrete. Generally, surfaces are not deemed durable for abrasion if damage extends down more than 3 mm (1/8 in.). For freeze-thaw durability, the air-void spacing factor should be less than 0.20 mm (0.008 in.). Other tests assess scaling and abrasion potential.

8-20 TROUBLESHOOTING GUIDE.

Common problems encountered at the job site and possible remedies are described in Table 8-2.

Table 8-2 Troubleshooting Placement, Finishing, Texturing, Curing

Problem	Probable Cause(s)	Action
Premature stiffening of concrete with little evolution of heat.	• False-setting cement.	• Do not add water. Plasticity can be restored with additional mixing. Notify cement supplier.
Premature stiffening of concrete with evolution of heat, lack of working time.	Any of the following could contribute to this problem: • Cement with too little or the wrong form of sulfates • High placement temperatures • Lignosulfonates in water-reducing admixture • Triethanolamine (TEA) in water-reducing admixture • Use of accelerator • Wrong mixture design for hot weather (high cement content, Type III cement, no supplementary cementitious materials) • Dry, absorptive aggregates absorbing water from the mix • Hot (fresh) cement	• If using an accelerator, stop using it or reduce the dosage. • Reduce the placement temperature of the concrete by any convenient method(s). See para. 8.17. • In hot weather, use the hot weather mixture design. • Make sure the aggregates are damp at the time of batching. Switch to a water reducer that does not contain lignosulfonates or triethanolamine (TEA). (Consult the admixture supplier for advice.)
Slump out of specifications or varying	• Change in water content or aggregate grading; concrete temperature too high.	• Check aggregate moisture contents and grading. • Stockpiles should be of consistent grading and aggregates must be moist. • Make sure batch water is adjusted for aggregate moisture content. • Check whether extra water was added at the site. • Perform mixer uniformity test. • Note the batch time on the concrete delivery ticket. Haul

Problem	Probable Cause(s)	Action
		times should not exceed allowable time.
Slump loss greater than 25 mm (1 in.) between the plant and the paver	• False setting tendency or material incompatibility	• Check cement composition • Check mixing time • Check admixture compatibility
Inconsistent air content	• Variations in pozzolan • Change in cement source, type, or brand • Change in sand grading • Inadequate or variable mixing due to worn mixer blades, an overloaded mixer, or varying mixing times • Concrete temperature effects	• Monitor air contents closely and adjust admixture dosages as necessary. • If the air contents drop between the cool morning and hot afternoon, it may be due to the change in concrete temperature. In that case, increase the dosage of air-entraining admixture as the temperature rises. • If a sudden change seems permanent, look for a change in the materials supplied. • Check the sand stockpile to see whether the grading has changed. • Examine the mixer (fins) and mixing procedures. • Contamination of one of the ingredients with organics can also effect a sudden change in the required dosage of the air-entraining admixture. Try to isolate the source.
Excessive concrete temperature	• Ingredients may be hot at batching: aggregates, cement, fly ash • Long haul times • Hot weather	• Follow hot weather concreting practice as appropriate. • Minimize haul times.

Problem	Probable Cause(s)	Action
Failure to set	• Organic contamination, excessive retarder, excessive water reducer, retarder not dispersed, and cold weather.	• Check for contamination of water, aggregates, and equipment. • Reduce dosage of retarder and water reducer. • Improve mixing to disperse retarder. • Follow cold weather concreting practices if appropriate.
Sticky mix	• Use of higher dosages (> 5 percent) of silica fume • Sand too fine • Using wood float on air-entrained concrete	• Change sand source. • Use magnesium or aluminum floats.
Honeycombing	• Hot weather may induce premature stiffening • Inadequate vibration • Changes in aggregate grading will affect workability • Dry aggregates • High paver speed	• Follow hot weather concreting practices, if appropriate. • Check that all vibrators are working properly and at the right frequency and amplitude. Paver speed should not be too high. • Check aggregate grading.
Edge slump	• Poor or nonuniform concrete • Improper operation of paving equipment	• Verify mixture design and batching procedures. • Check aggregate grading and moisture. • Check concrete placement procedures.
Smoothness problems	• Nonuniform concrete • “Stop and go” paver operation • Too much or too little concrete in front of paver • Frequent use of construction headers	• Check batching procedures. • Check aggregate grading. • Improve construction procedures. • Minimize delays in concrete delivery.

Problem	Probable Cause(s)	Action
	• Use of light paver	• Add extra haul trucks, if necessary, or slow paver. • Improve paver operation.
Popouts	• Unsound aggregates • Clay balls	• Check aggregates for soundness. • Check for inter-mixing of aggregate with soil.
Scaling, dusting	• Over-finishing • Premature finishing • Early freezing of concrete	• Improve finishing technique. • Protect concrete from freezing. Concrete damaged by freezing needs to be removed and replaced.
Plastic shrinkage cracking	• Excessive loss of moisture from fresh concrete	• Use an accelerator to make concrete set faster. • Protect concrete from loss of moisture both before and after placement: fog spray or immediate application of evaporation retardant or curing compound. • Make sure absorptive aggregates are kept moist. • Refer to hot weather concreting practices, if appropriate.
Random cracking	• Shallow sawcut/late sawing • Dowel misalignment • Bonding with stabilized base • Sudden cold front • Excessive joint spacing	• Saw sooner and check sawcut depth. • Check dowel alignment. • Take cores to check interface bond. • Review joint spacing.
Raveling of sawcut	• Sawing too soon	• Wait longer to saw. • Check blade compatibility. • Use early entry dry saw.

Problem	Probable Cause(s)	Action
Joint spalling	• Excessive hand finishing; trying to fix edge slump of low spots by hand-manipulated concrete; nonuniform concrete resulting in wavy longitudinal joint that spalls when sawed; and collateral damage from equipment, slipform paver tracks, and screeds	• Improve construction practice.
Low strength concrete samples	• Errors in batching or mixing of concrete • Incompatibility between cement and air-entraining admixture causing coalescence of air voids around aggregate particles • Improper sample preparation, curing, handling, or testing	• Verify entire process of making, curing, handling, and testing. Flexural specimens are particularly vulnerable to poor handling and testing procedures. • Verify entire batching and mixing process. • Trial batches can help eliminate the possibility of incompatibility. A quick visual examination of a cut specimen will identify any coalescence of air voids.

This Page Intentionally Left Blank

CHAPTER 9 JOINT SAWING AND SEALING

9-1 INTRODUCTION.

Joint sawing and sealing require an experienced crew to correctly perform associated tasks. Although improved guidelines are available for estimating when sawing can begin, speed of sawing, blade condition, and operator care combine to influence the final product. Find additional information in UFC 3-250-08, *Standard Practice for Sealing Joints and Cracks in Rigid and Flexible Pavements*.

9-2 JOINT DESIGN.

There are three pavement categories: isolation, construction, and contraction (Figure 9-1). Find detailed guidance for jointing roads and parking areas in UFC 3-250-01. Refer to UFC 3-260-02 for guidance on airfield pavement jointing.

9-2.1 Isolation/Expansion Joints.

The purpose of an isolation/expansion joint is to separate intersecting pavements, isolate embedded fixtures within the pavement such as pavement drains, or when pavements abut buildings.

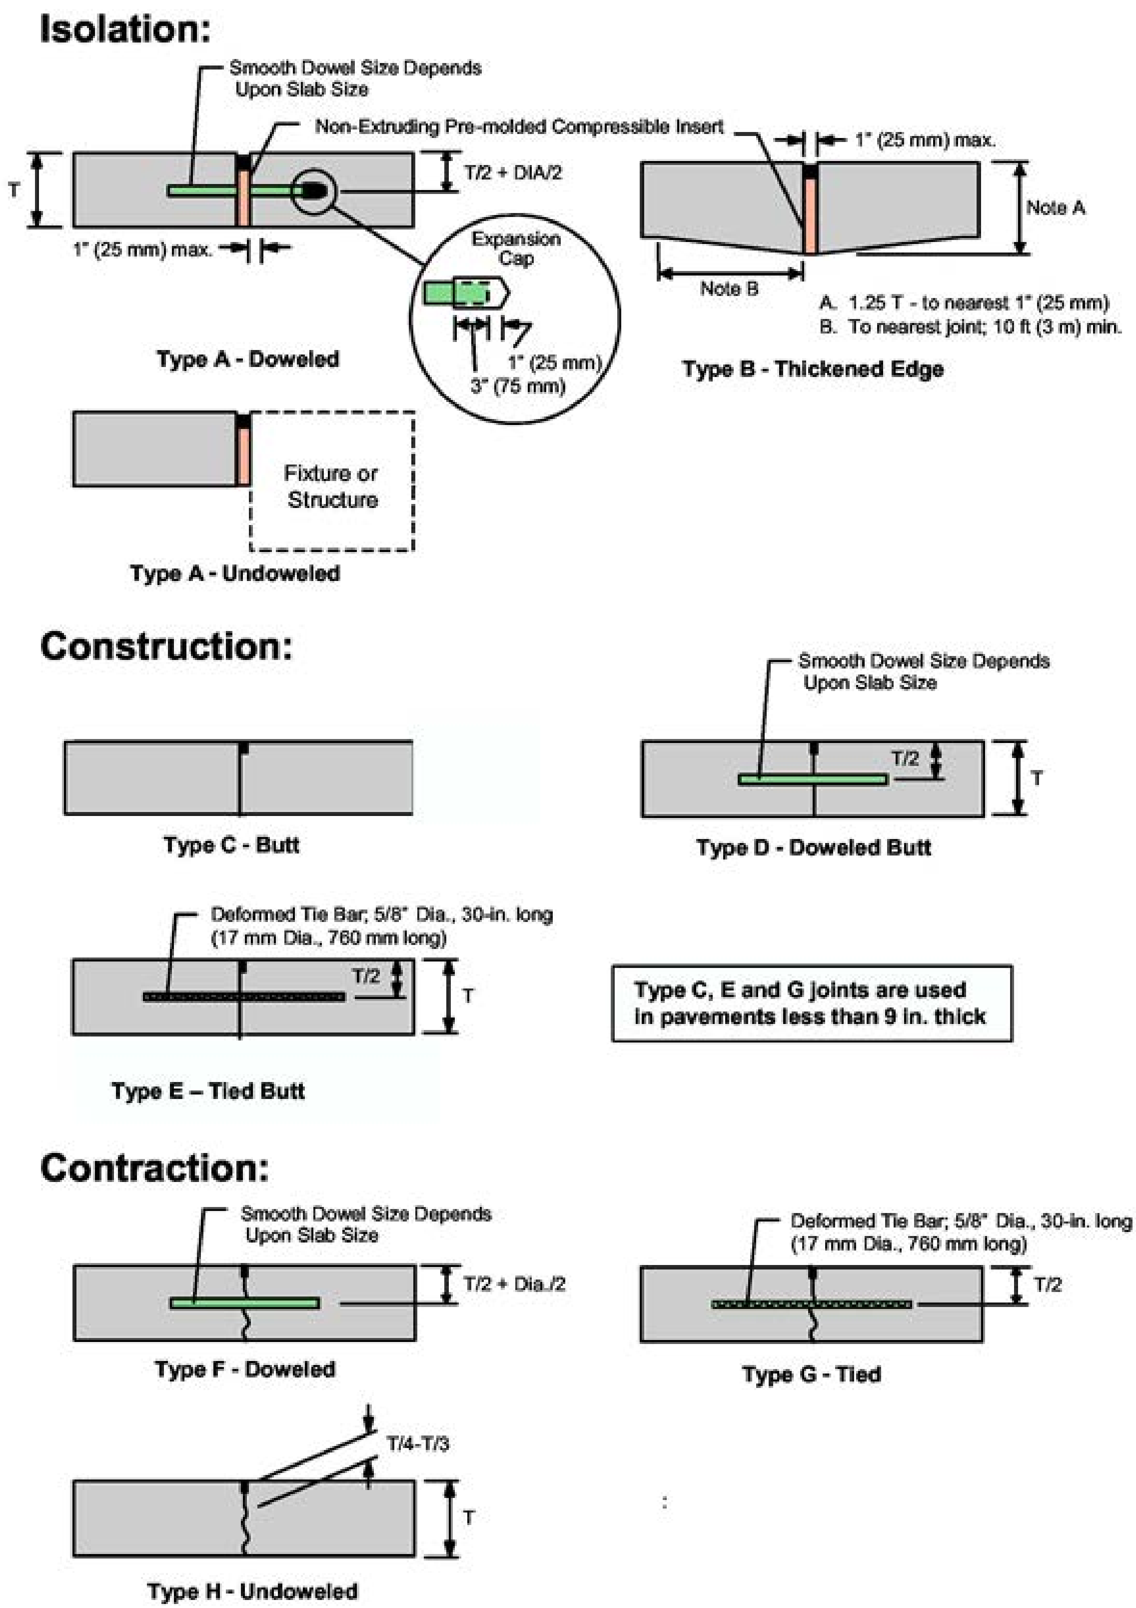
9-2.2 Construction Joints.

Construction joints separate abutting construction placed at different times, such as the end of a day’s placement or between paving lanes.

9-2.3 Contraction Joints.

Contraction joints control the location of pavement cracking caused by drying shrinkage or thermal contraction. Contraction joints also reduce stress caused by slab curling and warping.

Figure 9-1 Concrete Pavement Joint Types



9-3 JOINT LAYOUT PRACTICES.

Consider the following items when planning the joint layout.

- Check the plans for any conflicts with dowel bars and tie bars.
- Make sure joints line up across pilot lanes.
- Spot survey several locations to make sure joints will line up.
- Plan paving lanes such that only one longitudinal joint is sawcut.
- Plan blockouts and situate them more than 1.2 m (4 ft) from joints, when possible.

9-3.1 Joint Layout Considerations.

The following are necessary considerations.

9-3.1.1 Inspection.

Inspect the project drawings for the location of dowel bars and tie bars. If any problems are noted, discuss these elements with the engineer before paving.

9-3.1.2 Jointed Plain Concrete.

For jointed plain concrete pavements, do not exceed a slab length to width ratio of 1.25.

9-3.1.3 Odd-Shaped Panels.

Where rectangular-shaped slabs cannot be constructed (odd-shaped panels), embedded steel is placed in both directions at a ratio of at least 0.05 percent. The embedded steel will not prevent odd-shaped slabs from cracking but can minimize crack openings to reduce infiltration of debris and future spalling maintenance.

9-3.2 Factors Affecting Joint Spacing.

The primary function of all joints is crack control. Plain concrete pavement joints are spaced to reduce thermal and shrinkage restraint stresses such that no uncontrolled cracking occurs between joints due to these restraint stresses. The restraint stress magnitude influencing joint spacing depends on:

- Concrete temperature and moisture gradients (top and bottom of slab)
- Concrete temperature drop (relative to temperature at concrete final set)
- Concrete shrinkage
- Slab/base interface friction
- Modulus of base/subgrade reaction
- Pavement thickness

9-3.2.1 Concrete Properties Affecting Joint Spacing.

Concrete properties affect joint spacing. Concrete properties affecting restraint stress magnitudes are:

- Modulus of elasticity (generally 24,000 to 38,000 MPa (3.5 to 5.5 million psi); assumed as 27,000 MPa (4.0 million psi) for most design solutions)
- Coefficient of contraction (generally ranging from 9.0 to 11.8 x 10 ^{6} mm/mm/deg. C (5.0 to 6.5 x 10^{-6} in./in./deg. F)
- Shrinkage coefficient (generally ranging from 250 to 350 x 10 ^{6} in./in.)
- Density (generally 690 to 730 kg/m^2 (142 to 150 lb/ft^2) for air-entrained concrete)

Table 9-1 lists the maximum joint spacing.

Table 9-1 Maximum Joint Spacing

Slab Thickness, in.	Slab Thickness, mm	Joint Spacing, ft	Joint Spacing, m
< 9	230	12.5–15[1]	3.8–4.6
9–12	230–305	15–20	4.6–6
> 12	> 305	20	6

[1] 10–15 ft (3.0–4.6 m) for roads and parking lots

9-3.3 In-Pavement Structures.

9-3.3.1 Light Cans.

Pavements with light cans require special attention. Blockouts used to install light cans can restrain slab movement and increase restraint stresses associated with moisture and thermal changes. Design engineers typically add embedded steel to slabs containing light cans. While the embedded steel does not prevent restraint cracking around light can blockouts, the steel holds any cracks that develop tight and reduces the potential for crack spalling. Since most slab movements occur near longitudinal and transverse joints, establish jointing patterns such that light cans are located more than 1.2 m (4 ft) from planned joints. Cracks tend to emanate from light cans if the light cans are positioned closer than 1.2 m (4 ft) to joints.

9-3.3.2 Marking Joint Locations.

Mark joint locations on the base, edge of the slab, or on the forms. When paving a runway or wide taxiway, it is challenging to transfer joint locations across pilot lanes. Use surveying instruments to transfer joint locations across paving lanes. Small deviations in transferring joint locations across pavement can skew joint alignment. Carefully mark joint locations and construct joints at the proper locations.

9-4 TIMING OF JOINT SAWING.

Proper timing of sawcutting is critical to optimize joint performance. Consider the following factors.

9-4.1 Timing.

Commence sawing as soon as the concrete hardens sufficiently to permit cutting without chipping, spalling, or tearing.

9-4.2 Hardening.

Factors that influence the rate of concrete hardening:

- Air and concrete temperatures during placement
- Cement content of mixture
- Mixture characteristics

9-4.3 Readiness.

Regardless of the time of day or night, a contractor must be prepared to saw when concrete is ready.

9-4.4 Weather.

During warm weather, concrete is usually ready for sawing between 4 to 12 hours after placement. In cold weather, or when mixture water is below 10 °C (50 °F), sawing can be delayed as long as 24 hours.

9-4.5 Aggregate.

Generally, concrete mixtures with soft, coarse aggregate, like limestone, do not require as much strength development before sawing compared to mixtures with hard, coarse aggregates.

9-4.6 Delay.

If sawing is delayed, random cracking can occur.

9-4.7 Opportunity.

Several factors can reduce the length of the joint sawing window. If the sawing window becomes short, random cracking can develop.

9-4.8 Equipment.

When sawing, the concrete must support the equipment weight and associated personnel.

9-4.9 Hardness.

Spalling along a sawcut or aggregate tearing from the surface indicates inadequate concrete hardness.

9-5 EFFECTS FROM STABILIZED BASES.

Concrete pavement placed on a stabilized base is sensitive to sawcut timing. Inadequate precautions allow high slab/base interface friction to develop, producing uncontrolled cracking. A rapid overnight temperature drop causes shrinkage stresses in the concrete that can exceed the tensile strength of the concrete and lead to uncontrolled cracking. When adverse conditions are expected, saw as soon as possible and continue until complete. Conversely, the surface of a subbase can become hot during summer conditions. This increase in the temperature gradient through the slab significantly decreases sawing time. For asphalt treated bases, whitewash the surface of the material to increase reflectivity.

9-6 FACTORS THAT DECREASE SAWING TIME.

Factors that shorten the time frame available for joint sawing include:

- Sudden temperature drop
- High wind, low humidity
- High friction bases
- Bonding between base and slab
- Porous base
- Retarded set
- Paving fill in lanes
- Delay in curing application

9-6.1 Determining When to Saw.

It is difficult to determine when to saw. Sawing must occur before the concrete cracks on its own but after achieving sufficient strength to allow the saw to cut aggregate without dislodging.

9-6.1.1 Saw Equipment.

Determining the earliest time to cut joints is usually based on the equipment operator’s scratch test or observation of the raveling or spalling while making the initial saw cut.

9-6.1.2 Temperature.

As a rule of thumb, the limit of sawing is to cut before the surface concrete temperature significantly decreases.

a. Under most paving conditions, the top surface temperature starts to decrease while sub-surface concrete temperatures continue to increase. Once the concrete surface temperature decreases and a thermal gradient is generated, thermal curling restraint stresses start to develop. Concrete cracking results if the restraint stresses exceed the concrete tensile strength.

b. If saw cuts are installed before significant surface cooling, curling restraint stresses remain low and cracking develops only at planned joint locations.

c. Use surface thermometers or infrared guns to monitor concrete surface temperatures.

d. On larger projects, monitor slab surface temperature decreases to establish guidelines for allowable surface temperature changes.

- For example, assuming relatively constant paving conditions, if no slab cracking results in sections with a 5 degree drop in surface temperature, establish the last limit guideline for saw cuttings at a temperature drop of 5 degrees.
- Follow this guideline until weather condition changes or other data warrant establishment of new maximum allowable temperature decreases.
- The factor of safety is reduced as the maximum allowable temperature decrease increases.

9-6.1.3 Maturity Meter.

An improved method to establish the early limit window of opportunity uses a concrete maturity meter. The maturity method accounts for the combined effects of temperature and time on concrete strength development.

a. Concrete maturity meters use thermocouples installed in plastic concrete and automatically record temperatures at given time intervals.

b. Accounting for both curing temperature and time assumes that a given concrete mix has the same strength at equal maturities independent of curing time and temperature histories.

c. Thermocouples are typically inserted approximately 50 mm (2 in.) deep, as soon as possible after finishing operations. Set maturity meters to acquire temperatures at 15- to 30-minute intervals. The meters automatically calculate maturity. Early-age strength development is a function of ambient conditions, initial concrete temperatures, cement type, cement quantity, coarse aggregate type, and water-cementitious ratio. Maturity values can also establish early sawcutting times correlated with acceptable amounts of raveling or visual ratings.

9-7 JOINT SAWING OPERATION.

A two-step process is typical for sawing joints. In the first step, the initial cut relieves restraint stresses and allows cracking to develop at planned locations. A second cut forms the sealant reservoir after the hydration process is complete.

9-7.1 Initial Saw Cutting.

Items to be considered for the initial sawcut are as follows.

a. Make the first sawcut (early sawcut) with a single narrow blade (approximately 3 mm [1/8 in.] in width).

b. Perform early sawcuts made during rising concrete temperatures to the full design sawcut depth in one pass.

c. Early cuts made during falling concrete temperatures require special attention as concrete shrinkage occurs with falling temperatures.

d. Cuts to full design sawcut depth during falling concrete temperatures may cause random cracking (pop-off cracking) to occur ahead of the saw.

- It may be possible to avoid this problem by use of two sawcuts. Perform the first cut to one-half the design depth followed by a second pass to design depth.
- Discontinue sawing in any joint where a crack develops ahead of the sawcut.

e. Saw transverse joints consecutively in the same sequence as the concrete is placed in the lane.

- Sometimes a practice called skip sawing is used to control cracking. This practice involves cutting every other or every third joint.
- Skip sawing can result in variable joint width.
- Excessive sealant stresses may occur in those joints initially sawed.
- Before sawing each joint, examine the concrete closely for cracks. Do not saw planned joints if a crack appears near the planned joint.

9-7.2 Reservoir Cutting.

The following considerations are for the reservoir cut.

a. A second sawcut accommodates joint sealing material (reservoir cut).

b. A wide blade makes a second cut to the required depth.

c. Do not use gang blades to make the second cut. The gang blade system stability is insufficient to minimize spalling potential of the joint.

d. The second sawcut (in a single pass or two passes) is made at any time before sealant installation. However, the later in the concrete age the sealant reservoir is formed, the better the condition of the joint face.

e. Assure that the depth and width of the second sawcut meets the shape factor (width-to-depth ratio) requirements of the sealant. The satisfactory performance of the joint sealant depends on the shape factor of the sealant.

f. During both the early sawcut as well as during the second cut, periodically check the sawcut to verify proper depth.

- Saw blades tend to wear as well as ride up when hard aggregates are encountered.
- Periodically measure blade diameter to monitor blade wear.

9-7.3 Shape Factor.

The joint sealant shape factor is based on the width of the reservoir divided by the depth (W/D). The value of this factor is based primarily on the type of sealant, such as hot-poured, silicone and two-component cold pour, and preformed compression seals.

9-7.4 Cleaning the Saw Cuts.

Wet sawing leaves a slurry on the surface of the concrete and on the joint face. For the first cut, flush the slurry with low-pressure water followed by low-pressure air blasting. Once the slurry is removed, reapply the curing compound along the joint. For the reservoir cut, follow the same process except increase the air and water pressures since the concrete is hard and curing compound is not required if sufficient curing has occurred.

9-7.5 Sawcutting Equipment.

Sawcutting involves several types of equipment. Longitudinal contraction joints are installed with walk-behind saws or early age entry saws. Transverse contraction joints use one of the following:

- Spansaws
- Conventional walk-behind saws
- Early entry saws
    - o Do not use water.
    - o Are generally capable of sawing at earlier ages than spansaws or walk-behind saws.
    - o Depending on paving conditions and early-age concrete strength gain, early-age entry sawcutting is generally possible before any surface cooling and development of tensile restraint stresses.

- o Since sawcuts are performed earlier, the minimum depth requirements for the initial cut may be less. Current maximum depths for early entry saws are 100 mm (4 in.). This can limit their use to pavements less than 400 mm (16 in.) thick on aggregate base.

Other joint sawing items to consider include the following.

a. Both the longitudinal and transverse joints are cut at about the same time.

b. When concrete is slipformed, extend the transverse sawcuts completely through the longitudinal edge.

- If a sawcut is stopped short of the longitudinal edge, the transverse sawcut at the edge is not as deep and the potential for random cracks initiated at outside corners increases.
- When metal pavement forms are used, the saws must get as close to the forms as possible.

c. The risk of early-age restraint cracking before installing sawcuts increases if the concrete strength gain is retarded (slow strength gain) or the concrete surface temperatures rapidly decrease (surface cooling from rainfall).

d. If sawcuts cannot be installed quickly enough due to low strength gain or in relation to rapid generation of restraint stresses, consider concrete skip sawing.

- Installing every third or every other transverse joint may reduce the potential for random cracking. However, this can lead to variable crack widths at the planned transverse joints. Place roofing felt or a geotextile fabric over cracks that open significantly before placing an abutting lane.
- Only use skip sawing when there are no options.
- Consider adjusting the concrete mixture or paving procedure before using a skip saw technique.

e. Joint reservoir beveling (chamfering) at transverse joints increases angles at joint corners from 90 to about 120 degrees.

- Beveling reduces the potential of damage from snow removal equipment.
- A major disadvantage is the cost increase to install a beveled sealant reservoir.
- If beveling is used, calculate the shape factor based on the depth of sealant at the point where the joint face is vertical.

9-8 JOINT CLEANING BEFORE SEALING.

Joint reservoir cleaning before joint sealing ensures long-term service of the sealant. The following items are essential.

a. Immediately before sealing, thoroughly clean joints of all laitance, curing compound, and other foreign material.

b. Use sandblasting, wire brushing, water blasting, or some combination of these tools to clean the joint.

- Sandblasting or wire brushing is preferred.
- Prime joint faces immediately after cleaning.
- Perform sandblasting with great care because of the risk of sand particles filling the joint.
- The procedure for sandblasting applies it only to the joint face where the sealant will adhere.
- When sandblasting, hold the nozzle at an angle to prevent penetration of sand particles deeper into the joint.

c. Air blasting is the final cleaning step. The air stream must be free of oil. Many modem compressors automatically insert oil into the air lines to lubricate air-powered tools. For joint cleaning, disconnect this line and install an effective oil and moisture trap. In most cases, the inside of the hose of a lubricating air compressor is coated with oil. Use new hoses to clean joints. When air blasting, hold the nozzle no more than 50 mm (2 in.) from the pavement surface to blow debris at the front of the nozzle.

d. Once air blasting is complete, backer rod installation and sealant application can take place. Repeat air blasting at those joints remaining open overnight or for extended periods.

9-9 JOINT SEALING ISSUES.

Critical issues regarding joint sealing for pavement include timing of reservoir widening, beveling, joint cleaning, depth of sealant, and timing of sealing. Other joint sealing considerations include the following.

a. Joint sealants are used in concrete pavement joints to keep out damaging material and minimize infiltration of water.

b. To perform to expectations, sealant materials must be capable of withstanding repeated extension and compression as the pavement slabs expand and contract with temperature and moisture changes.

c. The size and shape of the sealant cross-section affects the sealant material performance.

d. In refueling locations and any airfield pavement area subject to fuel spillage, jet-fuel-resistant sealants are necessary.

e. Timing of sealing operations may vary from:

- As soon as possible
- Prior to placing the adjacent lane
- When the pavement achieves the minimum flexural strength for construction traffic
- Prior to grooving operations

f. Overall, it is better to wait as long as possible to seal the joints:

- Hard debris can infiltrate a green cut, causing spalling.
- The benefits of waiting to seal joints can outweigh the disadvantage of debris intrusion.
- Use a temporary filler such as backer rod or rope to prevent debris from infiltrating joints.
- Temporary filling of joints is a good practice to minimize infiltration by construction debris.

g. Clean joints are necessary for all sealant materials to perform properly.

9-9.1 Hot-Poured Joint Sealing Material.

Hot-poured sealants usually consist of some combination of asphalt, coal-tar, and rubber. Before sealing joints, the contractor must demonstrate that the equipment and procedures for preparing and placing the sealant will produce a satisfactory joint seal. The sealant must bond to the concrete surface of the joint walls, have no voids, and tack-free after a specified time period. The key to achieving good joint sealing include the following.

a. Install the closed-cell backer rod to the appropriate depth to achieve the right shape factor.

b. The backer rod should not bond to the concrete or sealant. If bonding occurs, it induces stress into the seal.

c. The backer road must be compressed about 25 percent if it is to maintain its position in the joint.

d. The heating kettle should be an indirect heating type. Direct heating elements can cause changes in materials properties. Kettles also need agitators to prevent localized overheating. Overheated material can lose plasticity. Discarded overheated material.

e. Fit the application wand with a re-circulation line. Otherwise, sealant in the hose can drop below application temperature.

f. Fill the reservoir from bottom to top. Take care to apply the sealer so the material is solid, with no entrapped air.

g. Conduct a trial installation to verify the sealant can achieve a good bond.

h. The sealant must recess from the surface to provide protection from early traffic.

9-9.2 Cold-Poured Joint Sealing Material.

Cold-poured sealants are usually polysulfides, polyurethanes, or silicones. The material is a single component ready to use or a two-component material requiring onsite mixing. Before sealing joints, the contractor should demonstrate that the equipment and procedures for preparing, mixing, and placing the sealant will produce a satisfactory installation. The sealant must bond to the concrete surface of the joint walls, have no voids, and must be tack-free after a specified time period. The following are key items to consider.

a. Depending on the material and the recommendation of the manufacturer, the cold poured materials may be mixed in a paddle wheel or other mixer or fed from separate containers to a mixing nozzle that injects the material into the joint.

b. Silicone is either self-leveling or non-self-leveling. These materials cure by chemical reaction, transforming from a liquid state to a solid state.

c. Check the potential for incompatibility between silicone seals and the concrete aggregates. A silicone sealant that does not develop proper bond with aggregates is going to fail.

d. Aggregate surface moisture at the time of sealing can affect the bond between silicone and concrete. Consider the use of a joint primer provided by the manufacturer to ensure the silicone seal develops a satisfactory bond.

e. Cold-poured materials are generally more sensitive to moisture in the reservoir; therefore, it is essential to ensure reservoirs are dry when installing sealant.

f. Cold-applied joint sealing compounds are applied by pressure equipment that forces the sealing material to the bottom of the joint and completely fills the joint without spilling material on the pavement surface.

g. Non-self-leveling sealants require additional tooling to maintain the required depth of sealant. Employ tooling on non-self-leveling sealants before the material cures.

9-9.3 Preformed Joint Sealer.

Most preformed seals are made of extruded neoprene rubber. These sealants are also called compression seals. The neoprene material is compressed and inserted into the joint reservoir. The pre-compression amount is based on the anticipated movement of the joint over the service life of the sealant. The key aspects of achieving a good preformed sealant application include the following.

a. For the sealant to be effective during its service life, the sealant material must be maintained in the sealant reservoir at a minimum amount of compression (it is always in compression).

b. Follow the sealant manufacturer’s recommendations for sealant sizing and installation.

c. Insert the sealant using a device that uniformly compresses the sealant with nominal stretch.

d. The sealant must be lubricated, straight, vertical, and not damaged.

e. The installation device should not stretch the sealant. Stretching reduces the allowable sealant compression and sealant failure can occur. The maximum stretch is 2 percent.

f. There are two ways to check for stretching.

   1. First, insert the sealant in a known length of joint and then remove the material and measure the extracted length.

   2. The second method is to pre-measure a length of sealant. A permanent mark is placed on the roll. After installation, the length of the installed sealant is measured.

9-10 TROUBLESHOOTING GUIDE.

Early age cracking problems are discussed in Appendix D. These problems may be due to a single cause or a combination of causes. The troubleshooting guide in Table 9-2 discusses the non-cracking problems associated with joint sawing and sealing.

Table 9-2 Troubleshooting Guide for Joint Sawing and Sealing

Problem	Probable Cause	Corrective Action
Poured joint sealant adhesion failure	• Joint face not clean • Joint shape factor not correct	• Check joint face for cleanliness • Check joint shape factor • Replace sealant
Poured joint sealant cohesive failure	• Sealant properties poor due to overheating or underheating	• Reduce heat • Apply proper heat • Use insulated hoses • Replace sealant
Loose preformed sealant	• Sealant not sized properly • Joint width too large • Sealant stretched	• Use properly sized sealant • Check joint width • Check sealant quality • Review installation procedure
Raveling or spalling of joint face.	• Sawcutting performed early • Poor sawcutting operation • Joint area not cured properly	• Apply curing compound after first cut • Delay the reservoir cut • Review sawcutting operation • Review joint face curing process

CHAPTER 10 IMPLEMENTING CQC REQUIREMENTS

10-1 INTRODUCTION.

The implementation of CQC programs in this chapter is limited to the framework of the project CQC plans in Chapter 3. Operational issues are presented instead of actual test performance.

10-2 CQC TESTING AND PRODUCTION PLANS.

The CQC plan should be specific and contain enough detail to implement during construction. For example, basic requirements of a QC plan for slump testing in fresh concrete may include the following:

- Specification item: PCC paving
- Item description: Process control testing
- Type of field or laboratory test: Slump of fresh concrete
- Test standard: ASTM C143/CRD-C 5
- Test frequency:
  - First three trucks each day
  - One test per 50 yd^3 (40 m^3)
- Responsibility: QC paving technician
- Specified tolerance: 40 mm ±25 mm (1.5 in. ±1.0 in.) (action limits) and ±38 mm (±1.5 in.) (suspension limits)
- Corrective action:

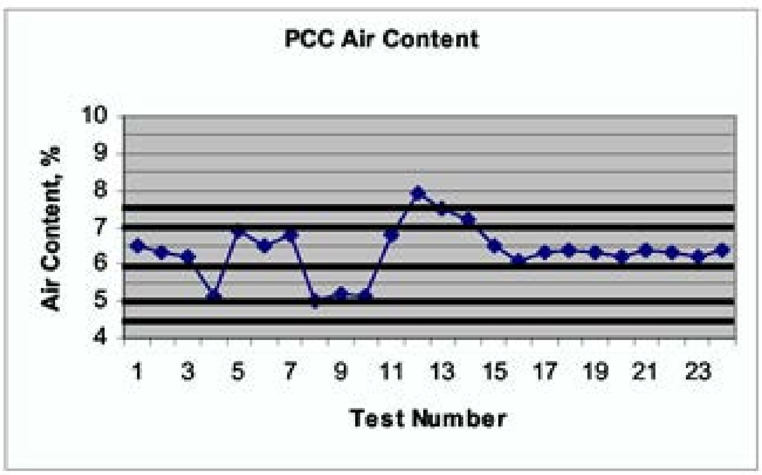
  If one individual slump test is outside the action limits, test the next three trucks. If those tests are within the action limits, then resume the normal testing frequency. If at any time one individual slump test is outside the suspension limits or two consecutive slump tests are outside the action limits, halt production and test each truck enroute. If the slump of any of the remaining trucks is outside the action limits, reject the loads. If the slump tests for the remaining trucks are acceptable, place the material. Production paving should not be resumed until the contractor has identified the problem and implemented corrective action. After concrete placement resumes, test the first three trucks for slump. If those tests are within the action limits, resume the normal testing frequency.

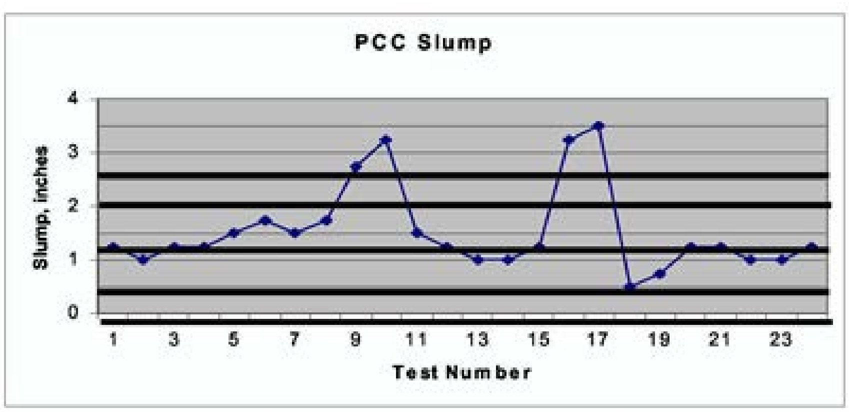
  Although it is impossible to account for all scenarios in the CQC plans, it is important to outline the procedures for known or possible recurring problems. CQC plans fail when there is no clear corrective action plan for each tested item.

10-3 CONTROL CHARTS.

Control charts (Figure 10-1) provide the inspection and testing team and senior management a summary of the construction process. Control charts are excellent tools to track trends and anticipate problems. The benefits of using control charts include the early detection of problems, monitoring variability, and establishing the process capabilities. Similar to other documentation on a construction project, control charts are only useful when updated and adjustments implemented on a timely basis. The CQC plan must contain a detailed procedure identifying which items require control charts, the information presented on each control chart, the required posting time, and distribution. Control charts should include individual test results, the average of all test results, and action limits at 3 standard deviations (3s). Action limits should not be based on specification requirements. Each contractor's process has a unique variability that dictates where to place the 3s limits.

Figure 10-1 Example Control Charts





10-4 TESTING PROCESS.

Field laboratories follow the same standards as permanent facilities for each test conducted (for example ASTM C1077/CRD-C 553 requirements). Items to address for a field laboratory include:

- Sufficient capacity for properly curing beams and cylinders. If curing tanks are used, identify the method that controls the water temperature, water level, and lime content of the water.
- Sufficient area for properly separating or quartering aggregates for testing.
- Calibration of testing and monitoring equipment, including test machine scales, sieves, and laboratory thermometers, by certified/qualified source. When practical, separate agencies perform calibration for QA and QC.
- Calibration of all field testing equipment, including air meters, slump cones, and field thermometers.

10-4.1 Definitions.

When test methods are specified and the variability in a test method affects the pay factor, it is important that the engineer and contractor understand the limitations inherent in the test methods as stated in their precision and bias statements. The following definitions are derived from ASTM E177.

10-4.1.1 Accuracy.

Accuracy refers to how close a test result is to a reference value and incorporates both the imprecision of the measurement and the bias of the test method.

10-4.1.2 Precision.

Precision refers to closeness of agreement between test results obtained under like conditions. The greater the scatter in test results, the poorer the precision.

10-4.1.3 Bias.

Bias is the consistent difference between a set of test results and an accepted reference value of a property being measured. When an accepted reference value is not available, bias cannot be determined.

10-4.1.4 Components of Variability.

Variability in a measured construction attribute may be due to:

- Natural (material) variability
- Variability introduced by the construction process
- Testing variability is introduced through the precision (or lack of precision) and bias of the test method

10-4.2 Achieving Quality.

Three conditions must be consistently met to achieve high levels of quality.

1. The process is stable (only common cause variability is present).
2. The process is capable (common cause variability must be small enough to permit consistent results within the specified tolerances).
3. The process is on target (the process is consistently performing near the specified target).

10-4.3 Subgrade, Subbase, and Base Testing.

Major testing items for subgrades, subbases, and bases include material characteristics such as gradation and appropriate density and moisture values, thickness, and grade control. A smooth, uniform pavement starts at the subgrade. The uniformity of these layers affects the overall performance of the pavement. If failed material is placed on the grade, typical remediation blends in loads of good material. However, to maximize quality, remove the failed material to reduce material variability. Items to address in CQC plans include:

- Density requirements for each material lift
- Density requirement for each different subgrade type
- Maximum and minimum placement thickness
- How to determine the target density for each material type
- Gradation requirements for each material
- Testing frequency and location for all tests
- Mix design requirements for stabilized layers
- Process for documenting, reporting, and distributing all test results, including schedule
- Action list for handling failed test results

10-4.4 Fresh Concrete Testing.

Take representative samples of concrete placed for paving. Collect from several different discharge areas. Remix the sample before performing any tests and keep the sample covered with a plastic sheet to prevent evaporation. Testing of fresh concrete typically includes assessing the air content, slump, temperature, and the unit weight. Consider the following items for concrete testing.

a. Properly calibrate meters for air content testing (ASTM C231/CRD-C 41, *Pressure Method*, and ASTM C173/CRD-C 8, *Volumetric Method*). Pressure meter accuracy depends on the altitude at which it is calibrated. Repeat tests before considering concrete out of specification.

b. The slump test (ASTM C143/CRD-C 5) determines consistency, but not necessarily the workability of concrete. Clean and pre-wet the cone for each test. Repeat test using another sample before deciding concrete is off specification.

c. Record the temperature of the fresh concrete (ASTM C1064/CRD-C 3) every time strength specimens are made and whenever concrete temperatures are suspected of nearing specification limits.

d. The density of the fresh concrete (ASTM C138/CRD-C 7) can indicate a possible change in air content and determines yield. Properly calibrate the container.

e. Although these tests are widely used and understood, often the details of the testing requirements are not. It is important for the contractor and inspectors to review testing standards and agree on testing procedures. Describe these details and logistics in detail in the CQC plans. Items to address in the CQC plans include:

- Testing frequency
- Testing location (**Note:** Testing is conducted at the plant or onsite to determine the effect transporting the concrete has on basic concrete material properties.)
- The process for updating and distributing control charts
- Clearly defined action items for test results that do not conform to the specifications or standards

Obtaining a representative sample of fresh concrete is very important to ensure reliable test results. Take the fresh concrete sample from the center one-third of the batch. The CQC plans need to address the location of sampling within each batch for each type of concrete delivery vehicle. Control charts are useful for evaluating fresh concrete test results. Create action and suspension limits for each test and in the CQC plans address the specific actions to take when test results are outside the action or suspension limits.

10-4.5 Thickness Testing.

Pavement thickness is tested in several ways. It is checked by using paving stringline as a guide, performing destructive testing by excavating non-stabilized material or taking cores from stabilized material and concrete layers, or surveying elevations before and after placement. Coring is the preferred method. Preferably, label and store cores (typically 100 mm [4 in.] in diameter) onsite until the end of the project. Items to address in CQC plans include:

- Testing frequency and location
- Clearly defined procedures for locating, measuring, and reporting the test results
- For projects with stabilized open-graded drainable bases, agree on the procedure to determine the bottom of the core

- Avoiding thickened edges and transition areas for test locations

10-4.6 Aggregate Tests (Gradation and Moisture Content).

Aggregate gradation testing varies based on the specifications for bases, stabilized bases, trench backfill, and concrete. Since projects use large quantities of aggregate, testing the gradations can become overwhelming. Items to address in the CQC plans include:

- Testing frequency
- Requirements for stabilized bases and concrete mixture verifications
- Sampling location (stockpiles or individual trucks)
- Aggregate moisture content tests - frequency (ASTM C70/CRD-C 111, ASTM C566/CRD-C 113)
- Gradation in fresh concrete, washed gradations
- Clearly defining action items when the aggregate fails the gradation tests
- How to determine the limits of unacceptable material
- Developing a clear reporting process to ensure timely distribution of test results
- Verifying bulk specific gravity of each aggregate at designated times throughout the project. This is not practical on a smaller project (less than 42,000 m^2 [50,000 yd^2])

10-4.7 Strength Testing.

Strength testing may include flexural and compressive testing.

10-4.7.1 Flexural Strength Testing.

Due to the importance of strength in the design and acceptance of pavements, flexural strength testing requires attention to detail. Test results are affected by minor changes in procedures that can lead to increased variability and, in some cases, suspect results. The test machine must be calibrated and operators must understand the testing requirements. Check the beam tester for the correct load and rate of loading and check for uniformity of loading (load distribution) between the two supports and across the width of the beam. Field supervisors must monitor the handling of the test specimens at the job site, during transportation, and at the laboratory. Beams are vulnerable to damage in handling and transport. Damaged beams will yield low strength results. Items to address in the CQC plans include:

- Location of material sampling, such as at the plant or delivery truck, or on-grade in front of the paver
- Sample fabrication location
    - Near the material sampling point

  - o Onsite laboratory

- Ensuring that requirements concerning the time allowed between material sampling and beam fabrication are met
- Dimensions of beam samples. Typically, 150 by 150 by 530 mm (6 by 6 by 21 in.) specimens are used
- Type of beam molds allowed: plastic or steel
- Fabrication procedures
- Field curing, transportation, and laboratory procedures
- Frequency of testing
- Number of beams per sample location
- Determination of sample locations
- Curing requirements for additional beams to be made for other reasons, such as opening to traffic (field cured or laboratory cured)
- Use of a consignment form that tracks each concrete sample from fabrication, field curing, transportation to laboratory, laboratory curing, and testing
- Procedure for disposition of possibly damaged beams and results of known bad tests

10-4.7.2 Compressive Strength Testing.

Compressive testing may be required in addition to flexural strength testing. Even if not required, it may be preferable to make companion sets of cylinders along with beams. The cylinders may help resolve future disputes over the in-place strength of the concrete pavement if flexural strength testing is found to be questionable. Items to address in the CQC plans include most of the flexural strength testing items previously discussed. Cylinder specimens are less vulnerable to damage in handling and transport than beam specimens. Coring, core conditioning, and core testing are conducted in accordance with ASTM C42/ CRD-C 26 and the use of the splitting tensile strength test is conducted in accordance with ASTM C496/CRD-C 77.

10-4.7.3 Core Strength Testing.

When beam or cylinder strength tests are not performed adequately or if test results are suspect, consider core strength testing to determine the strength quality of the in-place concrete. If core testing is used, consider the following items.

a. Test cores for compressive or splitting tensile strength.

b. Use core strength test results in accordance with established procedures, as defined in the specifications. These procedures typically involve use of project-specific correlations between the core strength and the beam or cylinder strength.

c. Initiate core testing at a test age close enough to the specified test age for the flexural or compressive strength testing.

d. Core conditioning before testing is important.

- Air-dry conditioning typically results in higher compressive or split tensile strengths.
- However, condition cores as defined in the project specifications.

10-5 EDGE SLUMP/JOINT FACE DEFORMATION/PROFILE TESTING.

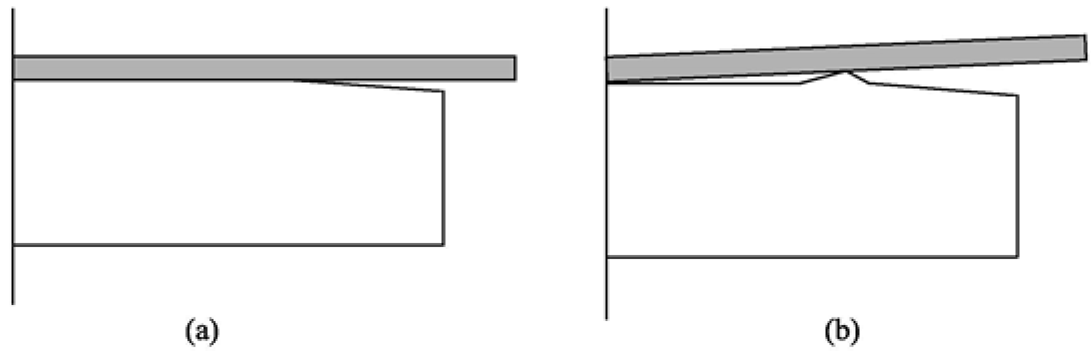
Excessive edge slump and joint face deformations under slipform paving are indications of improper concrete mixture proportioning, improper concrete placement, or improper equipment operation.

10-5.1 Edge Slump Testing.

Typical specifications require that edge slump not exceed 6 mm (0.25 in.) over 15 percent of the joint length and that edge slump be no greater than 10 mm (3/8 in.). Checking for edge slump requires a straight edge and level adjusted for the cross-slope, as shown in Figure 10-1. Edge slump can be measured on either fresh or hardened concrete. The straight edge must be of sufficient length, typically 3.1 to 3.7 m (10 to 12 ft), to support itself on the central portion of the slab and away from the area of edge slump, 300 to 600 mm (12 to 24 in.). Inspectors must be aware that small bumps or deviations, exaggerated in Figure 10-1 (b), might yield incorrect results. Items to address in the CQC plans include:

- How soon to begin edge slump testing
- Frequency of edge slump testing
- Detailed procedure, agreed upon by QA and QC, for measuring the edge slump
- Agreed upon corrective action for edge slump that occurs in the fresh concrete and the hardened concrete
- Is the contractor allowed to correct excessive edge slump in fresh concrete?
- Are temporary forms allowed in areas where edge slump is excessive?
- Is sawing of the edges of the hardened concrete an acceptable solution for edge slump? The distance back from the edge depends on the amount of edge slump.

Figure 10-2 Measurement of Edge Slump



10-5.2 Joint Face Deformation.

Items to address in the CQC plans include:

- Are the joint face tolerances the same for transverse and longitudinal joints?
- How are headers handled? Are they part of the testing or are they excluded?
- Can vertical deviations be corrected with concrete saws? If yes, do the cuts have to be full-depth?

10-5.3 Surface Smoothness Testing.

Conduct surface smoothness testing, per the project specifications, that may use a straight edge or a profilograph.

Items to address in the CQC plans include:

- Type of equipment allowed
- Method of evaluation used
- Are the criteria different for different facilities?
- Are any areas excluded?
- Are headers included in the smoothness evaluation?
- How soon after paving is profile testing conducted?
- If a straightedge is used, will the testing be continuous, random, or subjective?
- If using a rolling straightedge, where will the testing occur? In the center of the slab, near the longitudinal paving lane joint, or at the third points of the slab?
- If multiple passes are required, are these per lane or per paving width (which may incorporate two or more lanes)?

10-6 DOWEL BAR ALIGNMENT AND INSPECTION.

Specifications for dowel bar misalignment limit the skew misalignment and horizontal and vertical displacements. Items related to dowel bar placement to address in the CQC plans include:

- Dowel bar material transmittals and bond-breaker coatings
- Detailed procedures for transporting, storing, inspecting, installing, and securing dowel bars
- Detailed procedures for dowel bar inserters (roadways only) that include random checks to ensure equipment is operating properly
- Checking dowel bar assembly for trueness to eliminate skewed bars
- Allowable dowel bar misalignment and how to measure
- Joint saw cut line deviation: How much is acceptable with regards to dowel bar embedment?
- Permissible number of misaligned dowel bars per joint per panel

Note that dowel bar alignment is measured only for pre-placed baskets before concrete placement and for drill and grouted dowels along the longitudinal construction joints. The inspector must ensure that pre-placed baskets are properly positioned and fastened and that the paver operation does not indicate any potential for moving or dragging the dowel basket assemblies. For drill and grouted dowel bars, check the alignment after the epoxy grout sets. Cut and install new dowels for any dowel bars that are misaligned beyond the allowable limits. For machine-inserted dowel bars, as well as the pre-placed dowel bars, ground penetrating radar (GPR) can check the alignment after the concrete is about one day old. However, GPR testing can only determine vertical dowel bar alignment to an accuracy of 3 to 6 mm (1/8 to 0.25 in.); therefore, coring may be required for complete verification of dowel bar placement.

CHAPTER 11 EARLY DISTRESS REPAIR

11-1 INTRODUCTION.

Concrete pavements can exhibit early distress. This occurs while the concrete is in plastic state or soon after hardening. When early distress is observed, identify the cause of the failure and take appropriate corrective measures to reduce the potential for reoccurrence. It is good practice to discuss the disposition of slabs that exhibit early distress at the pre-construction meetings. Commonly encountered early distress are:

- Plastic shrinkage cracking
- Edge slump
- Joint spalling
- Full-depth cracking

11-2 PLASTIC SHRINKAGE CRACKING.

Plastic shrinkage cracking is surface cracking that may develop if the rate of evaporation at the surface is high. Plastic shrinkage cracking typically manifests as shallow 25 to 75 mm (1 to 3 in.) deep, closely spaced parallel cracks. In some cases, the cracking may extend deeper than 75 mm (3 in.) but it is unusual for the cracks to be full depth. It is recommended to take 100-mm (4 in.) -diameter cores over a few cracks to determine the depth of cracking. Repair plastic shrinkage cracking by injecting low-viscosity epoxy or high molecular weight methacrylate in each crack after concrete has hardened. Follow epoxy injection procedures in accordance with the epoxy manufacturer's instructions. The gravity-fed epoxy technique is not recommended, as the crack penetration is not fully effective. Cracking deeper than 75 mm (3 in.) or extensive cracking requires slab removal and replacement (paragraph 11-5).

11-3 EDGE SLUMP.

When a slipform paver pulls forward, there is a tendency for the unsupported edge to slump down at the edge, with depression extending inwards on the slab. If excessive edge slump occurs, adjust the concrete mixture, the paving equipment, or the paving operation. Edge slump is a serious defect because it creates an area for ponding of water and can affect joint performance.

11-3.1 Plastic Repair.

If the edge slump is detected before initial set of the concrete, a plastic repair can be attempted. The repair of edge slump must be carried out correctly to ensure durability of the repaired area. Important items to consider are as follows.

a. The edge must be formed along the repair area.

b. If additional material has to be added to repair the edge slump, the added material must contain a mixture of aggregate particles. Plain mortar addition is not allowed.

c. The repair area material must be vibrated into the existing material.

d. Repair should not be attempted after the curing compound has been applied as the repair area concrete can become contaminated with the curing compound.

e. If initial set has occurred, vibration is ineffective; it is too late to make a plastic edge slump repair.

f. Use of plain mortar or addition of material to hardened concrete may lead to spalling.

g. After vibrating the repaired concrete, screed and finish as uniformly as possible with the surrounding concrete.

h. Texture and cure the repaired area using the same processes as the surrounding concrete.

i. Plastic repairs should be the exception.

Note: Edge slump repairs should be isolated problems and not routine occurrences. If excessive edge slump is occurring, stop the paving until the problem is corrected.

11-3.2 Hardened Pavement.

If edge slump repair cannot be done in a timely manner, it may be necessary to allow the affected slab panels to harden and repair by:

- Sawing the slumped edge and performing a partial-depth repair at the surface depression
- Removing and replacing the slab with excessive edge slump

11-4 JOINT SPALLING.

Joint spalling or excessive joint raveling may develop as a result of the joint sawing operation—typically due to early joint sawing, use of wrong blade type, or poor operation of the sawing equipment. Minor or localized joint spalling is typically repaired using a partial-depth repair technique with the concrete mixture used for paving. If the spalling is severe and excessive in length, consider replacing the affected slab.

11-5 FULL-DEPTH CRACKING.

Localized full-depth cracking may result from the following causes:

- Late transverse joint sawing or insufficient depth of sawing
- Misaligned dowel bars
- Excessive curling or warping
- Rapid surface cooling
- Early-age loading by construction equipment
- Excessive drying shrinkage

- Excessive base frictional restraint

Full-depth cracking that appears within 30 days is usually the result of poor construction practices, poor design, or both. Important items to consider for repair of full-depth cracking include the following.

a. Replace panels in critical pavement areas with full-depth cracking that extends the full width or length of the slab panels. Critical pavement areas are those areas subject to aircraft landing gear loading.

b. Full-depth cracking in non-critical pavement areas (most exterior lanes of a runway or taxiway) may be left in place at the option of the owner. Rout and seal the crack.

c. Treat full-depth cracking in critical pavement areas that extends less than one-third the width or length of the slab as full-width cracking.

d. Repair full-depth corner cracking in critical pavement areas by full panel replacement.

e. Avoid using partial panel replacement in critical pavement areas on new pavement.

f. Follow proper procedures for slab removal and replacement. The procedures must include the following.

  - Remove slabs without damaging adjacent sound slabs or the base.
    - Use double saw cutting along slab perimeter.
    - No heavy impact loading to break slab into small pieces.
    - Sawcut panel into smaller segments and lift out.
  - Inspect the base for damage and correct before concrete placement.
  - Restore load transfer along all joints with dowel bars using the drill and epoxy grouting technique.
  - Use approved concrete mixtures for hand placement operations.
  - Use vibration to consolidate the concrete.
  - Use proper techniques to finish, texture, and cure the replacement slab.

This Page Intentionally Left Blank

APPENDIX A PRECONSTRUCTION REVIEW CHECKLIST

A-1 GENERAL ITEMS.

- Identify the chain of command in the decision-making process.
- Identify roles and responsibilities of key staff for all involved parties.
- Review all design and construction changes issued since bid.
- Certification of materials sources.
- Mix design submittals.
- CQC laboratory and personnel certifications.
- Batch plant certification and mixer efficiency tests.
- Construction schedule.
- Sub-contractor activities.
- Haul roads and access points.
- Conduct a joint half-day construction workshop.

A-2 BATCHING ACTIVITIES.

- Stockpile management.
- Aggregate moistures and added mixture water.

A-3 SUBGRADE.

- Review soil testing reports.
- Cut and fill plans.
- Borrow and waste areas.
- Acceptable fill.
- Removal of organic material or unacceptable soil.
- Procedures when cut depths exceeds engineer's estimate.
- Review of compaction requirements and acceptance testing (moisture and density).
- Proof rolling requirements and acceptance criteria.
- Expected production rates and tentative schedule.

A-4 SOIL STABILIZATION (IF APPLICABLE).

- Review soil stabilization QC plan.
- Review soil data regarding stabilization requirements.
- Mix design submittals (per soil type).

- Field testing requirements and frequency (soil gradation, minus No. 200, plasticity, density, strength, lime/cement/fly ash content, depth, grade elevation).
- Tentative division of project into various areas based on soil stabilization requirements.
- Identification in field as to soil type and stabilization requirements (visual or plasticity testing).
- Who is responsible in field for approving soil stabilization requirements and acceptance?
- Plasticity testing frequency or procedures to further subdivide area based on soil type.
- Trimming procedures and equipment.
- Disposal of trimmed material.
- Initial mixing and production requirements (calendar day restrictions).
- Lime spread rates.
- Minimum passes with mixing equipment.
- Mellowing and curing periods.
- Moisture control and limits during compaction.
- Ambient temperature requirements prior to covering.
- Moisture density, soil classification, pH, lime content, liquid and plastic limit, soluble sulfate, density, strength, and thickness acceptance testing frequency and procedures.
- Allowances for unprotected soil stabilization (protection requirements for various time periods and paving season).
- Allowances for finishing high then re-trimming if stabilized soil is not protected.
- Expected production rates and tentative schedule.

A-5 STABILIZED BASE.

- Review base stabilization in QC plan.
- Mix design submittal.
- Specifications and lot areas.
- Mixing procedures and quantity verification.
- Water content, strength, thickness verification, and grade testing and acceptance procedures.
- Weather (temperature) limitations for mixing and placement on-conformance procedures (under thick, under strength, and over strength).

- Placement procedures and cold joints.
- Rough grading and finish rolling procedures.
- Jointing procedures.
- Moist curing and curing membrane (coverage, time, and material) requirements.
- Aggregate durability, soundness, abrasion, and gradation test data and requirements.
- Grade survey issues (who decides action to be taken if grade is a concern).

A-6 CONCRETE PAVING/PLACING/FINISHING/TEXTURING/CURING.

- Placement and filler lane scheduling.
- Base conditioning.
- Equipment breakdown procedures.
- Maximum concrete haul times.
- Placement procedures.
- Thickness verification during placement.
- Hot/cold weather specifications and precautions.
- Vibrator testing/consolidation issues.
- Curing and texturing procedures.
- Drill and epoxy grouting of dowel bars.
- Tie bar/dowel alignment, spacing, offset verification.
- Straight edge and edge slump tolerances.
- Plastic shrinkage cracking, edge slump, joint spalling, and full-depth cracking treatments.

A-7 JOINT SAWCUTTING.

- Review of sawcutting QC plan.
- Use of early entrant saws.
- Backup saws.
- Rain conditions and skip sawing procedures.
- Reservoir and sealing installation and acceptance procedures.
- Sawcutting sequence and acceptable degree of sawcut raveling.
- Initial and reservoir cut dimension tolerances and dimensions.
- Joint sealant and backer rod material submittals.

- Removal and flushing of joint sawing residue.
- Joint beveling procedures.
- Sealant and concrete curing time.
- Sand blasting, reservoir cleanliness, and moisture condition requirements before sealing.
- Sealant depth tolerances.
- Reservoir priming material requirements.
- Sealant pump, water truck, and sawcutting equipment.
- Allowable ambient temperatures during sealing operations and compression seal reservoir requirements.
- Joint inspection procedures.

A-8 CQC ACTIVITIES.

- Review contractor's QC plan.
- Aggregate durability, soundness, abrasion, and gradation test data and requirements.
- Reinforcing steel and dowel bar submittals.
- Materials sampling and testing procedures.
- Using control charts.
- Concrete mixture designs and w/cm ratio effects on strength.
- Concrete beam sampling, fabrication, curing, and testing procedures.
- Sampling and pay factor computation overview.
- Effects of strength/thickness variability on pay factor.
- Determining locations for thickness tests.
- Partial lots consideration.
- Treatment of premature cracking and spalling.
- Edge slump and smoothness testing and timing.
- Actions to be taken if specification requirements are not met.
- Documentation of test results and deviations.
- Verification of failing acceptance tests, retesting, and referee testing.

APPENDIX B INSPECTION AND TESTING CHECKLIST

B-1 INSPECTION.

B-1.1 Materials.

- Cement and fly ash tickets conforming to accepted and approved sources.
- Approved liquid admixture type and manufacturer conforming to submitted mixture designs.
- Water testing requirements (suitable for concrete).
- Approved curing compound type and source.
- Approved joint sealant and type.
- Approved backer rod material.
- Approved expansion joint filler and dimensions.
- Certifications for embedded steel and dowel bars.
- Approved epoxy for dowel bar grouting.

B-1.2 Equipment.

- Batch plant inspection completed.
- Certification of scales (load cells/belts), water meters, liquid admixture dispensers.
- Batch plant and agitator truck mixer uniformity tests.
- Concrete haulers clean and free of debris and oil.
- Daily verification of slipform vibrator frequency and amplitude.
- Verification of spud vibrator and pan/surface vibrating screed frequency and amplitude.
- Sufficient number of saws to minimize potential for random cracking.
- Curing compound coverage and uniformity tests approved.
- Saw blades suitable for coarse aggregate type.

B-1.3 Base Condition.

- Grade acceptance.
- No equipment damage from loose debris.
- Moisture conditioning of base (granular).
- Application of bond breaker (stabilized base).
- No standing water or frost.
- Transverse grade checks off of string lines or forms.

B-1.4 Embedded Steel and Dowel Bars.

- Tie bar length, diameter, and epoxy coatings.
- Dowel bar length, diameter, and coatings meeting project/plan requirements.
- Dowel basket location, elevation, orientation, and alignment.
- Dowel baskets secured to base.

B-1.5 Concrete Batching.

- Use of stabilized pads for aggregate stockpiles (if required).
- Procedures to mitigate aggregate contamination.
- Uniform stockpile loading.
- Sprinkling for consistent aggregate moistures.
- Utilization of actual aggregate moisture contents.
- Computer printouts of date, time, mixing time, dry batch weights, water, and liquid admixtures.
- Procedures to document added water after batching.
- Minimum mixing times meeting mixer uniformity testing requirements.

B-1.6 Concrete Placement Conditions.

- Concrete placed within specified time after batching.
- Cold weather requirements (air temperatures, no ice in aggregates, initial concrete temperatures).
- Hot weather conditions (air temperatures, initial concrete temperatures).
- Plastic shrinkage potential (air temperatures, initial concrete temperatures, relative humidity, and wind speed).
- Foggers, windbreaks, and evaporative retardants (hot weather) are available.
- Polyethylene sheeting (or other approved covering) available in the event of rain.

B-1.7 Concrete Placement.

- Uniform placement in front of paver.
- No large pockets of entrapped air or voids at vertical slipformed edge.
- Transferring of accurate location for sawed transverse joints.
- Control chart action/suspension limits.

B-1.8 Concrete Consolidation and Finishing.

- Closed surface and adequate consolidation at inserted dowel bars.
- Minimizing concrete floating/finishing after striking off and consolidation.
- Minimizing application of water to surface during final finishing.

B-1.9 Concrete Placement Tolerances.

- Verify interior thickness and at slipformed edges regularly.
- Check final elevation of wire stretched transversely across pavement.
- Edge slump checks.
- Edge shoring needs and procedures.
- Straightedge testing.

B-1.10 Concrete Curing.

- Application of curing compound within 60 minutes of final finishing.
- Curing compound coverage rates and uniformity.
- Vertical longitudinal edges covered with curing compound.
- Minimum concrete curing temperature requirements.

B-1.11 Joint Sawcutting.

- Sawcut depth (initial and reservoir cuts).
- Alignment in relation to transverse joint dowel baskets.
- Acceptable amounts of spalling/raveling.
- Sawcut carried through vertical edge.
- Water/slurry containment.

B-1.12 Opening to Construction Traffic.

- Minimum strength and time requirements.

B-1.13 Joint Dowel Bar Installation (Construction Joint).

- Dowel bar elevation, spacing, alignment, and minimum clearance from transverse joints.
- Dowel bar diameter.
- Drilled hole dimensions meeting specification/plan requirements.
- Epoxy injection procedure.
- Use of epoxy retainer disks.

B-1.14 Joint Sealing.

- Sealant reservoir dimensions.
- Reservoir cleanliness.
- Backer rod placement.
- Sealant curing temperatures meet manufacturer's recommendations.
- Recessed sealant depths.

B-1.15 Grooving.

- Groove depth and spacing requirements.
- Clearance requirements at joints.

B-1.16 Cracking, Spalling, and Acceptance.

- Unacceptable cracking and spalling criteria.
- Repair of cracking and spalling.

B-2 TESTING.

B-2.1 Aggregate Testing.

- Gradation and durability test requirements.
- Sampling for gradations at daily frequencies off belt or representative samples from stockpiles.
- Control chart action/suspension limits.
- Representative sampling for aggregate moistures.
- Determination of aggregate moistures at specified frequencies.
- Frequency for flat and elongated aggregate requirements.

B-2.2 Concrete Sampling, Fabrication, and Curing.

- Sampling location on grade, frequency, and randomness requirements.
- Fresh sample transport requirements; preventing loss of moisture.
- Air content and slump frequency and control chart action/suspension limits.
- Beam mold water tightness, warping requirements.
- Vibration and consolidation sequence.
- Vibrator equipment inspection.
- Initial curing moisture loss control and temperature criteria.
- Transporting molded strength specimens to laboratory for final curing.

- Final curing temperatures and conditioning.

B-2.3 Concrete Flexural Strength Testing.

- Machine calibration and setup.
- Loading rate requirements.
- Sample preparation.
- Leather shims or grinding for beam testing.
- Moisture control during testing.
- Loading rate.
- Measuring beam dimensions.
- Strength calculation.
- Documentation of sample deficiencies.

B-2.4 Core Length (Thickness) Testing.

- Random locations.
- Number of measurements.
- Average core length determination.

B-2.5 Smoothness Testing.

- Straightedge and profile equipment.
- Recommended timing.
- Grinding limits.

This Page Intentionally Left Blank

APPENDIX C JOINT SAWING CHECKLIST

C-1 EQUIPMENT.

- Number of saws.
- Early-age entry saws.
- Saw blade type; compatible with concrete aggregate type.

C-2 INSPECTION ITEMS.

- Test strip sawing.
- Planned versus actual sawcut locations.
- Acceptable raveling and spalling.
- Sawcut depth (initial and reservoir).
- Timing of longitudinal joint sawing.
- Sawcut carried through vertical edge.
- Odd-shaped slabs at radii.
- High tie bar situations.

C-3 COLD WEATHER, RAIN, AND SLOW CONCRETE SETTING TIMES.

- Use of insulation or geotextile fabric.
- Check fly ash usage requirements.
- Consider early-age entry sawing.
- Consider skip sawing.

C-4 POST-CUTTING ISSUES.

- Flushing joints.
- Re-application of curing compound.
- Timing of backer rod placement.
- Early-age cracking inspection.

APPENDIX D DECISION TREE FOR EARLY-AGE CRACKING

D-1 INVESTIGATION.

Determine cause(s) of early age-cracking immediately and action items to minimize/eliminate causes or their effects implemented before proceeding further with paving. Early-age cracking is typically classified as any cracking within the first seven days after concrete placement. However, some cracking may initiate at the slab bottom that is not visible for days or weeks. Table D-1 contains the types of cracks and possible causes and investigative techniques for each type of crack. The following are types of early-age cracking.

- Plastic shrinkage cracking
- Random cracking (no orientation)
- Longitudinal cracking
- Transverse cracking
- Corner cracking
- Cracks just ahead of sawing (pop-off cracks)
- Later age cracking (early age slab bottom cracking propagating to surface)
- Sympathy cracks
- Settlement cracks over dowel bars or tie bars
- Re-entrant cracks

Note the following when early age cracking develops:

a. Some cracking has an obvious cause and requires immediate corrective actions.

b. Marginal conditions can cause cracking.

   - Correcting one marginal condition may resolve an immediate problem but may not reduce the cracking potential for subsequent paving.
   - It is important to identify as many marginal conditions as possible and rectify as many that are under the control of the design engineer or the contractor as possible.

The process of investigating early-age distress, for which the obvious cause is not readily apparent, involves the following steps:

1. Gather relevant information.
2. Identify if the distress manifests as isolated or systematic (widespread) occurrences. If the distress is systematic, undertake a thorough review of the design features as well as all key construction procedures.

3. Work through an iteration of logical steps to pinpoint one or more causes. This involves a process of elimination, starting with obvious factors verified by field and laboratory personnel. As causes are eliminated, additional steps may require more rigorous evaluation of data, coring, and laboratory testing.

D-2 GATHER RELEVANT INFORMATION.

D-2.1 Design Information.

- Pavement thickness as designed.
- Pavement thickness as constructed.
- Joint spacing.
    - Transverse
    - Longitudinal
- Base type.

D-2.2 Concrete Mix Information.

- Cement type and source.
- Cement grind history: fresh grind / not fresh grind.
- Supplementary cementitious materials.
    - Type F fly ash source
    - Slag source
- Cement content.
- Supplementary cementitious content.
    - Type F fly ash
    - Slag
- Aggregate data.
    - Gradation: uniform / gap graded / other
    - Gradation description
    - Coarse aggregate type, source and amount
    - Fine aggregate type, source and amount
    - Coarse aggregate coefficient of thermal expansion
- Admixture manufacturer, type and dosage.
    - Air entraining
    - Water reducer
    - Other admixture

D-2.3 Environmental Data.

- Weather condition for three (3) days before paving to 14 days after or present, whichever is earlier.
- Hot/cold weather precautions taken.
- Temperature readings for three (3) days prior to paving to 14 days after or present, whichever is earlier (attach table).
- Rainfall history during and up to three (3) days after concrete paving or present, whichever is earlier.

D-2.4 Construction Data.

- Paving history.
  - Start time
  - Finish time
  - Curing time
- Method used for minimizing bond for stabilized base.
- Base surface condition.
- Concrete curing method.
  - Curing compound type and rate of application (if used)
  - Number of days of moisture curing, if applicable
- Timing of sawcut.
  - Transverse joints
  - Longitudinal joint
- Depth of sawcut.
  - Transverse joint - As specified: Actual range:
  - Longitudinal joint - As specified: Actual range:
- Dowel alignment verification results.
- Early-age loading history.
  - Construction equipment loadings
  - Drill rig loading
  - Other

D-2.5 Other Relevant Data.

- Develop distress maps. Estimate or measure crack widths. Note ambient temperature at time of distress survey.
- Update maps regularly (every day or every few days) to determine if the distress is progressive and if cracks are getting wider.

Table D-1 Early Age Cracking Types/Possible Causes/Investigation

Cracking Type	Plastic Shrinkage	Random Cracking (No Orientation)	Longitudinal Cracking	Transverse Cracking (Partial or Full Width)	Corner Cracking	Cracks Just Ahead of Sawing (Pop-off Cracks)	Late Cracking (After About 7 Days to About 60 Days or Before Aircraft Loading)	Sympathy Cracks	Settlement Cracks over Dowel or Tie Bars (not allowed on airfields)	Re-entrant Cracks
Possible Causes	High rate of evaporation - Warm temp. - Low humidity - Windy	Slab to base bonding	Late sawing for prevailing conditions	Late sawing for prevailing conditions	Early loading	Late sawing for prevailing conditions	Early-age slab bottom cracking finally becoming visible	Joints in paved lane do not match joints in adjacent lanes	Higher slump concrete	Use of odd-shaped slab panels
	Dry concrete mix	Concrete slab friction against rough base or concrete penetration into open graded base	Shallow sawing of longitudinal contraction joint in relation to actual slab thickness	Shallow sawing of transverse contraction joints in relation to actual slab thickness	Excessive curling and warping due to temperature changes or moisture loss	Sawing against high wind	Frost heave	Different joint cracking patterns in adjacent lanes	Shallow dowel bars or tie bars (not allowed on airfields)	Rigid penetrations (in-place structures)
	Dry aggregates	Reflection cracking (from base cracking)	Slabs too wide in relation to thickness and length	Slabs too long in relation to thickness and width	Dowel bars too close to each other at transverse and longitudinal joints		Foundation settlement	Joints match in location but not in type	Delay in setting time	
	Late or inadequate curing	Late or inadequate curing	Temperature drop due to sudden cold front or rain	Temperature drop due to sudden cold front or rain	Late or inadequate curing					
	Delay in finishing	Late sawing for prevailing conditions	Misaligned or bonded dowels in adjacent longitudinal joints preventing cracked joints to function	Misaligned or bonded dowels in adjacent transverse joints preventing cracked joints to function	Misaligned or bonded dowels in adjacent transverse joints preventing cracked joints to function					
	Temperature drop due to sudden cold front or rain	Shallow sawing of contraction joints in relation to actual slab thickness	Excessive curling/ warping	Excessive curling/warping						
	Material incompatibility leading to higher concrete shrinkage and delay in setting time	Poor aggregate gradation (sand too fine; gap gradation)	Poor aggregate gradation (sand too fine; gap gradation)	Retarded concrete						
	Poor aggregate gradation (sand too fine; gap gradation)		Early loading	Poor aggregate gradation (sand too fine; gap gradation)						

Cracking Type	Plastic Shrinkage	Random Cracking (No Orientation)	Longitudinal Cracking	Transverse Cracking (Partial or Full Width)	Corner Cracking	Cracks Just Ahead of Sawing (Pop-off Cracks)	Late Cracking (After About 7 Days to About 60 Days or Before Aircraft Loading)	Sympathy Cracks	Settlement Cracks over Dowel or Tie Bars (not allowed on airfields)	Re-entrant Cracks
			Infill lane restraints	High shrinkage concrete						
			Late or inadequate curing	Early loading						
			High-shrinkage concrete							
			Slab to base bonding							

APPENDIX E ROLLER-COMPACTED CONCRETE PAVEMENTS

E-1 APPLICATION.

Procedures and criteria described in this appendix are applicable to the design and construction of roller-compacted concrete (RCC) pavement (RCCP). RCCP is prohibited for airfield pavement use unless approved by the USACE TSC or appropriate TSPDWG Service representative.

E-2 GENERAL.

RCCP is a concrete paving process that involves laydown and compaction of a no-slump PCC mixture using techniques similar to that used for hot-mix asphalt (HMA) pavement. RCC combines existing HMA paving and cement treated base construction procedures with the final product of a PCC pavement. This construction technique can place a large amount of concrete quickly with no forms, dowels, or reinforcing steel. Construction cost savings of 10 to 30 percent, or even more, of the cost of slipformed or fixed formed concrete pavements have been realized. The surface smoothness and surface texture of RCC pavement is somewhat rougher and coarser than conventional concrete pavement and this tends to limit RCC pavement applications to areas where low-speed, heavy-load traffic is the primary user of the pavement. Non-pavement applications that employ a similar construction method include slope protection of embankment or dams, providing an impermeable lining for sludge drying basins or wastewater lagoons, platforms for handling containerized freight, for recycling yards, for composting yards, for log sorting yards, and for mine storage areas.

E-3 CONSTRUCTION PROCESS.

RCC is typically mixed in a continuously mixing pugmill plant located near the paving site. In the plant, the aggregates, cement, and fly ash are weighed with belt scales or volumetrically proportioned on a continuous conveyer belt, which dumps the dry materials in the pugmill, where the water is added. The pugmill provides the vigorous mixing action necessary to evenly distribute the relatively small amount of water throughout the relatively stiff, no slump concrete mixture. The freshly mixed RCC is discharged into dump trucks equipped with protective covers for hauling to the paving site. At the paving site, the base course material is graded and compacted to form a smooth, firm working platform for the RCC pavement. The surface of the base course is moistened with water just before placing the RCC and setting up stringlines along the paving lanes to guide the height of the paving screed during placement. The RCC is placed with a paving machine to a uniform density and smoothness. Immediately after placement, the fresh RCC is compacted with several passes of a dual-drum vibratory roller to the specified final densities. After the compaction, make several passes of a rubber-tired roller to tighten the surface texture of the pavement. In some instances, finish rolling with steel-drum rollers to remove roller marks. When the rubber-tire rolling is complete, keep the surface of the RCC moist using water trucks equipped with fogger spray bars until an irrigation sprinkler system is set up by the end of the day. The sprinkler system keeps the surface of the RCC pavement continuously moist for the duration of the curing period, usually seven days (although 14 days is better).

Membrane-forming curing compounds and asphalt emulsions are also successful. Cold joints are construction joints formed between paving lanes placed more than one hour apart and always between two separate days of paving. Perpendicular cold joints are formed between lanes placed perpendicular to each other, longitudinal cold joints are oriented in the direction of paving, and transverse cold joints are located perpendicular to the direction of paving, between lanes oriented in the same direction. Transverse cold joints are constructed by sawing across the ends of the paving lanes, which have been rounded off from rolling, and removing the excess material. Finally, transverse contraction joints may be cut with a concrete saw within four to 20 hours after the RCC is placed and compacted. Historically, the standard practice has been to allow the RCC pavement to crack; however, current practice is to sawcut contraction joints to improve pavement aesthetics and ease the application and maintenance of joint sealants.

E-4 SUBGRADE AND BASE COURSE PREPARATION.

The subgrade and base course should conform to the requirements outlined in UFC 3-250-01 and UFC 3-260-02. The freeze-thaw durability of RCC is not fully understood, but the long-term performance of non-air-entrained RCCP is generally satisfactory, despite marginal laboratory performance. For this reason, in areas where the pavement or base course might be subject to seasonal frost action, give particular attention to providing a base course that adequately drains any water infiltrating through the pavement or subgrade. The base course should provide sufficient support to permit full consolidation of the RCCP through its entire thickness upon compaction.

E-5 SELECTION OF MATERIALS.

E-5.1 General.

One of the most important factors in determining the quality and economy of concrete is the selection of a suitable aggregate source. The recommended RCC gradation is shown in Table E-1. This gradation is similar to gradations used for asphalt concrete. This gradation should produce an RCCP surface with relatively few surface voids. Conventional PCC mixtures are generally obtained by combining coarse and fine aggregates. The well-graded blend of aggregates given in Table E-1 may be difficult to produce from two groups due to segregation of the different-sized aggregate particles. When possible, using more than two aggregate groups (coarse and fine) at the plant provides more flexibility in blending aggregates to control the gradation of the RCC.

Table E-1 Recommended Combined RCC Gradation

Sieve Size, mm (in.)	Cumulative Percent Passing, by Weight
25 (1)	100
19 (3/4)	85–100
12.5 (1/2)	70–95
9.5 (3/8)	55–85
4.75 (No. 4)	40–65
2.36 (No. 8)	30–55
1.18 (No. 16)	20–45
0.60 (No. 30)	15–35
0.30 (No. 50)	10–25
0.15 (No. 100)	5–15
0.075 (No.200)	2–10

E-5.2 Coarse Aggregate.

The coarse aggregate may consist of crushed or uncrushed gravel, recycled concrete, crushed stone, or a combination thereof. The quality of coarse aggregate used by the Corps of Engineers to date in RCCP generally complies with ASTM C33, although satisfactory RCC is possible with coarse aggregate not meeting these requirements. Local state highway department coarse aggregate grading limits, for example, are generally acceptable. Primarily, regardless of the grading limits imposed, the grading of aggregate delivered to a project must be relatively consistent throughout the production of RCC. This is an important factor to maintain control of the concrete mixture's workability. The nominal maximum aggregate size normally should not exceed 19 mm (0.25 in.), particularly if pavement surface texture is a consideration. Using aggregate larger than 19 mm (0.75 in.) results in segregation and rock pockets are likely.

E-5.3 Fine Aggregate.

Fine aggregate may consist of natural sand, manufactured sand, or a combination of the two, and should be composed of hard, durable particles. Base fine aggregate quality on the limits given in ASTM C33 except give consideration to relaxing the maximum 5.0 percent limit of material finer than the 0.075 mm (No. 200) sieve. Canada has increased the amount of material passing the 0.075 mm (No. 200) sieve to 8 percent of the total weight of aggregates with acceptable results. Sands with higher quantities of nonplastic silt particles may be beneficial as mineral filler and may allow some reduction in the amount of cement required. However, mixtures made with fine aggregates having an excessive amount of clay may have a high water demand, with attendant shrinkage, cracking, and reduced strength. Determine the specific gravity and absorption of these sands with high quantities of fines according to Note 3 in ASTM C128. Expedient construction with RCC can utilize minimally processed aggregates such as pit- or quarry-run aggregates to produce an RCC pavement. This RCC pavement may require greater water content, be less durable, and have a lower flexible strength.

E-5.4 Other Aggregates.

Recent experience with RCC shows that aggregate produced for uses other than PCC are successful as aggregate for RCC. Material produced for asphalt paving and base courses are effective as RCC aggregate. These materials typically have a higher percentage of fines passing the 0.075 mm (No. 200) sieve than conventional concrete aggregates and, as a result, may produce a “tighter” pavement surface texture. Because these aggregates range in size from 19 mm (0.75 in.) to the 0.075 mm (No. 200) sieve, control of the grading may be more difficult due to segregation. Therefore, direct due attention toward stockpile formation and subsequent handling of a single size group aggregate.

E-5.5 Cement.

The Portland cement for use in RCC must meet the requirements of ASTM C595, Type I or II.

E-5.6 Admixtures.

A proper air void system prevents frost damage in concrete that freezes when critically saturated. Research indicates that air-entrained RCC pavement mixtures can be successfully produced in the laboratory; however, field production and placement have only been tried on a very limited basis. The most widely used method to minimize freezing and thawing damage to RCC pavement is to combine a low w/cm ratio with a highly compacted RCC. The low w/cm ratio and good compaction ensure the concrete has a minimum amount of freezable water in the capillaries and has low permeability. This makes it difficult for sufficient water to enter the RCC and reach critical saturation. A free-draining base under the RCC pavement will further prevent water from saturating the RCC pavement. As long as the RCC pavement is not critically saturated, freezing and thawing will cause no damage. Laboratory studies show that water-reducing or -retarding admixtures are successful with RCC but not as effective as in conventional concrete because they affect the paste content of the mixture. RCC contains less paste than conventional PCC mixtures. If these admixtures are proposed, base such use on investigations demonstrating that the benefits outweigh the cost.

E-6 MIXTURE PROPORTIONING.

E-6.1 General.

The basic mixture proportioning procedures and properties of conventional concrete and RCC are essentially the same; however, conventional concrete cannot be reproportioned for use as RCC by any single action such as (1) altering proportions of the mortar and concrete aggregates, (2) reducing the water content, (3) changing the w/cm ratio, or (4) increasing the fine aggregate content. Differences in mixture proportioning procedures and properties are mainly due to the relatively dry consistency of the fresh RCC and the selected use of nonconventionally graded aggregates. The primary differences in the properties of RCC are (1) RCC generally is not air entrained, (2) RCC has a lower water content, (3) RCC has a lower paste content, and (4) RCC generally requires a higher fine aggregate content to limit segregation. Several methods are available to proportion RCC pavement mixtures, including those found in CRD-C 161, ASTM D 558, EM 1110-2-2006, ACI 211.3, and ACI 207.5R. The first two of these methods treat the material as cement stabilized soils rather than concrete and establishes a relationship between moisture and the density obtained from a particular compactive effort. The latter three methods follow an approach similar to that used in proportioning conventional concrete. Currently, CRD-C 161 is the method recommended for RCC pavement mix design. The procedures for RCC pavement mixture proportioning are not as well defined as for conventional concrete. The key to successfully selecting an RCC trial batch that performs well in the field is the experience of the laboratory personnel conducting the proportioning study.

E-6.2 CRD-C 161 Method.

This method covers the procedures for proportioning RCC mixtures with 19 mm (0.75 in.) nominal maximum size aggregates and having a workability suitable for placement with the vibratory screed of an asphalt paving machine. Select RCCP mixture proportions based on test data or experience with the materials actually used. Where such data or experience is limited or not available, estimates given in this standard practice provide a first approximation for air-entrained or non-air-entrained RCCP mixture proportions. Check these proportions by trial batches in the laboratory or field and adjust, as necessary, to achieve the desired RCC characteristics.

E-6.3 ASTM D558 Method.

A proportioning based on ASTM D558 has produced satisfactory RCC mixtures. The method produces the optimum moisture content necessary to obtain maximum density for a particular set of materials and compaction procedures. Previous tests indicate that the optimum moisture content obtained by CRD-C 653 may produce a mixture too wet to allow efficient operation of a vibratory roller.

E-6.4 ACI 207.5R Method.

The method in ACI 207.5R, with some modifications, is used on many RCC mixtures. The primary consideration for this method is proper selection of the ratio (Pv) of the air-free volume of paste (Vp) to the air-free volume of mortar (Vm). This selection is based primarily upon the grading and particle shape of the fine aggregate. The Pv affects both the compactability of the mixture and the resulting surface texture of the pavement. Ratios of 0.36 to 0.41 are satisfactory for mixtures having a nominal maximum size aggregate of 19 or 38 mm (0.75 or 1.5 in.). Include the fraction of fine aggregate finer than the 0.075 mm (No. 200) sieve in Vp when calculations use Pv.

E-7 MIXTURE PROPERTIES.

E-7.1 Handling Characteristics.

The workability of RCC determines its capacity for successful mixing, placement, and compaction. It embodies the concepts of compatibility and to some degree moldability and cohesiveness. The same factors that affect the workability of conventional concrete affect RCC: the grading, particle shape, and proportion of the aggregate; the cementitious material content; and the presence of chemical and mineral admixtures in the mixture. However, the effect of each factor is not necessarily of the same magnitude for RCC as for conventional concrete. When placing RCC or conventional concrete, the consistency of the mixture is important. The slump test measures the consistency of conventional concrete. The slump test is not meaningful for RCC since it has no slump. Make a preliminary judgment of the workability, placeability, and compatibility of RCC pavement mixtures during mixture proportioning studies by determining the optimum moisture content using soil compaction concepts. Use the soil compaction procedures described in CRD-C 161, paragraphs 7.1 through 7.6, to determine the optimum moisture content. Experience indicates that the actual optimum RCC water content necessary may need to be slightly greater than the lab-determined optimum moisture content. This is probably due to the loss of water from the mixture due to evaporation during transport and placement operations or to different compaction in the field. Ambient conditions determine the water content variation of a mixture. Typically, moisture increases are 0.1 to 0.5 percent above optimum. Construct a test section for each RCC project to adjust the mixture proportions as necessary to achieve the required workability.

E-7.2 Sample Fabrication.

Primarily, the w/cm ratio and the degree of compaction attained control the strength of an RCC mixture. All RCC pavement mixtures placed by the Corps of Engineers to date had w/cm ratios ranging from 0.30 to 0.40. Fabricate cylindrical laboratory test specimens for strength determinations per ASTM C1176 or CRD-C 160. There is no standardized procedure for fabricating RCC beam specimens to determine concrete flexural strength. However, as described in CRD-C 161, some success has been achieved by filling beam molds in two layers. Consolidate by vibrating each layer on a vibrating table having a frequency of 3,600 vibrations per minute under a surcharge of 57 kg (125 lb). Uniformly distribute the surcharge over the entire specimen area during molding and vibrate until a ring of mortar forms around the complete periphery of the mold. Cure all specimens fabricated in the laboratory according to ASTM C192.

E-7.3 Strength Results.

Test specimens fabricated and cured in the laboratory generally exhibit higher strengths than those cored or sawn from an RCCP. This is probably due to the higher unit weights typically obtained with the fabricated specimens and the more efficient laboratory moist curing. Laboratory test specimens generally have unit weights that are 98 to 99 percent of the theoretical maximum (air-free) weight of the mixture, while core samples taken from RCCP typically have unit weights ranging from 95 to 98 percent of the theoretical weight. Therefore, during the laboratory mixture proportioning studies, consider fabricating a companion set of test specimens having the lowest relative density allowed by the contract specifications.

E-8 THICKNESS DESIGN.

E-8.1 General.

The thickness design procedure for RCC pavement is outlined in UFC 3-250-01 and UFC 3-260-02. The primary difference in the approaches to RCC pavement and plain concrete pavement thickness design is the assumption of no load transfer at any joint or crack in the RCC pavement. Limited load transfer tests conducted at Fort Hood, Texas and Fort Stewart, Georgia revealed average load transfer at transverse contraction cracks of 16 to 19 percent. The load transfer at longitudinal and construction joints will be lower and all were less than the 25 percent used for plain concrete pavement design for parking areas, open storage areas, and airfields. Placement of RCC pavement immediately adjacent to existing structures is not practical. Conventional formed concrete should be used between the structure and the RCC pavement. The RCC pavement can be placed first and cut back to the desired line or the RCC can be placed against the previously placed formed concrete. Beams sawn from various RCCP at various locations have shown that the actual flexural strength of the pavement was 20 to 50 percent higher than the typical strength assumed in the design for those pavements. This suggests that the thickness design for compacted RCCP could be modified based upon the 28-day strength of beams sawn from a test section constructed using the same aggregate, cement, and construction procedure as planned for the entire work. However, until additional performance records and testing procedures are developed for RCCP, conventional pavement thickness design will be used.

E-8.2 Lift Thickness.

The maximum thickness of a lift of RCCP is governed by the ability of the pavers to place the RCCP in a smooth and continuous fashion. This maximum uncompacted thickness is usually 250 to 300 mm (10 to 12 in.). The maximum uncompacted thickness can be approximated by multiplying the design thickness by 1.25, thus accounting for the reduction in thickness due to compaction. The minimum thickness of any lift should be 100 mm (4 in.).

E-8.3 Two-Lift Construction.

If the total uncompacted thickness exceeds the capacity of the paver, the RCCP should be placed in two or more lifts, thus creating a horizontal joint (or horizontal plane between the layers) in the RCCP. Sufficient bond develops at a fresh horizontal joint in RCCP (top lift placed within one hour of bottom lift) to allow the use of a monolithic thickness design. If the top lift is not placed within one hour of the bottom lift, the thickness should be designed as a rigid overlay of a rigid base pavement. The surface of the lower lift should be kept moist and clean until the upper lift is placed, and the upper lift should be placed and compacted within one hour of compacting the lower lift to ensure a bond between lifts is formed. In two-lift construction, the uncompacted thickness of the first lift should be two-thirds the total uncompacted height of the RCCP (or the maximum lift thickness the paver can handle, whichever is smaller). The thinner section in the upper lift aids in creating a smoother final surface, and because of the smaller volume of material, allows the paver placing the second lift to move quicker than and follow closer behind the paver placing the first lift. Multiple lifts will be necessary if the total uncompacted thickness of the RCCP is greater than twice the maximum lift capacity of the paver.

E-9 TEST SECTION.

E-9.1 General.

A test section must be constructed to determine the ability of the contractor to mix, haul, place, compact, and cure RCC pavement. The test section must be constructed of the same material using the same equipment intended to be used in production placement. The test section must be constructed at a location near the jobsite at least 10 days before construction of the RCC pavement. The test section should be large enough to establish the rolling pattern for the vibratory and finish rollers, the correlation between laboratory and nuclear gauge densities, and the correlation between the number of passes and relative density. The density tests should be obtained with a nuclear gauge in accordance with ASTM C1040. The test section should contain both longitudinal and transverse cold joints and a fresh joint. A suggested minimum size is two 3.7- to 4.3-m (12 to 14 ft) -wide lanes, with each joint type a minimum of 38 m (125 ft) long, with one and one-half lanes placed the first day and the rest placed the next day.

E-9.2 Optimum Number of Rolling Passes.

During the test strip construction, use a nuclear gauge operated in the direct transmission mode and standardized with a calibration block to determine the optimum number of passes with the vibratory roller to reach maximum density. The density should be measured by inserting the nuclear gauge probe into the same hole after each pass of the vibratory roller. The hole should be made with an instrument specifically designed for the purpose, and should be formed using the same method throughout the test section and main construction. This rolling and measuring procedure should be continued until there is less than a 1 percent change in successive readings. These data may be used in conjunction with correlation between the nuclear gauge and the laboratory density to determine the minimum number of passes needed to achieve or slightly exceed the specified density in the RCCP construction. However, a minimum of four vibratory passes should be used, and this minimum will probably prevail in most cases.

E-9.3 Nuclear Density Gauge/Lab Density Correlation Calibration Block.

Use a calibration block each day before paving begins to calibrate the full-depth readings of the nuclear density gauges. The block should be fabricated from the RCC mixture to be used in the project before the test section construction begins. The block size should be 460 mm by 460 mm (18 in. by 18 in.) by the maximum thickness of one lift, plus 25 mm (1 in.). The block should be compacted to between 98 and 100 percent of the maximum wet density determined in accordance with ASTM D1557. The block should be measured and weighed to determine the actual density (unit weight) and used to check the calibration of the nuclear density gauge. After drilling a hole in the block to accommodate the nuclear density gauge probe, three full-depth nuclear density gauge tests should be performed in the direct transmission mode and the results averaged. This average nuclear density gauge reading should then be compared with the measured unit weight of the block and the difference used as a correction factor for all readings taken that day. If the adjusted nuclear gauge density is less than the specified density, additional passes with the vibratory roller should be made on the fresh RCC until the specified density is reached. Two nuclear density gauges should be calibrated (using the same holes) during the test section construction, so that an extra one is available during construction.

E-9.4 Strength Tests.

Pavement strength is determined from samples obtained from the test section. The testing should determine the flexural and splitting tensile strength of the RCC pavement. If the design strength requirements are not met, adjust the mix proportions (or the compaction procedure or curing altered, and another test section built) until the strength results meet specifications.

E-10 BATCHING, MIXING, AND TRANSPORTING.

RCC requires a vigorous mixing action to disperse the relatively small amount of water evenly throughout the matrix. This action has been best achieved by using a twin shaft pugmill mixer as commonly used in asphalt concrete mixing. RCC may be produced successfully in either a continuous mixing plant or batch-type plant. The continuous mixing plant is recommended for mixing RCC because it is easier to transport to the site, takes less time to set up, and has a greater output (or production) capacity than the batch-type plant. The batch-type plant allows more accurate control over the proportions of material in each batch, but generally does not have enough output capacity for larger paving jobs. The most widely used and recommended equipment is a continuous plant with weight controls (belt scales) for the materials. The output of the plant should be such that the smooth, continuous operation of the paver(s) is not interrupted. Generally, for all but the smaller jobs (840 m^2 [1,000 yd^2] or smaller), the capacity of the plant should be no less than 225 metric tons (250 tons) per hour. The output of the plant should match the laydown capacity of the paver(s) and the rollers. The plant should be located as close as possible to the paving site, but in no case should the haul time between the batch plant and the paver(s) exceed 15 minutes. The RCC should be hauled from the mixer to the paver(s) in dump trucks. These trucks should be equipped with protective covers to guard against adverse environmental effects on the RCC, such as rain or extreme cold or heat. The truck should dump the concrete directly into the paver hopper.

E-11 PLACING.

For most pavement applications, RCC should be placed with a paving machine. The paver should be equipped with automatic grade control devices such as a traveling ski or electronic stringline grade control device. Pavers should have at least two tamping bars. These machines provide a satisfactory surface texture and some initial compaction when the RCC is placed. Necessary adjustments on the paver to handle the RCC include enlarging the feeding gates between the feed hopper and the screed to accommodate the large volume of stiff material moving through the paver, and adjusting the spreading screws in front of the screed to ensure the RCC is spread uniformly across the width of the paving lane. Care should be taken to keep the paver hopper from becoming empty to prevent any gaps or other discontinuities from forming in the pavement. The concrete should be placed and compacted within 45 minutes after water has been added to the batch. When paving adjacent lanes, the new concrete should be placed within 60 minutes of placing the first lane to form a fresh joint. This time may have to be reduced, depending on ambient conditions. If these time restraints cannot be met then a cold joint is formed. The height of the screed should be set even with the uncompacted height of the adjacent lane, thus allowing simultaneous compaction of the edges of the adjacent lanes into a fresh joint. Two or more pavers operating in echelon may reduce the number of cold joints by one-half or greater, and are especially recommended in road construction where the entire width of the road can be placed at the same time.

E-12 COMPACTION.

E-12.1 General.

RCCP has usually been compacted with a dual-drum (9 metric ton [10 ton] static weight) vibratory roller making four or more passes over the surface to achieve the design density (one back-and-forth motion is two passes). To achieve a higher quality pavement, the primary compaction should be followed with two or more passes of an 18 metric ton (20 ton) pneumatic-tired roller (620 kPa [90 psi] minimum tire pressure) to close up any surface voids or cracks. The use of a dual-drum static (non-vibratory) roller may be required to remove any roller marks left by the vibratory or pneumatic-tired roller. A single-drum (9 metric ton [10 ton]) vibratory roller has been successfully used to compact RCCP, but may require the use of a pneumatic-tired or dual-drum static roller to remove tire marks.

E-12.2 Proper Time for Rolling.

The consistency of the RCC when placed should be such that it may be compacted immediately behind the paver without undue displacement of the RCC pavement surface. If rolling has to be delayed, the cause should be investigated and the problem corrected. In no case should more than 10 minutes pass between placement and the beginning of the rolling procedure. The rolling should be completed within 45 minutes of the time the water was added at the mixing plant. A good indication that the RCC is ready for compaction is obtained by observing the displacement of the surface after two static passes with the 9 metric ton (10 ton) vibratory roller. A mixture that is too wet may appear "rubbery" under the roller, or even spread to form a deep rut after two passes. A mixture that is too dry will hardly consolidate at all under the first passes. In either case, only minor changes in the design water content should be made at the plant to correct the problem; otherwise, a new mix design may be needed. With practice, the roller operator should be able to tell whether the consistency of the RCC is satisfactory for compaction.

E-12.3 Rolling Pattern.

After making the static passes, the vibratory roller should make four vibratory passes on the RCCP using the following pattern: two passes on the exterior edge of the first paving lane (the perimeter of the parking area or the edge of a road) so that the rolling wheel extends over the edge of the pavement 25 to 50 mm (1 to 2 in.) (done to “confine” the RCCP to help prevent excessive lateral displacement of the lane upon further rolling), followed by two passes within 300 to 450 mm (12 to 18 in.) of the interior edge. This will leave an uncompacted edge to set the height of the screed for an adjacent lane, and allows both lanes of the fresh joint to be compacted simultaneously. Any remaining uncompacted material in the center of the lane should be compacted with two passes of the roller. This pattern should be repeated once to make a total of four passes on the lane (or more if the specified density is not achieved). If the interior edge will be used to form a cold joint, it should be rolled exactly as the exterior edge was rolled, taking care to maintain a level surface at the joint and not round the edge. When the adjacent lane is placed, two passes should be made about 300 to 450 mm (12 to 18 in.) from the outer edge of the lane (again, to confine the concrete) followed by two passes on the fresh joint. The first two passes should extend 25 to 50 mm (1 to 2 in.) over the outer edge of this adjacent lane if the lane will form an outer edge of the completed pavement. Any remaining uncompacted material in the lane should be rolled with two passes of the roller. This pattern should be repeated to make a total of four passes over the RCCP. Additional passes may be necessary along the fresh joint to ensure smoothness and density across the joint.

E-12.4 Compacting the End of a Lane.

When the end of a lane is reached, the roller should roll off the end of the lane, creating a rounded ramp. The recommended procedure is to cut the ramp with a power saw full depth to form a vertical face. This will eliminate hand work and lessen the possibility of damage to the in-place RCC pavement. Another method is to saw the concrete to at least one-half the depth of the pavement, then trim the lower portion of the joint by hand to form a nearly vertical face, clean from debris and loose particles.

E-12.5 Proper Roller Operation.

During vibratory compaction, the roller should never stop on the pavement with the vibrator on. Instead, the vibrator should be turned on only after the roller is in motion and should be turned off several feet before the roller stops moving. The stopping points of successive rolling passes should be staggered to avoid forming depressions in the fresh pavement surface. The roller should be operated at the proper speed, amplitude, and frequency to achieve optimum compaction. Experience has shown that the best compaction will probably occur at high amplitude and low frequency (because of the thick lifts) and a speed not exceeding 2 km (1.5 mi.) per hour. A low amplitude/high frequency combination may be necessary if the surface is disturbed during the high amplitude rolling.

E-12.6 Finish Rolling.

The vibratory compaction should be immediately followed with two or more passes of the pneumatic-tired roller so the surface voids and fissures close to form a tight surface texture. This rolling may be followed by a light dual-drum roller to remove any roller marks on the surface, but this will probably not be necessary. It is very important that all exposed surfaces of the RCCP be kept moist with a light water spray after the rolling process until the curing procedure is implemented.

E-13 COLD JOINTS.

E-13.1 General.

A cold joint in RCC pavement is somewhat analogous to a construction joint in conventional concrete pavement. It is formed between two adjacent lanes of RCC when the first lane has hardened to such an extent that the uncompacted edge cannot be consolidated with the fresher second lane. This happens when there is some time delay between placement of adjacent lanes such as at the end of the day’s construction. This hardening typically takes approximately one hour, depending on properties of the concrete and environmental conditions. The adjacent lane should be placed against the first lane and compacted within this time frame. Otherwise, the joint between the two lanes should be considered a cold joint.

E-13.2 Cold Joint Construction.

Before placing fresh concrete against hardened in-place pavement to form a longitudinal cold joint, the edge of the in-place pavement should be cut with a power concrete saw. As discussed in paragraph E-16.8, the recommended procedure is to saw full depth with a power concrete saw to form a vertical face. This will eliminate hand work and lessen the possibility of damage to the in-place pavement. Another method is to saw to at least one-half the depth of the pavement, then the lower unsawed portion of the joint should be trimmed by hand to form a nearly vertical face, clean of debris and loose particles. Care should be taken to avoid undercutting the pavement edge. This vertical face should be dampened before the placement of the fresh lane begins. The height of the screed should be set to a sufficient elevation to compensate for the reduction in thickness due to compaction. The screed should overlap the edge of the hardened concrete surface 25 to 75 mm (1 to 3 in.). The excess fresh concrete should be pushed back to the edge of the fresh concrete with rakes or lutes and rounded off so no fresh material is left on the surface of the hardened concrete before compacting the joint. The loose material should not be broadcast over the area to be compacted; this may leave a rough surface texture after rolling. The edge of the fresh lane adjacent to the hardened concrete should be rolled first in the static mode, with about 300 mm (1 ft) of the roller on the fresh concrete, to form a smooth longitudinal joint. Transverse cold joints are constructed in a similar manner. After cutting back the rounded-off edge and wetting the vertical face, the paver is backed into place and the screed set to the proper elevation using shims sitting on top of the hardened concrete. The excess material should be pushed back (as mentioned before) and a static pass made in the transverse direction across the first 300 mm (1 ft) of the freshly placed lane. The joint should be carefully rolled to ensure a smooth surface transition across the joint.

E-13.3 Sawing of Contraction Joints.

RCC pavement has been allowed to crack naturally in many previous projects to save the cost of sawing joints. However, this has probably resulted in larger crack openings, increased raveling, and higher maintenance costs than if cracking was controlled. Contraction joints may be sawn in RCC pavement to induce controlled crack formation. The weakened plane should be sawn at least one-fourth the slab depth using a 3 mm (1/8 in.) blade. Sawing of joints can commence when the concrete strength is sufficient to enable the saw to cut through the concrete with a minimum of spalling, tearing, or aggregate pullouts. The use of special green-cut saws that penetrate the pavement surface to only a depth of about 1 in. have been shown to be effective on at least one RCC paving project. The time of sawing is very important and usually ranges from 4 to 20 hours after compaction, depending on weather conditions and other factors. To date, sawn transverse contraction joints in RCC pavement have typically been spaced from 9 to 18 m (30 to 60 ft). These spacings may vary with different materials and thicker pavements, so optimum contraction joint spacing should be determined during test section construction. Local service records may also be helpful to establish a joint spacing that will effectively control transverse cracking. Joint spacing greater than 12 m (40 ft) should never be used without backup data.

E-13.4 Sealing Joints and Cracks.

Rigid pavements that do not receive adequate joint and crack seal maintenance will rapidly deteriorate due to the intrusion of water and incompressible materials that migrate through and into the pavement joints and cracks. Incompressible materials lodge between the individual pavement slabs and parts of slabs, restricting movement that allows for expansion and contraction. This restriction of movement causes spalling and cracking along the edges of the joints and cracks and can result in breakage and blowup of entire slabs. Water in the subgrade material causes a migration of fines that eventually results in loss of support under the edge of the pavement slab.

E-13.5 Load-Transfer Devices.

The stiff consistency of RCCP does not lend itself to application of load-transfer devices such as dowels or keyed joints. Until an efficient method is developed to insert and align dowels properly in RCCP, the use of dowels should be limited.

E-13.6 Vertical Joints in Two-Lift Construction.

In two-lift construction, care should be taken to align the cold transverse and longitudinal joints in the upper and lower lifts to form a uniform, vertical face through the depth of the pavement along the joint. If the edge of the upper lift is not even with the edge of the lower lift, the lower lift should be cut back even with the edge of the upper lift.

E-14 CURING.

E-14.1 General.

The relatively rough or open surface texture of the compacted RCC pavement will tend to dry very quickly. To prevent this, moist curing has been commonly recommended to prevent drying and scaling of the RCC pavement surface. For moist curing, the pavement surface should be kept continuously moist after final rolling for at least seven days by means of a water spray truck, sprinkler (fog spray) system, wet burlap, or cotton mat covering. If burlap mats are used, they should be thoroughly wetted, placed on the RCC pavement so the entire surface and exposed edges are covered, and kept continuously wet. An irrigation sprinkler system has been used to cure RCC pavement on some projects, but caution should be exercised so that the fines in the surface of the RCC pavement are not washed away by excessive pressure, particularly in the first few hours. Curing RCC pavement with water can generate considerable runoff and, if not properly handled, cause erosion or saturation of exposed subgrade. Curing with membrane-forming curing compound and asphalt emulsion applied at double the rates used on conventional concrete have been used successfully.

E-14.2 Effect of Moist Curing on Frost Resistance.

Preliminary results of laboratory freezing and thawing tests indicate that RCC having a sufficiently low w/cm ratio and moist cured for an extended period is more frost resistant. The improved frost resistance may be due to more complete hydration reducing the fractional volume of freezable water at saturation or by reducing the permeability of the RCC, making it more difficult to saturate under wet conditions.

E-14.3 Early Loading.

All vehicular traffic should be kept off the RCCP until the end of the curing period. If it is absolutely necessary, a water-spraying truck may be driven onto the pavement before that age but any turns must be kept to a minimum. Water-spraying trucks or any other traffic should be kept to a minimum.

E-15 QUALITY CONTROL/ASSURANCE.

E-15.1 General.

The UFGSs provide requirements on the construction method and outline expected QC and QA measures and limits for density, smoothness, thickness, and surface texture.

E-15.2 Quality Control Operations.

QC operations for DoD RCC pavement projects are the responsibility of the contractor. QC consists of sampling, gradation, quality, and moisture testing of aggregates going into the concrete; checking the plant calibration regularly; conducting moisture-density relationship tests (ASTM D1557) on the fresh RCC; measuring the in-place density and moisture content of the RCC by using a nuclear gauge; checking the smoothness of the finished RCC with a straightedge; taking core samples from the RCC for measurement of density, strength, and thickness; and, if desired, fabricating RCC cylinders and beams.

E-15.3 Quality Assurance Operations.

QA consists of providing the RCC mixture proportions, testing cementitious materials and aggregates for quality, and testing in-place density, smoothness, surface texture, and thickness for acceptance. QA testing by the government may also consist of randomly duplicating any QC test to determine if consistent results are being obtained. Payment is based on the results of the QA tests (density, smoothness, surface texture, and thickness) for each lot, which represents a day's placement of pavement. If the QA test results show deficiencies in any of these four areas, the payment for the lot is reduced, and the lot is rejected if the deficiency is too great.

E-15.4 Tests at Plant.

Moisture contents of the fine and coarse aggregates should be determined daily, as necessary, and appropriate changes made in the amount of mixing water. Washed gradation tests should normally be performed on the combined aggregates three times per day: in the morning, at midday, and in the afternoon. The samples should be taken from the conveyor before the cement or fly ash is added to the combined aggregates. The amount of materials passing the 0.150 mm (No. 100) sieve should be determined during this analysis. Whenever the characteristics of the mixture change or a check on the ingredients is required, a proportioning check can be performed on the combined dry ingredients on samples taken from the conveyor belt between the cement and fly ash hoppers and the pugmill using a washout test according to procedures in ASTM C685 (paragraph 6.5). By washing the dry ingredients over the 4.75 and 0.150 mm (No. 4 and No. 100) sieves and weighing the material in each size category, the approximate proportions of coarse aggregate, fine aggregate, and cement and fly ash combined may be determined and checked against predetermined limits.

E-15.5 Field Density Tests.

Field density tests should be performed on the RCC pavement using a nuclear density gauge operated in the direct transmission mode according to ASTM D6938, with the full-depth reading being used for control and acceptance. At least one field reading should be taken for every 30 m (100 ft) of each paving lane. The readings should be taken as closely behind the rolling operation as possible. The reading should be adjusted using the correlation determined in the test section construction and checked against a specified density. Areas that indicate a deficient density should be rolled again with the vibratory roller until the specified density is achieved.

E-15.6 Obtaining Core Samples.

The acceptance criteria for the thickness of the RCC pavement are based on appropriate tests conducted on cores taken from the pavement. Take cores from the pavement when it is no less than five days old. Take one core at a random location selected within each sublot, which is one-fourth the size of a lot, and measure the thickness. Take additional cores as determined by the government for density and splitting tensile strength.

E-15.7 Smoothness.

Do not finish the surface of the RCCP outside the tolerances given in the specifications. Check the smoothness as closely behind the finish roller as possible. Correct excessive variations in the surface with the finish roller. Pay particular attention to the smoothness across fresh and cold joints because this is typically a critical area for surface variations. A skilled vibratory roller operator is essential to minimize smoothness problems.

E-15.8 Surface Texture.

The final surface texture of an RCC pavement resembles that of an asphalt concrete pavement surface: a coarse surface texture with regularly spaced voids and interconnected fissures. The final surface texture should be devoid of surface tears, check cracking, segregation, rock pockets, surface patches, pumped areas, aggregate drag marks, loose aggregate, or exposed aggregate from washed fines.

E-15.9 Cylinder and Beam Fabrication.

The fabrication of cylinders and beams during RCCP construction may be specified and is encouraged if not specified. These beams and cylinders complement the coring operation to check RCCP strength and density. When fabricated cylinders and beams are used as a QC aid during construction, determine and report a correlation between their strength and density and those obtained from cores and sawed beams obtained from the test section.

E-15.10 Method of Cylinder and Beam Fabrication.

Fabricate cylinders in the field by filling cylinder molds in three equal layers. Each layer is consolidated by vibrating each layer on a vibrating table having a frequency of 3,600 vibrations per minute, under a surcharge of 9.1 kg (20 lb). Vibrate each layer until a mortar ring is visible around the entire periphery of the surcharge. Fabricate eight cylinders for every 225 m^3 (300 yd^3) of RCC placed. Test two cylinders each at 7, 14, 28, and 90 days. Test the cylinders for splitting tensile strength according to ASTM C496. No procedure has been standardized for fabricating RCC beam specimens such as those used to determine concrete flexural strength. However, CDR-C 161 details a procedure that fills beam molds in two layers. Each layer is consolidated by vibrating each layer on a vibrating table having a frequency of 3,600 vibrations per minute, under a surcharge of 57 kg (125 lb). The surcharge is uniformly distributed over the entire specimen area during molding and vibration is continued until a ring of mortar forms around the complete periphery of the mold. Fabricate four beams during each shift of construction: two to be tested at 14 days and two at 28 days. Test the beams for flexural strength according to ASTM C78.

E-15.11 Inspectors.

Inspections are vital in QC operations. Station at least one inspector at the mixing plant and at the jobsite to ensure a quality pavement is being built. At the mixing plant, check mixing times and spot-check the consistency and appearance of the mix coming out of the plant. The inspector coordinates the aggregate moisture content tests, the gradation tests, calibration of the plant, and washout tests to see that they are performed properly and at the right frequency. At the jobsite, the inspector ensures the base course and cold joints are moistened before the RCC is placed against them and that the RCC is placed and compacted within the proper time limitations. The inspector checks the paver operation to ensure proper grade control is continuously maintained and ensures no gaps or discontinuities are left in the pavement before rolling. The inspector ensures the roller begins compaction at the proper time and that the proper rolling pattern and number of passes are used. The inspector ensures adequate smoothness across joints is achieved and that the surface texture is tight after final rolling. The inspector spot-checks the final compacted thickness of the RCCP and corrects when out of tolerance. The inspector ensures the curing procedures are implemented as specified. The inspector also ensures all exposed surfaces of the RCCP are kept moist at all times and that the curing compound, if used, is applied properly and in a continuous fashion. The inspector coordinates the nuclear gauge density test, the coring procedures, cylinder and beam fabrication, and the surface smoothness test to ensure they are performed properly and at the required frequency.

F-2 DEFINITION OF TERMS.

Alkali-Silica Reaction (ASR): A chemical reaction between alkalis in cement and certain reactive silica minerals with aggregate that forms a gel. The gel absorbs water and expands, thereby damaging the concrete.

Compaction: The process of reducing the void volume by applying mechanical energy.

Compressive Strength: The maximum resistance of a concrete specimen to axial compressive loading.

Curing: Maintaining moisture and temperature conditions in a freshly placed cementitious mixture to allow cement hydration to occur.

Dowels: A round steel bar that extends into adjoining slabs at an expansion or contraction joint to transfer shear loads.

D-Cracking: Pattern of cracks formed parallel to a joint or linear crack due to the inability of the concrete to withstand environmental factors such as freeze-thaw cycles.

Durability: Ability of concrete to resist weathering action, chemical attack, and abrasion.

Flexural Strength: Maximum resistance of a concrete specimen to flexural loading.

Fly Ash: Fine powder that is a byproduct of burning pulverized coal in electric power generating plants. Used as a supplementary cementitious material.

Gap-Graded Aggregate: An aggregate graded so one or more intermediate-size fractions are absent.

Ground Granulated Blast Furnace Slag (GGBFS): A granular byproduct of the iron- and steel-making process, which is dried and ground into a fine powder. GGBFS is highly cementitious and high in calcium silicate hydrates.

Pozzolan: A siliceous or siliceous and aluminous material that in itself possesses little or no cementitious value, but in finely divided form and in the presence of moisture, chemically reacts with calcium hydroxide to form compounds having cementitious properties.

Silica Fume: A byproduct of producing silicon metal or ferrosilicon alloys and a very reactive pozzolan.

Slump: Measure of consistency of freshly mixed concrete equal to the subsidence of a molded specimen immediately after removal of the slump cone.

Slipform Paver: A paver that does not use fixed forms but has forms that are pulled or raised as concrete is placed.

Tie-Bar: Deformed steel bars or connectors used to hold the faces of abutting slabs in contact. Typically used at longitudinal joints.

FOREWORD

The Unified Facilities Criteria (UFC) system is prescribed by MIL-STD 3007 and provides planning, design, construction, sustainment, restoration, and modernization criteria, and applies to the Military Departments, the Defense Agencies, and the DoD Field Activities in accordance with USD (AT&L) Memorandum dated 29 May 2002. UFC will be used for all DoD projects and work for other customers where appropriate. All construction outside of the United States is also governed by Status of Forces Agreements (SOFA), Host Nation Funded Construction Agreements (HNFA), and in some instances, Bilateral Infrastructure Agreements (BIA.) Therefore, the acquisition team must ensure compliance with the most stringent of the UFC, the SOFA, the HNFA, and the BIA, as applicable.

UFC are living documents and will be periodically reviewed, updated, and made available to users as part of the Services' responsibility for providing technical criteria for military construction. Headquarters, U.S. Army Corps of Engineers (HQUSACE), Naval Facilities Engineering Command (NAVFAC), and Air Force Civil Engineer Center (AFCEC) are responsible for administration of the UFC system. Defense agencies should contact the preparing service for document interpretation and improvements. Technical content of a UFC is the responsibility of the cognizant DoD working group. Send recommended changes with supporting rationale to the respective service proponent office by the following electronic form: Criteria Change Request. The form is also accessible from the Internet sites listed below.

UFC are effective upon issuance and are distributed only in electronic media from the following source:

- Whole Building Design Guide web site http://DoD.wbdg.org/.

Refer to UFC 1-200-01, *DoD Building Code (General Building Requirements)*, for implementation of new issuances on projects.

UNIFIED FACILITIES CRITERIA (UFC)
REVISION SUMMARY SHEET

Document: UFC 3-250-07, *Standard Practice for Pavement Recycling*

Superseding: This UFC supersedes UFC 3-250-07, *Standard Practice for Pavement Recycling*, dated 16 January 2004.

Description: This UFC documents and explains standard operating practices for recycling pavement materials and using the material in pavement structures. These practices apply to roads, airfields, and construction platforms having a stabilized surface layer.

Reasons for Document: This update brings the document in compliance with UFC 1-300-01, *Criteria Format Standard*. Editorial changes were to improve readability, correct typographical errors, update outdated references, and clarify standard practices.

Impact: Cost impact is negligible; improved guidance typically results in improved performance and reduced lifecycle cost.

Unification Issues: None

TABLE OF CONTENTS

TABLES

CHAPTER 1 INTRODUCTION

1-1 PURPOSE AND SCOPE.

This UFC documents the standard practices for recycling pavement materials and using recycled materials in the Department of Defense (DoD) and the National Aeronautics and Space Administration (NASA) pavement structures. It covers recycling methods permitted on DoD and NASA pavements. It provides requirements for the selection of recycling methods as well as the design of pavement cross sections using the recycled materials and recycling methods.

1-2 APPLICABILITY.

These standard practices apply to DoD and NASA pavements. These practices apply to roads, airfields, and construction platforms having a stabilized surface layer. Do not use, plan to use, or bid on a project while planning to use any materials or methods on or in DoD or NASA pavements that are not outlined in this or any other applicable UFC or UFGS without prior approval of the Pavements Discipline Working Group (DWG) and contracting officer and Designer of Record (DOR).

1-3 GENERAL BUILDING REQUIREMENTS.

Comply with UFC 1-200-01, *DoD Building Code (General Building Requirements).* UFC 1-200-01 provides applicability of model building codes and government unique criteria for typical design disciplines and building systems, as well as for accessibility, antiterrorism, security, high performance and sustainability requirements, and safety. Use this UFC in addition to UFC 1-200-01 and the UFC and government criteria referenced therein.

1-4 BEST PRACTICES AND OTHER CONTENT.

Appendix A is reserved for future use.

1-5 SUPPLEMENTAL RESOURCES.

Appendix B contains a list of supplemental resources and references not used herein.

1-6 GLOSSARY.

Appendix C contains a list of acronyms, abbreviations, and definitions

1-7 REFERENCES.

Appendix D contains a list of references used in this document. The publication date of the code or standard is not included in this document. Unless otherwise specified, the most recent edition of the referenced publication applies.

1-8 BACKGROUND.

Pavement recycling reuses pavement materials from existing pavement. Pavement recycling may remove and reprocess existing pavement materials at a central plant and then incorporate them into a new pavement structure, or it may involve reprocessing or modification of existing material in-place and making them part of a new pavement. Recycling is an economical and feasible alternative to using all virgin materials for pavement rehabilitation, reconstruction, and new construction. This is especially true at remote sites. The primary advantages are in reduced cost and time savings, reduced environmental impact, conservation and protection of natural resources, and ability to maintain existing pavement lines and grade.

Recycling presents many advantages for the rehabilitation of fatigued and deteriorated airfield and roadway pavements. Technical advances (since the adoption of early recycling concepts in the 1970s) in terms of materials and mixes, construction methods, and equipment, make recycling a viable solution for rehabilitation or reconstruction. Recycling of pavement materials plays a significant role in sustainable development and reuse of materials.

This UFC contains guidance from a variety of documents, to include:

- Asphalt Recycling and Reclaiming Association (ARRA) *Basic Asphalt Recycling Manual*, 2015.
- Federal Highway Administration (FHWA) *Pavement Recycling Guidelines for State and Local Government,* 1997.
- FHWA National Highway Institute (NHI) *4R Participant's Manual* (Course 131008), *HMA Pavement Evaluation and Rehabilitation Reference Manual* (Course 131063), *PCC Pavement Evaluation and Rehabilitation Reference Manual* (Course 131062), and *Asphalt Pavement Recycling Technologies Manual* (Course 131050).
- Permanent International Association of Road Congresses (PIARC) *Pavement Recycling Guidelines,* 2003.
- Airfield Asphalt Pavement Technology Program (AAPTP) *Use of Reclaimed Asphalt Pavements* and *Development of Guidelines for Rubblization July 2008*.
- Innovative Pavement Research Foundation (IPRF) *Evaluation, Design, and Construction Techniques for Airfield Concrete Pavement Used as Recycled Material for Base,* 2006.
- Federal Aviation Administration (FAA) Advisory Circulars and Engineering Briefs.
- Transportation Research Board (TRB) Recycling Reports.

Key DoD documents used in preparing this manual are:

- UFC 3-250-01, *Pavement Design for Roads and Parking Areas*
- UFC 3-250-04, *Standard Practice for Concrete Pavements*
- UFC 3-260-02, *Pavement Design for Airfields*
- UFC 3-260-03, *Airfield Pavement Evaluation*
- UFC 3-260-16, *O&M Manual: Standard Practice for Airfield Pavement Condition Surveys*
- UFC 3-270-08, *Pavement Maintenance Management*
- UFGS 32 01 16.70, *Cold-Mix Reused Asphalt Paving*
- UFGS 32 01 16.71, *Cold Milling Asphalt Paving*
- UFGS 32 01 16.74, *In-Place Hot Reused Asphalt Paving*

- UFGS 32 11 16.16, *[Base Course for Rigid] and [Subbase Course for Flexible][Subbase Course for Pervious] Paving*
- UFGS 32 11 23, *Aggregate Base Course*
- UFGS 32 11 36.13, *Lean Concrete Base Course*
- UFGS 32 12 15.13, *Asphalt Paving for Airfields*
- UFGS 32 12 16.16, *Road-Mix Asphalt Paving*
- UFGS 32 13 13.06, *Portland Cement Concrete Pavement for Roads and Site Facilities*
- UFGS 32 13 14.13, *Concrete Paving for Airfields and Other Heavy-Duty Pavements*
- TSPWG 3-260-03.02-19, *Airfield Pavement Evaluation Standards and Procedures*
- TSPWG M 3-250-04.06-2 *Alkali-Aggregate Reaction in Portland Cement Concrete (PCC) Airfield Pavements*
- TSPWG 3-250-07.07-6, *Risk Assessment Procedure for Recycling PCC Suffering from Alkali-Aggregate Reaction in Airfield Pavement Structures*

Always consider recycling materials when repairing or rehabilitating existing pavements. The remaining sections of this chapter provide guidance for industry-wide recycling practices. To determine the latest restrictions/limitations on using recycled materials on DoD projects consult the following UFGS documents:

32 01 13 64
32 01 16.70
32 01 16.71

32 01 16.74
32 01 16.75
32 12 15.13 and 32 12 16.16 for asphalt recycling applications
32 13 14.13 and 32 13 13.06 for concrete recycling applications

Do not alter or waive UFGS requirements without prior approval of the Pavements DWG Representative. Chapters 4 through 5 detail the current restrictions/limitations.

1-9 JUSTIFICATION FOR RECYCLING.

Recycling pavement materials is a feasible approach to rehabilitate distressed pavements. Reclaimed materials can reduce the cost of rehabilitation or reconstruction and provide other benefits. Therefore, consider using recycled materials when repairing, rehabilitating, or reconstructing existing pavements. The following are reasons for using reclaimed pavement materials:

- *Environment.* Prior to the inception of recycling techniques, reconstructing old pavements consisted of removing, stockpiling, or disposing of old pavement materials. Recycling can reuse these pavement materials and often offers a cost reduction compared to purchasing virgin materials. Recycling eliminates the disposal problem and conserves natural resources. Some recycling methods reduce greenhouse gases and save energy (Mueller, 2008).
- *Material availability and cost.* The supply of natural material is limited. Even though there is presently an abundant supply of aggregates in the US, the distribution of these sources does not always coincide with the project location. The amount of asphalt and high-quality aggregate available for construction is limited. The high cost of aggregates and asphalt binder increase the unit cost of pavement and encourages the use of recycled materials. The rising cost of fuel and equipment operations encourages recycling, especially for longer haul distances.
- *Technology and equipment.* The increased interest in recycling pavements drives technology and equipment development for recycling that improve performance and reduce cost when utilizing recycled materials. While there are problems peculiar to recycling, the number and complexity of these problems has declined significantly in recent years.
- *Performance*. Studies show that properly designed recycled mixes perform as well as virgin mixes. Experience of different states in the U.S. indicates that, in most cases, the performance of the recycled asphalt pavements is comparable to asphalt pavements constructed with virgin materials. Successfully incorporating recycled asphalt requires; good project selection criteria, proper mix design and good quality control and acceptance (QC/QA) criteria as is with asphalt mixtures using virgin materials.

- *Recycling of non-pavement materials.* Several materials in recycled pavements come from non-pavement sources including reclaimed asphalt shingles, crumb rubber, plastics, and many other products. While widely used elsewhere, this manual does not cover their use.
- *Improved structural capacity*. Except for asphalt surface recycling, all other recycling methods can improve the structural capacity of pavements through the improvement of material properties, increased layer thickness, and/or the addition of a structural layer.
- *Maintain geometry of pavement surface.* Recycling can help maintain pavement surface geometry. This is important in relation to existing curbs and gutters, maintaining clearances underneath bridges or other structures, and in other areas where the design requirements require matching the elevation of adjacent structures.
- *Construction at remote sites.* In some instances, recycling is a necessity such as for pavements at remote sites and/or island bases, where local aggregate materials are not available or are extremely expensive to crush, screen, and mine.

1-10 RECYCLING METHODS AND MATERIALS.

The processes, technologies, and equipment for pavement recycling have greatly improved since the early adoption of recycling techniques in the 1980s. The following sections describe basic recycling methods used in the United States (ARRA, 2001; Kandhal and Mallick, 1997; Bozkurt et al., 2002; Buncher and Jones, 2006; ARRA and FHWA, 2015) along with the applicable UFGS and other documents covering the construction requirements for DoD airfield and roadway pavements.

1-10.1 Asphalt Pavement Recycling.

1-10.1.1 Cold milling (CM).

Cold milling is the controlled removal of an existing pavement to some desired depth. CM is used to correct the surface profile and/or cross-slope or to remove a pavement surface exhibiting distresses such as raveling, top down cracking, rutting, bleeding, and polished aggregate. Overlay the milled surface with hot mix asphalt (HMA), apply a surface treatment, or use as a temporary surface for immediate correction of friction problems (UFGS 32 01 16.71). Construction contracts often state that the milled pavement material is the property of the contractor, who may stockpile and process the material as reclaimed asphalt pavement (RAP) for a future project.

1-10.1.2 Hot recycling (HR).

Hot recycling is the process in which RAP is combined with virgin aggregate, asphalt binder, and/or recycling agents in a central plant blending and mixing operation to produce HMA paving mixtures. The primary benefit of HR is to offset the high cost of virgin asphalt binder. Allow the use of HR on all DoD pavements except the surface course for airfields. Other DoD airfield mixtures may contain RAP such that the amount of asphalt binder from RAP does not exceed 20 percent of the total asphalt content in the recycled asphalt mixture. DoD roadway mixtures may contain RAP such that the amount of asphalt binder from RAP does not exceed 30 percent of the total asphalt content in the recycled asphalt mixture. (UFGS 32 12 15.13 *and UFGS 32 12 16.16*).

1-10.1.3 Hot in-place recycling (HIR).

Hot in-place recycling is the process of heating and softening the existing pavement to allow it to be scarified/milled to a specified depth and combined in-place with virgin aggregate, asphalt binder, and/or HMA. HIR is then re-laid to serve as a base or intermediate course under a new HMA overlay. In some cases, HIR is used as the final wearing surface. HIR is comprised of three specific types:

1-10.1.3.1 HIR-I, Surface Recycling.

In HIR-I, Surface Recycling, the top 0.75 to 2.0 inches (19 to 50 mm) of the existing pavement surface is heated, scarified, combined with new asphalt binder, and re-laid for the purpose of minor mix improvement/modification. Surface recycling can be single-pass or double-pass. In single-pass, the recycled mix is re-laid and serves as the final wearing surface (mix heated-scarified material with new asphalt binder or recycling agent to produce in-place hot recycled mixture). HIR-I is typically used on roadways with low traffic volume (UFGS 32 01 16.75 and UFGS 32 01 16.74).

1-10.1.3.2 HIR-II, Remixing.

In HIR-II, Remixing, the existing pavement is heated, loosened, combined with virgin aggregate and new asphalt binder or new HMA, and re-laid for significant mix improvement and modest pavement strengthening. Remixing can be single stage or multiple stage. In single stage remixing, heat and scarify the pavement to a specified depth in one pass, mix with additional virgin aggregate and asphalt binder, relay mix, and compact. In the double pass method of remixing, the first pass of remixed material is covered with a layer of HMA prior to compaction (UFGS 32 01 16.75 and UFGS 32 01 16.74).

1-10.1.3.3 HIR-III, Repaving.

In HIR-III, Repaving, heat, loosen and combine the pavement surface with virgin asphalt binder and re-lay in tandem with an HMA overlay to strengthen and restore the surface profile and/or friction characteristics. Repaving is surface recycling with an integrally applied thermally bonded overlay (Kandhal and Mallick, 1997). Repaving is single-pass or double-pass. The single-pass method uses one unit equipped with two screeds. In-place material is recycled and repaved with the first screed. New HMA is dumped into the front of the unit, conveyed past the first screed, placed atop the recycled mix, and paved with the second screed. The double-pass method uses two separate units. The first unit recycles and repaves using its own screed. The second unit is a conventional asphalt paver that places and spreads new HMA on top of recycled layer (UFGS 32 01 16.75 and UFGS 32 01 16.74).

1-10.1.4 Cold Recycling.

1-10.1.4.1 Cold in-place recycling (CIR).

Cold in-place recycling is the process of milling and sizing RAP, in-place mixing of RAP with recycling additive and new aggregate (either in the milling machine cutting chamber or in a mix paver) to produce a recycled cold mix, and then placing and compacting the recycled cold mix, typically in a single pass. Use CIR to restore the profile or cross-slope of the existing surface or to mitigate surface and base layer distresses. HMA overlays are required for airfields and higher volume roads (UFGS 32 01 16.71; UFGS 32 01 16.70).

1-10.1.4.2 Cold central-plant recycling (CCPR).

Cold central-plant recycling combines stockpiled RAP with virgin aggregate, recycling additives, and water at a central plant to produce recycled cold mix for use as a new base course. Like CIR, use CCPR to restore the profile or cross-slope of the existing surface or to mitigate surface and base layer distresses. CCPR is generally a viable alternative when stockpiles of high-quality RAP are available or when it is not possible to recycle the pavement in-place (ARRA, 2015). An HMA overlay is required for airfields and higher volume roads (UFGS 32 01 16.70).

1-10.1.4.3 Full-depth reclamation (FDR).

Full-depth reclamation is a process in which all of the asphalt pavement section and a predetermined amount of underlying base material is integrally mixed, treated, and re-laid in-place using a reclaiming machine to produce a stabilized base course. Add asphalt emulsion or portland cement as part of the process. Type C fly ash and lime-fly ash are also used to as chemical stabilization agents in FDR. FDR eliminates existing distresses and restores structural capacity by creating a stronger, higher load-carrying base and is recommended for pavements having a base or subgrade problem. FDR is generally used on low volume roads (Kandhal and Mallick, 1997, UFGS 32 01 16.70*).*

1-10.2 Portland Cement Concrete (PCC) Pavement Recycling.

1-10.2.1 Slab Fracturing (SF).

The process consists of in-place recycling involving breaking or cracking of the existing PCC pavement to prevent reflection cracking in an HMA overlay. SF comprises the following three specific types:

1-10.2.2 Crack and Seat.

Slabs of a jointed plain concrete pavement (JPCP) are fractured into small segments 2 to 6 feet (0.6 to 1.8 m) in length, which are then seated firmly into place in preparation for an HMA overlay.

1-10.2.2.1 Break and Seat.

Fracture slabs of a jointed reinforced concrete pavement (JRCP) into small segments 1.5 to 4 feet (0.5 to 1.2 m) long, with reinforcing steel adequately ruptured/sheared to ensure discontinuity among the fracture pieces. Seat the pieces firmly into place in preparation for an HMA overlay.

1-10.2.2.2 Rubblization.

The rubblization process breaks and pulverizes slabs of JPCP, JRCP, and continuously reinforced concrete pavement (CRCP) into small, discontinuous pieces which no longer act as slabs, but rather function as a high quality granular base. At the slab surface, sizes range from sand-sized particles to 6 inches (150 mm). At the slab bottom sizes are 6 to 15 inches (150 to 375 mm). The rubblized PCC is compacted prior to receiving an HMA overlay. Rubblization is the most widely used slab fracturing process since it best prevents reflective cracking.

1-10.2.3 Recycled Concrete Aggregate.

Recycled concrete aggregate is the product of PCC demolition and removal and off-site processing (i.e., crushing, sizing, and steel removal) of broken concrete into aggregate for use in unbound layers, lean concrete base, or PCC surfacing. (UFGS 32 11 23; UFGS 32 11 20, *[Base Course for Rigid] [and] [Subbases for Flexible] Paving*; UFGS 32 11 36.13; UFGS 32 13 14.13.

There are a number of variations of each method using various additives and different equipment. Moreover, a wide array of construction techniques is possible in terms of the depth of existing pavement removal, the thickness of the recycled material layer, and the type and thickness of cover layer (e.g., chip seal, HMA surface course), if used.

Table 1-1 provides a summary of the basic recycling methods used on asphalt-surfaced pavements while Table 1-2 provides a summary of PCC pavement recycling methods.

1-11 DESIGN CONSIDERATIONS IN RECYCLING.

To achieve satisfactory results by recycling requires an evaluation of the available materials and proper mix design. Additionally, determine the structural adequacy of the existing pavement and design calculations to ensure that the recycled pavement section suffices for the anticipated traffic levels.

Consider the functional aspects of pavement performance in the selection of recycling treatments. In cases where the recycled mix serves as the wearing course, the mix must be capable of (a) placement to the required level of smoothness, (b) providing adequate long-term friction, and (c) providing long-term durability to environmental and traffic effects. The sections below provide brief discussions of these critical aspects of recycling and present relevant DoD specifications and guidance documents corresponding to pavement recycling methods.

Table 1-1 Summary of Asphalt Pavement Recycling Applications

Type	Treatment Equipment	Product	Central Plant or In-Place	Placement and Compaction Equipment	Use
Cold Planing/ Milling (CM)	Milling machine[1]	RAP for Hot or Cold recycling (HR/CR)	N/A	N/A	Controlled removal of the existing pavement to the desired depth
Hot Recycling (HR)	Milling machine[1] or ripper crusher to produce RAP[2]	HMA with RAP	Central plant	Conventional paver and rollers	Some RAP can generally be used in all HMA pavements, except as a surface course on airfields
Hot In-Place Recycling, Type I—Surface Recycling (HIR-I)	Heater-scarifier or hot rotary milling machine	Recycled HMA	In-place	Screed attached to recycling equipment and conventional rollers	Surface course or base course. HMA overlay required on airfields
Hot In-Place Recycling Type II—Remixing (HIR-II)	Heater-scarifier or hot rotary milling machine	Recycled HMA	In-place	Screed attached to recycling equipment and conventional rollers	Typically used as surface course but can serve as base course. HMA overlay required on airfields
Hot In-Place Recycling Type III—Repaving (HIR-III)	Heater-scarifier or hot rotary milling machine	Recycled HMA integrally laid with new HMA overlay	In-place	Screed attached to mixer and conventional rollers	Surface course, except on airfields and high volume roads.
Cold In-Place Recycling (CIR)	Milling machine	Recycled asphalt mixture	In-place	Screed or auger/screed system, or conventional asphalt paver, rollers	Base course
Cold Central Plant Recycling (CCPR)	Milling machine[1] or ripper/ crusher equipment[2]	Recycled asphalt mixture	Central plant	Conventional HMA paver, motor grader, or Jersey spreader, conventional rollers	Base course

Type	Treatment Equipment	Product	Central Plant or In-Place	Placement and Compaction Equipment	Use
Full-Depth Reclamation (FDR)	Reclaiming machine	Recycled mix of asphalt, base and subgrade soil	In-place	Motor grader, vibratory pad-foot roller, steel drum roller, pneumatic rollers	Base course

N/A: Not applicable.
[1] Cold planing/milling machine cut/pulverize W/grinding heads, e.g. conventional or micro milling machine.
[2] Ripping/crushing machine, earthmovers (dozer, excavator, backhoe) W/ripper teeth, scarifiers, grid rollers

Table 1-2 Summary of Concrete Pavement Recycling Applications

Recycle Method	Demolition and/or Removal Equipment	Recycle Material	Use
Slab Fracturing, Crack and Seat	Cracking equipment[1], pneumatic roller	PCC slabs resized through cracking operation	Converts JPCP into base layer to support new HMA overlay
Slab Fracturing, Break and Seat	Cracking equipment[1], pneumatic roller	PCC slabs resized through cracking operation	Converts JRCP and CRCP into base layer to support new HMA overlay
Slab Fracturing, Rubblization	Rubblizing equipment[2], vibratory roller	PCC material resized by rubblizing operation	Converts JPCP, JRCP and CRCP into high quality granular base layer to support new HMA overlay
Recycled Concrete Aggregate (RCA)	Demolition equipment[3], backhoe or front-end loaders (with Rhino horn), crushing plant	RCA	In PCC, lean concrete base, asphalt treated base mixes. As unbound base or subbase. Small sizes of RCA used as aggregates for HMA and PCC mixtures

[1]Cracking equipment includes pile drivers, guillotine hammers, whip hammers, and impact hammers.
[2]Rubblizing equipment includes resonant pavement breakers and multi-head breakers.
[3]Demolition equipment includes drop balls, gravity-drop hammers, hydraulic or pneumatic hammers, trailer-mounted diesel hammers, spring-arm whiphammers, and vibrating-beam breakers.

CHAPTER 2 EVALUATION AND SELECTION OF REHABILITATION STRATEGY

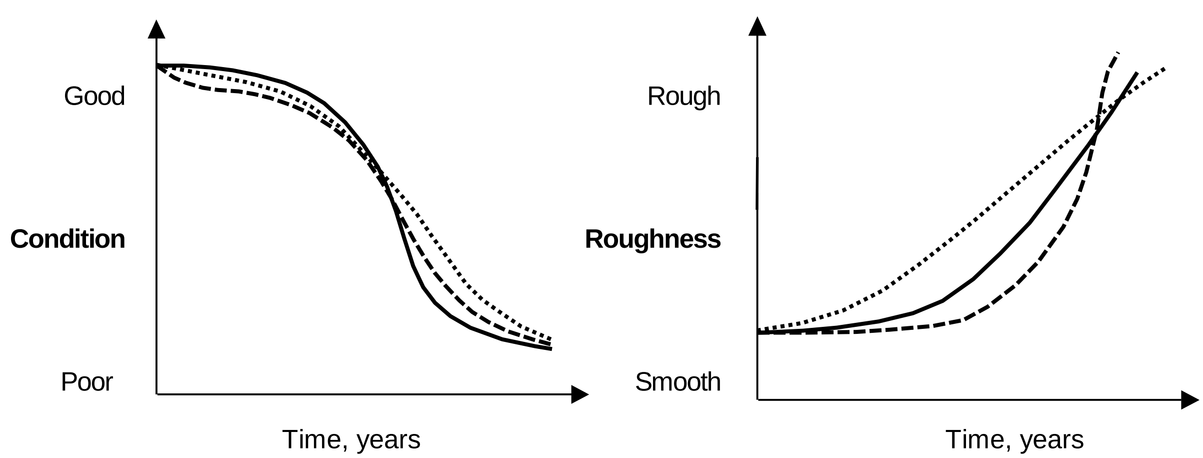
2-1 INTRODUCTION.

The detrimental effects of traffic loading and environmental factors degrade all pavements. The deterioration manifests in a variety of ways (such as cracking, rutting, raveling, spalling), that reduce the structural integrity and functional quality of the pavement. Loss of structural integrity translates into a loss of load-carrying capacity. Loss of functional quality (increased roughness, decreased friction and surface drainage, foreign object damage (FOD) potential) compromises safety and reduces comfort of operation.

Although the manner and speed with which pavements deteriorate differs, the overall trend is one in which the pavement condition changes from good to poor and the pavement surface condition progresses from smooth to rough, as illustrated in Figure 2-1. Factors governing changes in pavement condition include (ARRA, 2015):

- Pavement type
- Quality of project design
- Quality of original construction, including mixes and materials
- Type, thickness, and properties (strength, stiffness, durability, etc.) of individual pavement layers
- Subgrade soil type, bearing properties, and moisture content
- Traffic composition and loading characteristics
- Environmental conditions
- Types, levels, and effectiveness of maintenance activities

Figure 2-1 Pavement Deterioration Trends



(a) Condition deterioration
(b) Roughness progression

2-1.1 Pavement maintenance and rehabilitation (M&R) slows deterioration, extends pavement life and addresses the following (Zimmerman):

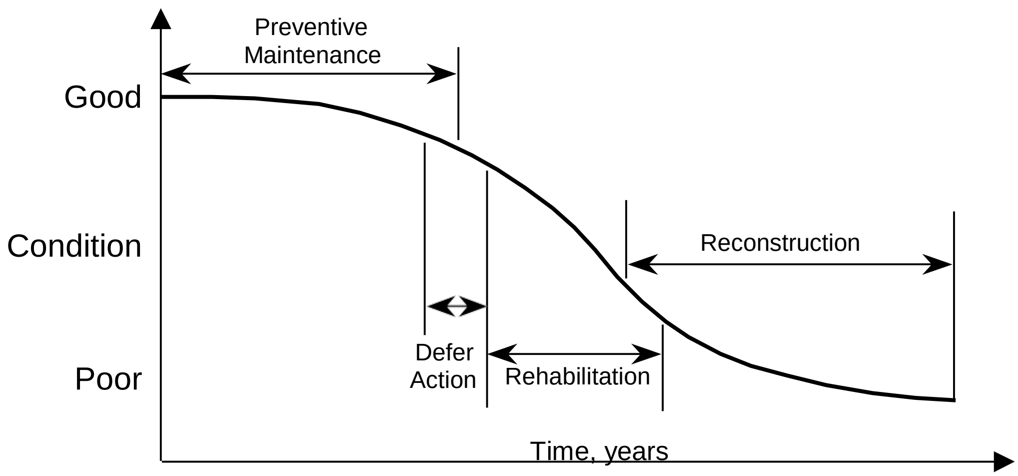
- Inadequate smoothness.
- Excessive pavement distress.
- FOD potential (generally airfields only).
- Reduced surface friction.
- Excessive maintenance requirement.
- Unacceptable user costs.
- Inadequate structural capacity for planned use or projected traffic.

2-1.1.1 Many types of M&R treatments are available for these purposes. They range from localized corrective maintenance (e.g., surface patching, full-depth repairs, rut patching and filling) to preventive maintenance (e.g., crack and joint sealing, surface treatments, thin overlays) to minor rehabilitation (e.g., grooving, functional overlays, limited restoration) to major rehabilitation (e.g., structural overlays, extensive restoration, rubblize-and-overlay).

2-1.1.2 The selection of M&R treatment and timing is a critical component in the economical operation of a pavement network. In the pavement life cycle shown in Figure 2-2, localized corrective maintenance is required at any point on the deterioration curve except at the highest condition levels. However, as the condition level significantly decreases, the costs of corrective maintenance become excessive in the absence of rehabilitation or reconstruction.

2-1.2 Preventive maintenance is a cost-effective treatment that preserves the pavement, retards future deterioration, and maintains or improves functional condition. It is most appropriate when the pavement is in relatively good condition (Zimmerman). As seen in Figure 2-2, the window of opportunity for cost-effectiveness is during the early stages of pavement life.

Figure 2-2 Timing of Pavement Activities*



*Source: Zimmerman.

Rehabilitation, defined as the structural or functional enhancement of a pavement that produces substantial extension in service life (Hall et al., 2001), is most appropriate when preventive maintenance is no longer cost-effective, yet the structure has not deteriorated so badly to warrant reconstruction. During this period, structural capacity remains such that one or several rehabilitation techniques are economically justified over reconstruction.

2-1.3 Although recycling techniques generally fall under the category of rehabilitation, certain forms of recycling, such as CM and HIR-I, constitute corrective maintenance. While HIR-I with an overlay is preventive maintenance. FDR is characterized as reconstruction.

2-2 SELECTION OF PREFERRED REHABILITATION ALTERNATIVE.

2-2.1 Introduction.

2-2.1.1 This chapter provides an overview of the rehabilitation selection process, as it pertains to asphalt and concrete pavement recycling methods. It is a general familiarization tool and a lead-in for the detailed, project-level applications presented in Chapter 3.

2-2.1.2 The selection process favors those recycling techniques that fall under the rehabilitation and reconstruction categories. Such treatments transform an existing deteriorated pavement into a new pavement with significant future performance expectations that necessitate an economic analysis. UFC 3-270-08 provides useful background guidance in the determination of feasible M&R alternatives, including many of the recycling techniques discussed in this manual.

2-2.1.3 Determining the most appropriate rehabilitation strategy for a given pavement at a given time is not a simple process, especially if cost-effectiveness is a consideration. The process requires information about the existing pavement as well as the needs and constraints of the rehabilitation proposed. In addition, there are usually several solutions to consider, each with unique advantages and disadvantages.

2-2.1.4 When identifying a pavement for possible rehabilitation, perform a sequential approach to evaluate strategies and identify possible solutions. First survey the existing pavement to identify and quantify the various types of distress and the rate(s) at which they are developing. Prepare a list of feasible rehabilitation techniques based on the distresses identified. Next, collect historical information, and perform a detailed evaluation to identify the mechanisms causing the distress and to determine the structural and functional capacities of the pavement. Formulate rehabilitation strategies (i.e., a specific treatment or a combination of treatments) that adequately address the cause of the distress. These strategies may or may not include recycling materials and techniques.

2-2.1.5 Then further develop the strategies to satisfy the needs and constraints of the project. After identifying a final set of feasible rehabilitation strategies, perform a cost analysis and evaluate the results in conjunction with non-monetary factors to select the preferred alternative.

2-2.2 Identification of Feasible Recycling Techniques.

2-2.1.1 As discussed in Chapter 1, there are several basic recycling methods for rehabilitating existing asphalt-surfaced pavements and rehabilitating existing concrete-surfaced pavements. Perform the basic asphalt recycling methods individually or in combination with other methods and supplement with HMA overlays or surface treatments to satisfy design life requirements. A summary of asphalt recycling methods covered in this document follows below. (*Asphalt Pavement Recycling* (ARRA and FHWA, 2001; Kandhal and Mallick, 1997) and *Basic Asphalt Recycling Manual*, Second Edition (FHWA/ARRA, 2015)).

- Cold Milling/Planing (CM)
- Hot Recycling (HR)
- HIR Type I—Surface Recycling (HIR-I)
- HIR Type II—Remixing (HIR-II)
- HIR Type III—Repaving (HIR-III)
- Cold In-Place Recycling (CIR)
- Cold Central Plant Recycling (CCPR)
- Full Depth Reclamation (FDR)

2-2.1.2 Concrete recycling methods:

- Slab Fracturing—Crack and Seat
- Slab Fracturing—Break and Seat
- Slab Fracturing—Rubblization
- Recycled concrete aggregate (RCA)

2-2.1.3 Consider many factors to determine the feasibility of each application. Obtain a preliminary indication by examining the current condition of the pavement, as reflected by pavement condition index (PCI) survey data and identify the types of pavement distress. Complete descriptions of the PCI procedure, including the distresses evaluated and distress deduct values, are provided in UFC 3-260-16, American Society for Testing and Materials (ASTM) D5340, *Standard Test Method for Airport Pavement Condition Index Surveys*, and ASTM D6433 *Standard Practice for Roads and Parking Lots Pavement Condition Index Surveys*.

2-2.1.4 Currently, airfield pavement PCI surveys are required on a regular basis for DoD pavements. Conducting PCI surveys on DoD roadway pavements helps determine the appropriate pavement maintenance, repair, or rehabilitation technique.

2-2.1.5 DoD agencies use the MicroPAVER™ pavement management system (PMS) to enter and store PCI survey data and track pavement conditions over time. The MicroPAVER™ system computes the structural condition index (SCI) of a pavement from the distress data collected in PCI surveys. The SCI represents the structural component of the PCI and considers only load-related distresses. Hence, deduct values are applied for distresses, such as, fatigue cracking, potholes, rutting, and shoving in asphalt pavements and corner breaks, longitudinal, transverse, and diagonal cracking, corner spalling, and divided/shattered slabs in concrete pavements.

2-2.1.6 A PCI trigger is more difficult to establish because of the inclusion of non-load-related distresses, but values of 65 to 70 are typical. Trigger levels for reconstruction on major facilities generally span the PCI range of 45 to 50.

2-2.1.7 The PCI is a good measure for determining the timing of an M&R activity; however, selection of an appropriate recycling method is best determined by considering the distresses exhibited. Table 2-1 illustrates typical pavement distresses along with recommended recycling techniques for repair. Repair techniques other than those presented in Table 2-1 may be appropriate, but Table 2-1 presents only recycling techniques. From functional treatments like CM with an HMA overlay to reconstruction using FDR with an HMA overlay, asphalt recycling provides a host of options.

2-2.1.8 Concrete pavements include two approaches for recycling: fractured slab technologies (crack and seat, break and seat, and rubblization) and recycled concrete aggregate.

2-2.1.9 Each recycling technique features advantages and disadvantages in terms of the specific pavement distresses treated and the ability to meet project objectives (e.g., design, construction, and environmental). Table 2-3 provides guidance in identifying feasible recycling techniques for deteriorated asphalt and concrete pavements. The table lists the appropriateness of each recycling technique in terms of how well it mitigates a particular distress.

Table 2-1 Suitability of Asphalt Recycling Techniques Based on Distresses

Pavement Distress	Suitable Asphalt Recycling Techniques					
	CM[2]	HIR[1]	HR[3]	CIR[4]	CCPR[4]	FDR[4]
Alligator Cracking	Green	Red	Green	Green	Green	Green
Jet Blast Erosion	Green	Yellow	Green	Red	Red	Red
Reflection Cracking	Red	Red	Yellow	Yellow	Yellow	Yellow
L&T Cracking	Red	Yellow	Red	Red	Red	Yellow
POL Spillage	Green	Yellow	Green	Red	Red	Red
Raveling	Yellow	Green	Green	Red	Red	Red
Rutting	Green	Yellow	Yellow	Yellow	Yellow	Yellow
Loss of Friction	Green	Green	Green	Red	Red	Red
Slippage Cracking	Green	Red	Green	Red	Red	Red

Key: Green—Likely applicable
Yellow—Maybe applicable
Red—Highly unlikely to be applicable

Notes:
[1] Do not use HIR on airfields without HMA overlay.
[2] CM generates FOD. Do not open milled surface to aircraft traffic under normal operations. Apply HMA overlay prior to opening to traffic. Milled roadway surfaces may be temporarily open to traffic with appropriate traffic control and warning measures. Due to safety concerns, noise and the rough surface associated with milled surfaces, do not allow traffic for extended periods.
[3] HR is suitable in all HMA mixes, except for airfield surface courses. Most HMA contains some RAP, so use HR where HMA is used. See specification requirements for limits on the amount of RAP allowed.
[4] Adhere to the minimum surface thickness requirements for flexible pavements above these recycled mixtures.

Table 2-2 Ideal Candidates for Asphalt and Concrete Recycling Techniques

Recycling Technique	Ideal Candidate Pavement Based on Existing Distresses
CM Only	Expedient repair technique to correct a friction-related and other surface problems, such as roughness, POL spillage, jet blast, etc. This technique is not allowed on airfields since it significantly increases FOD.
CM with HMA Overlay	Milling followed by HMA overlay is the most common approach for repairing existing asphalt pavements. This process works well for raveling, bleeding, cross-slope adjustment, rutting, and roughness.

Recycling Technique	**Ideal Candidate Pavement Based on Existing Distresses**
Hot Recycling (HR)	RAP is not allowed in HMA mixtures used as surface courses on DoD airfields. RAP is allowed in HMA mixtures used as base course or shoulder pavements on airfields. For DoD airfield pavements, the amount of RAP is limited such that the asphalt binder contributed by the RAP does not exceed 20 percent of the total asphalt content of the mixture, by weight. For DoD roadway and parking lot pavements, the amount of RAP is limited such that the asphalt binder contributed by the RAP does not exceed 30 percent of the total asphalt content of the mixture, by weight.
Hot In-Place Recycling (HIR)	HIR can solve surface problems such as raveling, surface cracking, minor rutting, and friction. Along with HMA overlays, HIR can solve more severe cases of rutting and cracking and add additional structure to the pavement. Do not use HIR on airfields without an HMA overlay.
HIR-I, Surface Recycling	HIR-I typically treats the uppermost pavement surface by heating, scarifying, adding virgin asphalt binder, and placing and compacting for minor HMA mix improvement and modification. Use HIR-I to rejuvenate surfaces that have experienced oxidation and to solve minor surface deficiencies. HIR-I is not allowed on airfields or on high volume roadway pavements.
HIR-II, Remixing	HIR-II is a remixing process that heats and loosens the existing asphalt pavement, combines with virgin aggregate and asphalt binder (or new HMA mix), and places and compacts for significant mix improvement, mix modification, or minor pavement strengthening. This process addresses pavement distresses such as rutting, raveling, loss of friction when confined to the pavement surface. HIR-II is not allowed on airfields or high volume roadway pavements.
HIR-III, Repaving	HIR-III is a more complex process in which the uppermost pavement surface is heated, loosened, combined with virgin asphalt binder, and placed integrally with an HMA overlay for the purpose of pavement strengthening or surface restoration.
Cold In-Place Recycling (CIR)	CIR is used for pavements with significant surface problems such as smoothness, rutting, and cracking. Works well to provide additional structural capacity when coupled with an HMA overlay. When used on an airfield or on high volume roadways, an HMA overlay is required.
Cold Central Plant Recycling (CCPR)	Same as for CIR.

Recycling Technique	Ideal Candidate Pavement Based on Existing Distresses
Full Depth Reclamation (FDR)	Use FDR to correct significant performance problems in an existing pavement, including fatigue cracking, rutting and other distresses that reduce the ability of the pavement to support traffic. Use FDR to significantly strengthen pavements. Rarely used on airfields or high volume roadways. Best used for low volume roads.
Crack and Seat	Crack and seat is a fractured slab technology appropriate for JPCP to reduce to delay, minimize or prevent the onset of reflective cracking in an HMA overlay. Crack and seat technology reduces the length of the existing PCC slabs to approximately 2 to 6 ft (0.6 to 1.8 m) to reduce the inducement of tensile strains at the interface with the new HMA overlay.
Break and Seat	Break and seat is similar to crack and seat, except that it is applied to JRCP and CRCP. In addition to reducing the base PCC slab size to approximately 1.5 to 4 ft (0.45 to 1.2 m), this method breaks the bond of reinforcing steel in the base slab prior to the application of the new HMA overlay.
Rubblization	As the name implies, rubblization is a fractured slab technology that breaks the base PCC slab apart into individual concrete particles ranging from dust to 15 inches (375 mm) diameter, depending on the thickness of the base slab, drainage and subgrade support. Rubblization is appropriate for JPCP, JRCP and CRCP and is effective in minimizing or preventing the onset of reflective cracking in an HMA overlay.
Recycled Concrete Aggregate (RCA)	RCA is appropriate for deteriorated concrete pavements where removal and replacement is the best rehabilitation alternative. Crush old concrete to acceptable particle sizes to produce unbound structural layers for use as base or subbase, and for blending into HMA or PCC mixtures. If used to produce concrete, RCA cannot contain particles that result in alkali silica reaction (ASR). For airfield pavements, only use RCA for aggregate base or lean concrete base.

2-2.3 Formulation of Feasible Rehabilitation Strategies.

Each pavement project comprises a unique set of conditions and circumstances beyond the types, severities, and extents of distresses present. These conditions and circumstances pose constraints on or limits to the effectiveness of individual recycling techniques, as well as the other forms of rehabilitation. A detailed project evaluation is crucial in determining the root cause(s) of pavement distress(es)—design inadequacies, applied loads, water, temperature, materials/construction shortcomings—and formulating a set of feasible rehabilitation strategies that adequately address the cause(s). Such an evaluation requires collecting key information about the existing pavement, establishing rehabilitation performance requirements/expectations, and identifying all factors affecting the suitability of alternative rehabilitation strategies.

Listed below are several specific informational items needed or desirable to formulating feasible recycling strategies. For some of these items, the airfield pavement structural evaluations and runway friction tests are valuable, especially if conducted recently. Pavement Information to collect includes the following:

- Pavement Cross Section—Define the existing pavement structure in terms of material layer types and thicknesses based on design information, as-built construction records, and maintenance data.
- Construction and Materials Quality—QC/QA data provides important information regarding the types of aggregates, binders, and additives used in HMA and PCC mixtures, as well as the mix properties (gradation, binder content, laboratory air voids, in-place density).
- Maintenance—Maintenance records may indicate the presence of chip seals, surface treatments, crack or joint sealant, machine patches, and other material applications that may factor into decisions about recycling and other rehabilitation strategies.

2-2.3.1 Detailed Evaluation of Existing Pavement Properties.

- Layer thicknesses—If historical data cannot characterize the pavement cross section or to obtain additional insight regarding the thickness and uniformity of material layers, then perform coring or ground penetrating radar (GPR) testing.
- Roughness and Friction—A detailed assessment of the pavement profile will quantify the overall roughness of the existing pavement and identify any significant differences in roughness throughout the limits of the project. Similarly, a detailed assessment of pavement friction using the Grip Tester or Mu-Meter will quantify the level of friction on the existing pavement and could identify differences in friction throughout the limits of the project. Texture depth testing via the sand patch method or laser systems (e.g., circular texture meter) can help assess the micro-texture and macro-texture components of pavement friction.
- Drainage—If needed, conduct a drainage survey to further assess the drainage characteristics of the existing pavement structure and determine the appropriateness of individual recycling alternatives. Moisture-related distresses identified in the PCI survey are a key part of this evaluation, as are cross-sectional design information and information about the design and condition of ditches, daylighted bases, and edge drains.
- Strength/Deflection—Nondestructive deflection testing (NDT) using impulse loading devices like the falling-weight deflectometer (FWD) and the heavy-weight deflectometer (HWD) can provide important information about the strength and structural capacity of the existing pavement.

- Strength/Bearing Capacity—The dynamic cone penetrometer (DCP) can evaluate the strength of unbound materials contained in the existing pavement structure. DCP readings can be directly correlated to the California Bearing Ratio (CBR). Like NDT data, CBR data may indicate a deficient unbound layer.
- Material properties—Examine and test pavement cores and other samples taken from throughout the project to gain additional information about the composition and condition of the pavement structure and the physical properties of the material layers.

2-2.3.2 Project Physical Characteristics.

- Project Size and Location—Although available funding may dictate project size, projects are typically defined as those pavement sections of an airfield or roadway pavement facility experiencing similar distresses. Develop a general idea of the project size and the proximity of the project to local aggregate sources and determine material production plants to understand mobilization and hauling considerations.
- Project Geometrics—Project geometrics include the need to maintain vertical alignment (adjacent pavements, in-pavement lighting, manholes, shoulders, curb-and-gutter, etc.), observe overhead clearances (bridges, power lines) or subsurface clearances (electrical circuitry, drainage structures), and address the impacts of lateral structures (e.g., buildings, hangars, lighting, barrier walls) on construction operations.

2-2.3.3 Design Characteristics/Performance Requirements.

- Design Life—Establish the required or desired design life of the rehabilitated or reconstructed pavement. Consider short and long term solutions and balance with budget considerations. Consider staged construction when appropriate.
- Traffic Projections—Determine the current composition of aircraft or vehicles using the pavement facility and their current levels of operation or volume, along with the projected growth rates of individual aircraft or vehicle types over the expected performance period.
- Climate—Climatic variables, such as temperature, precipitation, and freeze-thaw cycles can significantly impact the performance of recycled materials and must considered in the formulation of pavement rehabilitation strategies.

2-2.3.4 Construction Considerations.

- Construction Time Requirements—The available time for construction is often limited due to the scope of the project, the availability of alternate routes or facilities, regular traffic volume and the need to minimize disruptions due to mission requirements or safety concerns.

- Availability of Local Experience and Resources—Determine the knowledge and experience base of local contractors to perform rehabilitation or reconstruction activities, along with the availability of necessary equipment and local aggregates to fulfill the work requirements.
- Support of Construction Equipment—Consider how the removal or alteration of portions of a pavement structure may affect the ability to provide an adequate platform to support construction equipment and compaction of the constructed layers. Special consideration must be given to support of construction equipment when subgrade soils are saturated.

2-2.4 Selection of the Preferred Rehabilitation Strategy.

Selecting the preferred rehabilitation strategy requires evaluating economic and non-economic factors. The sections below briefly describe these factors.

2-2.4.1 Evaluation of Economic Factors.

Chapter 5 of UFC 3-270-08 outlines a procedure for conducting life cycle cost analysis (LCCA) for DoD pavement facilities. This procedure uses the net present worth (NPW) economic formula, an analysis period long enough to capture at least one major rehabilitation activity for each alternative, and a discount rate based on Army policies. An analyst estimates performance lives of the initial rehabilitation treatment and the sequence of M&R treatments expected over the analysis period, along with treatment costs. For each alternative, compute the NPW by summing the initial rehabilitation cost and each of the discounted future M&R costs. Compare the NPW of all feasible alternatives to identify the lowest life cycle cost alternative.

Use other economic factors in addition to life cycle costs for evaluation to include the following:

- Initial costs—Ensure that a project level alternative does not compromise the needs of the entire network (i.e., overall pavement management).
- Indirect/user costs—Costs incurred due to closures for construction and/or M&R work. These are a concern if the expected initial construction and/or future M&R operations generate a high degree of user dissatisfaction.
- Future maintenance costs—Alternatives requiring a disproportionate amount of future maintenance to sustain an adequate level of service, may exceed the personnel and/or equipment available.

2-2.4.2 Evaluation of Non-Economic Factors.

Evaluate numerous non-economic factors when selecting the preferred rehabilitation technique to include: Airfield class/type and traffic area type, roadway traffic level/composition, geometrics (lane widths affecting shoulder dimensions, drainage features, and horizontal and vertical alignment influence on traffic speed, drainage features), continuity of adjacent pavements and/or lanes, peripheral features, and future rehabilitation options and needs. Construction/materials considerations include availability of local materials and contractor capabilities, traffic control during construction (safety and congestion), duration of facility closure, recycling, conservation of materials and energy, roughness, and environmental implications. Consider the following maintenance issues: future maintenance operations, performance of treatment elsewhere under similar conditions, and maintenance capability. Design issues include noise issues (pavement-tire noise), subgrade soils, climate, DoD component or Base preference, safety considerations (friction/texture characteristics, pavement/shoulder contrast, and reflectivity).

CHAPTER 3 PROJECT PROCESS SELECTION AND STRUCTURAL DESIGN

3-1 INTRODUCTION.

This chapter describes a process of analyzing a pavement project to identify acceptable rehabilitation strategies and techniques. It also provides information on the structural design of recycled pavements and life cycle costs.

Airfield pavement conditions at individual military Bases are monitored through PCI surveys and structural evaluations utilizing an FWD. The collected condition data are entered and stored in the MicroPAVER™ pavement management system database. Some installations perform PCI surveys of roadway pavements. Airfield pavement PCI data and other available information determine maintenance and rehabilitation needs and identify those pavements that need detailed pavement structural evaluation or runway pavement friction testing. Base roadway pavements do not typically receive detailed structural evaluations.

Data used to determine the best treatment method includes PCI, FWD, construction and maintenance history, pavement coring and analysis, dynamic cone penetrometer (DCP), and other information. Since PCI and FWD data may have been collected over a considerable length of time, it may not be representative of current conditions. For that reason, a visual inspection may be needed to verify the overall condition and assess the need for additional testing.

3-2 PAVEMENT INFORMATION TO COLLECT.

3-2.1 Layer Thicknesses.

Coring, GPR, FWD, other tests and layered elastic analysis provide the layer information to validate recycling alternatives. The data also indicates the depth of pavement issues. The layer thicknesses and existing pavement issues influence the pavement design and help identify acceptable recycling alternatives.

3-2.2 Friction.

Friction test results and texture depth data provide information about the friction characteristics of the pavement surface. Steps to improve friction will require modifications to the pavement surface. Since friction is a surface problem, treatment for low friction are typically limited to surface repairs. Treatments include HIR, HR, or an HMA overlay. Surface milling can temporarily solve friction problems by improving the surface texture. Utilizing a milled surface is not ideal since the surface tends to have loose aggregate, is noisy under traffic, and can more quickly wear and damage tires of the vehicles and aircraft. FOD is a significant problem for milled pavement surfaces, so it is generally not acceptable to operate aircraft on this type of surface.

3-2.3 Roughness.

If available, roughness measurements, along with distress data from PCI surveys, can help determine specific performance problems causing increased roughness. Some roughness is attributable to design and construction, but most pavement roughness is the result of traffic operations and environmental effects. Performance problems causing roughness in the surface layer including segregation, raveling, and rutting favor recycling strategies such as HIR, HR, and HMA overlays. Conversely, roughness caused by problems in subsurface layers suggests the need for deeper, more extensive forms of recycling such as CM with HMA overlay, CIR, CCPR, FDR.

3-2.4 Drainage.

A drainage survey can identify excessive moisture, the sources of moisture, and the affected pavement layers and materials (Grogg et al., 2001). Surface drainage issues causing performance issues in the upper pavement structure are suitable for treatment using recycling strategies that address the upper layers.. However, if damage extends more deeply into the structure, consider more extensive recycling and/or drainage retrofitting. Subsurface drainage improvement may involve the installation or replacement of longitudinal edge drains and lateral outlets, or daylighting a base layer by replacing base material under shoulders with better-draining material (Hall et al., 2001).

3-2.5 Material Properties.

Pavement cores and other samples provide additional information concerning the cause of pavement distress. Evidence of asphalt binder stripping, bare and uncoated aggregate, friable or disintegrating mix, retention of excessive moisture, bleeding, and a tendency for layer debonding are examples of material deficiencies (ARRA, 2001) that aid in selecting feasible asphalt recycling alternatives. HMA mix properties (binder content and binder properties, aggregate gradation and quality, and voids in the mixture, etc.) and unbound material and subgrade properties influence the effectiveness of techniques that improve the existing materials. PCC pavement with ASR issues precludes the use of RCA materials on most airfield pavements as well as break/crack-and-seat and rubblization techniques.

3-3 RECYCLING METHODS TO ADDRESS PAVEMENT DISTRESSES.

3-3.1 Pavement Performance Problems.

Figures 3-1 through 3-12 illustrate pavement conditions suitable for recycling techniques. Other forms of rehabilitation, such as conventional overlays, with or without RAP, or pavement preservation activities, are also viable options. Use a combination of these techniques to compare their life cycle costs to select the final approach.

3-3.1.1 Alligator Cracking (Figure 3-1).

Alligator cracking often occurs in asphalt pavements and is an indicator of structural weakness. It can occur locally due to localized moisture problems or contamination in the underlying materials. Localized alligator cracking may be repaired by cutting out and patching the affected areas, but more widespread cracking throughout an entire section of pavement indicates pavement failure and likely requires rehabilitation. Alligator cracking is a structural problem that may be related to weakness in the underlying base or subgrade layer or may be related to a drainage problem. For these reasons, treatment of alligator cracking may require significant effort to address.

Figure 3-1 Alligator Cracking

3-3.1.1.1 Alligator cracking requires a detailed inspection and evaluation to determine potential causes. Identify whether drainage is a factor. Cutting a trench across the traffic lane allows inspection, sampling and testing of all layers including subsurface materials. Review available design and construction data. Nondestructive pavement evaluation provides insight into the pavement structure. If cracking is substantial, it may be difficult to conduct FWD testing since the cracking affects the pavement response making it difficult to obtain a good nondestructive evaluation.

3-3.1.1.2 Repair alligator cracking by cutting out and patching or by applying an HMA overlay to the surface. It is often difficult to obtain funding for a pavement just beginning to show distresses, hence, some justification for early repair is needed.

3-3.1.1.3 Rehabilitating alligator cracking often requires removing extra material to eliminate all unsatisfactory material. This is an ideal situation for cold recycling processes (CIR, CCPR, and FDR). For example, remove unsatisfactory material including the base course and pull it to the side for reuse. Stabilize the underlying material before reapplying the base course and a new HMA layer. Perform adjustments to the base materials prior to placement. Adjustments to the base course may include additional aggregate or water.

3-3.1.1.4 Remove the HMA mixture by milling. Treat the milled material with a small percentage of asphalt emulsion before replacing. Place one or more lifts of HMA as an overlay to the milled material. This process is acceptable for low volume roads and airfields. For high volume roads and airfields, HMA over the CIR are required to meet the minimum thickness requirements for HMA over crushed aggregate base course.

3-3.1.1.5 Some low volume roads are suitable for mixing the top several inches of existing structurally deficient pavement with a pulvimixer to produce homogenous underlying materials (FDR). Use this process to mix up to 15 to 20 inches of materials. Move the material to the side of the pavement under repair to rebuild the structure in layers having adequate density and smoothness. Add water or asphalt emulsion to aid in handling and compaction and provide some cohesion. Once the materials are thoroughly mixed, placed, and compacted, cover with an asphalt surface treatment or the minimum required thickness of HMA pavement.

3-3.1.2 Jet Blast Erosion (Figure 3-2).

Jet blast erosion occurs on asphalt pavements in areas where jets operate in slow moving or stopped conditions. The jet blast heats the pavement surface turning the area of direct heat impact black and in some cases actually blasting aggregate particles from the surface and burning the asphalt binder. In extreme cases, the blast removes the entire top layer. This generally only happens when there is delamination between the asphalt surface course and the underlying layer or when the total thickness of asphalt mixture is thin allowing removal of the entire thickness of asphalt.

Figure 3-2 Jet Blast Damage

3-3.1.2.1 Jet blast erosion is a surface problem that does not typically cause significant damage to underlying pavement layers. The normal procedure mills down approximately 2 inches or deeper as needed followed by a patch. On larger projects, recycle the milled material into the project. This is especially beneficial in remote areas. Clearly define in the statement of work whether the millings are contractor property or are retained in a government stockpile.

3-3.1.2.2 Do not use the HIR processes to repair the areas damaged by jet blast erosion. HIR on airfields require the placement of an HMA overlay, hence, HIR is not a good option for correcting areas of blast effect. It is also very difficult to modify the in-place asphalt binder due to the jet blast damage.

3-3.1.2.3 While surface recycling methods can potentially treat jet blast areas, these methods are not normally the best approach. A more straightforward approach is CM with an HMA overlay, which generally provides more satisfactory performance compared to HIR.

3-3.1.3 Reflective Cracking (Figure 3-3).

Applying an HMA overlay directly on an old concrete pavement frequently results in reflective cracking in the new HMA overlay. Applying an HMA overlay to a cracked HMA pavement can result in reflective cracking, but it seldom occurs and is typically not as distinctive the reflective cracking that develops in HMA over PCC. Reflective cracking is caused by the opening and closing of joints and cracks in the underlying layer due to temperature fluctuations. Seal reflective cracks as soon as they occur. If reflective cracks continue to propagate and deteriorate, additional work may be required, such as CM with an HMA overlay. Placement of a fabric or stress absorbing membrane interlayer (SAMI) prior to the HMA overlay may delay the onset or minimize reflective cracking in the HMA overlay, especially over cracked HMA pavements. If the pavement is in poor condition, consider using CIR or CCPR procedures to recycle an HMA pavement exhibiting reflective cracking. CIR or CCPR must incorporate an HMA overlay on DoD airfields and high volume roads.

Figure 3-3 Reflective Cracking

HIR may be effective to address reflective cracking on roadways. For moderate to high volume roadway pavements, apply an HMA overlay or asphalt surface treatment to the HIR surface. HIR may serve as the wearing course on low volume roadways.

3-3.1.4 Longitudinal and Transverse Cracking (Figures 3-4 and 3-5).

Longitudinal and transverse cracking is a common distress on HMA roadway and airfield pavements. Much of the longitudinal cracking is deterioration of the longitudinal paving joints (Figure 3-4). Low density at the longitudinal joint results in cracks forming over time. Longitudinal cracks can develop in the middle of the paving lane at the paver gear box. This phenomenon occurs when the auger flights fail to adequately maintain a uniform head of material in front of the screed. Identify and correct this problem during construction to promote long term performance. Longitudinal cracking can develop into fatigue cracking. In this case, the initial crack occurs longitudinally followed over time by additional cracking parallel and transverse to the intial crack, forming a system of interconnected cracks.

Low ambient temperatures and frequent and significant temperature changes cause cracking in the transverse direction (Figure 3-5) at some spacing along the roadway/airfield. As the pavement ages and becomes embrittled, transverse cracks develop between the earlier cracks, resulting in more closely spaced transverse cracking.

The first maintenance procedure for longitudinal and transverse cracks to seal the cracks to prevent water from entering into the joint and weakening the underlying layers. When cracks widen and become more closely spaced, more aggressive repairs are required. Consider CM with an HMA overlay or HIR with an HMA overlay.

Figure 3-4 Longitudinal Cracking

Figure 3-5 Transverse Cracking

3-3.1.5 Petroleum, Oil or Lubricants (POL) Spillage (Figure 3-6).

Petroleum, oil or lubricant spillage generally occurs under aircraft or vehicles during maintenance or refueling operations. This spillage can soften HMA pavements and can result in the loss of asphalt binder and fine aggregate particles. On roads, this type of damage usually arises from accidents or equipment malfunction. On airfields, POL spillage typically occurs in areas where refueling or minor maintenance is performed. Fuel-resistant HMA mixes should be specified for the surface of airfield pavements where there is risk of POL spillage.

Repair POL spills (Figure 3-6) to prevent raveling and subsequent loss of aggregate particles. Treat by milling the damaged areas and overlaying with HMA.

In many cases, blotting the POL spill on a roadway with sand or sawdust minimizes the damage and quickly allows the road to be opened to traffic. Large spills that are not promptly cleaned up will penetrate the pavement and lead to rapid failure. Remove the damaged material and patch with HMA. Collect the damaged material for treatment and off-site recycling. Further recycling is not cost effective for small areas.

Figure 3-6 Fuel or Oil Spillage

3-3.1.6 Raveling (Figure 3-7).

Raveling (Figure 3-7) typically occurs in areas having segregation or low density, such as longitudinal joints. Areas of segregation or low density observed on the surface may exist through the full depth of the layer. Localized problem areas may ravel enough to require some type of repair. The most common repair is to mill the problem area and patch with HMA. Bituminous surface treatment or an HMA overlay may also be suitable treatments.

When raveling is more widespread, rehabilitate the entire surface by mill and overlay with HMA. For large projects, remove the material from the project site for use as RAP.

Use the HIR process to treat raveled areas followed by application of an HMA overlay on airfields and high volume roads. The HIR process may eliminate the need for milling and may be more cost effective than traditional CM and HMA overlay. On low volume roads, the HIR process without an HMA overlay can be used to treat raveled pavement. HIR may reduce the initial cost and overall life cycle cost.

Figure 3-7 Raveling.

3-3.1.7 Rutting (Figures 3-8 and 3-9).

Rutting can occur in HMA pavements when subjected to slow moving traffic. Rutting can be related to structural weakness (Figure 3-8) in the underlying base, subbase, or subgrade layers or relatively high tire contact pressure that affects the surface layer (Figure 3-9). Rutting, when caused by underlying structural problems, is typically wider and deeper than rutting in the HMA layer caused by high tire pressures. The recycling techniques shown in Table 2-1, except HIR, may be considered for repair of rutted pavement. Rutting due to structural weakness requires excavating and replacing deficient material with satisfactory material. Repair rutting of the HMA layer by removing the top 2-4 inches (25 to 50 mm) of surface and replacing with acceptable HMA.

Prior to repairing a pavement experiencing rutting, investigate the extent of the rutting by cutting trenches across a rutted pavement. If the rutting extends into the base and underlying layers this is an indication that the underlying materials may require improvement or removal and replacement.

Consider recycling processes such as CIR and CCPR to rehabilitate rutted pavement caused by weakness of the underlying layers. For example, the investigation may indicate that there is a problem in the subgrade. In this case, excavate to the subgrade and repair by stabilization. Place the recovered materials back in their appropriate layer in the pavement. It may be necessary to modify or stabilize some of the materials prior to putting back in place.

Repair rutting confined to the existing HMA surface by CM followed by HMA overlay. Use the milled material as RAP in the recycled mixture.

Figure 3-8 Rutting of the Pavement Structure

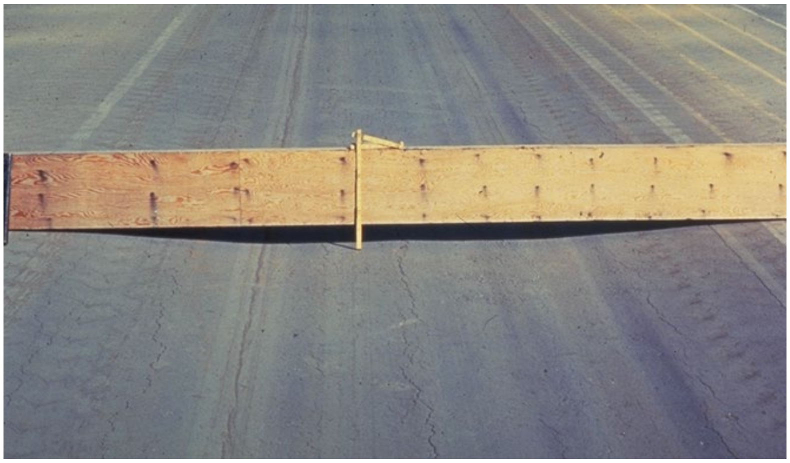


Figure 3-9 Rutting in the HMA Layers

3-3.1.8 Loss of Friction.

Loss of friction often occurs due to polishing of aggregate or asphalt binder bleeding to the pavement surface. Loss of friction can generate significant safety issues and requires prompt repair. Pavement surface issues cause friction problems and are corrected by modifying the surface.

As an expedient repair, mill the surface to improve friction. A milled surface has a rough surface texture that significantly improves friction. The milled surface may deteriorate with time when exposed to environmental conditions and traffic. Therefore, the milled surface is a temporary method. Be aware, using a milled surface to improve surface friction is a significant problem on airfields due to the potential for FOD as aggregates may ravel from the milled surface. Permanently correct the surface with an HMA overlay as soon as practical.

Friction test results and, if available, texture depth data, provide information about the friction characteristics of the pavement surface. Steps to improve friction require modifications to the pavement surface. Friction is a surface issue and the repair for low friction does not require significant modifications below the pavement surface. Repairs for friction problems include HIR, HR, or an HMA overlay.

3-3.1.9 Slippage (Figure 3-10).

Slippage occurs when delamination occurs between two layers of asphalt mixture (typically the top two layers). This is due to a number of factors including the type of tack coat used, application procedures for tack coat, and the cleanliness of underlying surface. Moisture problems can also cause delamination and loss of bond. If slippage occurs, remove the top layer by milling below the depth of delamination and applying an HMA overlay. The overlay can consist of HR.

Figure 3-10 Slippage due to Loss of Bond

3-3.1.10 Alkali Silica Reaction (ASR) (Figure 3-11).

ASR results in scaling or map cracking around joints or other areas subject to moisture. The ASR generates swelling in the concrete resulting in internal stresses. In time this leads to deterioration of the concrete surface. Typically, concrete pavements with ASR continue deteriorating, eventually requiring repairs. There is a risk of expansion and breakdown of this material if left in place, even if cracked and seated or rubblized, This risk increases in the presence of soils or ground water that contain Alkalis and/or Sulfates. ASR or sulfate reactions may generate additional swelling of the mixture, cause breakdown of the material or generate additional performance problems. Remove and crush this material to aggregate size and use as base course or similar use for roadways. Do not design, place or use this material under airfield pavement without prior approval of the DoD’s Pavements Discipline Working Group (DWG). Requests to the Pavements DWG for use of ASR infected recycled concrete under airfield pavements must include a detailed risk assessment, the type of cement in the concrete or the type of cement used in concrete supplied by local ready mix plants for building foundations, field measurements of sulfate concentrations in the soil and ground water, the pH of the soil and ground water, a list and drawing showing the location of any utility, drain, gutter, foundation, or arresting system component within 20 feet (6 meters) of the material placement and a detailed list of design and operational means and methods that will be employed to monitor and mitigate any expansion of the material that may develop. Only submit such requests as value engineering proposal requests in Design-build or construction contracts of designs not including the reuse of the ASR recycled material on airfields. Do not bid a design-build contract assuming or accepting or calculating the use of ASR infected recycled concrete is or will be allowed in any airfield pavement.

Figure 3-11 ASR Distress (Scaling/Map Cracking) on Concrete Pavement

3-3.1.11 Shattered Slabs (Figure 3-12).

Shattered slabs occur when the pavement has exceeded its design life or the pavement is overloaded. Fractured slab technologies, such as crack and seat, break and seat, or rubblization, coupled with HMA overlay, work well to address concrete with shattered slab distress. Account for the loss of strength in the fractured concrete in the structural design of the HMA overlay. Alternately, remove and crush the concrete for use in HMA or PCC mixes or as base course.

Figure 3-12 Shattered Slabs on Concrete Pavement

3-4 PAVEMENT CONDITION AND PERFORMANCE TRENDS.

Finally, assess the feasibility of recycling based on pavement condition/performance trends. Historical PCI or SCI trends, or even trends of key distresses, indicate the rate of deterioration. Knowing the PCI or SCI deterioration rate allows a more accurate selection of techniques to address future conditions. As a general note, UFC 3-270-08 provides illustrations of low, normal, and high long-term rates of deterioration for four pavement types: asphalt concrete (AC) pavements, AC overlays of AC pavements, PCC pavements, and AC overlays of PCC pavements. Measure the long-term rate from the time of construction or last overall M&R activity. It also categorizes short-term deterioration rates, i.e. a drop in the pavement condition index (PCI) during the last year, as low (≤3 PCI points), normal (4 to 6 points), and high (≥7 points).

3-4.1 Evaluating Existing Pavement.

If available, detailed pavement structural and/or functional information may shed light on the causes of pavement distress, leading to a more viable set of candidate recycling strategies. PCI results are useful. Inspecting the project is essential. The following paragraphs discuss the indicators that pavement properties provide to identify appropriate repair strategies.

3-4.2 Design Considerations.

Following are aspects of CIR design.

3-4.2.1 Existing Pavement Structure and Conditions Analysis (ARRA, 2001).

Carry out a detailed review of written and/or verbal historical information. While much of this information may not exist, collect as much data as possible. If sufficient data is lacking, collect it through the site inspection and additional testing.

Past project design documents and construction records such as QC data and inspection reports are helpful. Other useful information includes data collected since the construction of the road/airfield such as the types of maintenance performed and documentation of observed performance problems. Surface treatments are particularly important as they have a high asphalt binder content to account for in the new mix design.

The following is information and techniques useful in evaluating the composition and condition of a pavement structure.

a. General information.

- Thickness of HMA layers
- Moisture problems such as delamination, poor bond, and stripped aggregates
- Asphalt binder properties in HMA layers
- Maximum aggregate size
- Presence of paving fabric
- Presence of special mixes such as porous friction course (PFC), open graded, or stone matrix asphalt (SMA).
- Patch location and age
- Patch materials (e.g., HMA, cold mix asphalt, injection spray patching)
- Crack seal material type and ages
- QC/QA information, including:
    - Asphalt binder content
    - Aggregate gradation, angularity, flat/elongated particles and/or petrographic analysis
    - Voids total mix (VTM), voids in mineral aggregates (VMA), voids filled with asphalt (VFA)
    - Field compaction
    - Recovered asphalt binder properties

b. Pavement performance curves or data that indicates the rate of pavement deterioration

c. Visual inspection of the pavement conducted by an experienced person. Verify the following information:

- Type and severity of the surface and structural distresses (localized or generalized problems)
- Segments with similar problems
- Identification of localized problems that may need special treatment
- Segments that need correction of the surface profiles
- Presence of manholes or similar structures
- Characteristics of the shoulders
- Adequate area to stage construction equipment

d. Non-destructive deflection testing (NDT) evaluation to identify limits of sections with relatively uniform support. It is important to know if the pavement has structural capacity to support the CIR construction equipment and to verify the design for repair. Conduct destructive evaluation on pavement having special problems or to obtain samples for laboratory testing.

e. Obtain representative RAP samples using random sampling techniques for adequate CIR mixture design. Take sufficient cores to provide material for the testing described in the mix design section.

f. Core samples are typically 6 inches (150 mm) in diameter. The number of samples depends upon the size of the project. Large projects, greater than 4 miles (6.4 km) long, require at least two samples per lane-mile (1.6 lane-km) with a minimum of six samples per project. Additional cores may be required to provide enough material for mix design. Small projects require at least eight samples per mile (1.6 km) or one per block if the pavement is not homogeneous (ARRA, 2001; FHWA, 1997).

3-4.2.2 Identifying Distress Causes.

Identifying distresses and their likely causes during the visual inspection is mandatory to identify all root causes to consider in the decision-making process. For example, rutting on the pavement surface may be caused by a number of factors including but not limited to weak subgrade or an unstable mixture. The repair for rutting in asphalt layers is much different from repairing rutting in the underlying layers.

3-4.2.3 Analysis of Road/Airfield Profile/Geometric Assessment.

Analysis of the road or airfield pavement profile and a geometric assessment is of paramount importance to determine project requirements, including the following:

- Major realignment, widening or drainage corrections
- Special consideration for underground utilities and drainage structures

- Attention to bridges and overpasses. Evaluate structural capacity to determine if they provide adequate support of construction equipment
- Longitudinal grade corrections
- Corrections for cross slope and fall

These analyses assist in evaluating whether the project is a good candidate for recycling or other alternatives.

In urban areas, check whether construction equipment can maneuver onto or exit the construction site.

In general, correct small problems with longitudinal/transverse profiles during the paving process. If these defects are serious, consider the following alternatives:

- Use CM to correct profile deficiencies if the road or airfield HMA pavement has adequate thickness
- Use additional granular material or RAP to correct profile
- Correct during CIR and add a leveling course or HMA overlay

3-4.2.4 Selection of Best Materials and Methods.

It is essential to know the properties of the existing in-place materials before selecting the best new materials to add. The mix design topic discusses how to evaluate material properties.

3-4.2.5 Traffic Assessment.

For an existing pavement, historical traffic data can be used to assess remaining structural life as well as the effect of construction quality on the adequacy of the original design. For new pavements, the designer develops a forecast of future traffic to support the selection of layer materials and compute individual layer thicknesses within the optimized design solution.

3-4.2.6 Layer thicknesses.

Results of coring and other tests such as GPR and NDT can provide the layer information needed to verify the appropriateness of recycling alternatives and indicate the depth of any pavement problems that must be addressed. This information, in turn, may determine acceptable recycling alternatives.

3-4.2.7 Friction.

Friction test results and texture depth data provide information about the friction characteristics of the pavement surface. Steps to improve friction require modifications to the pavement surface. Friction is a surface issue and the repair for low friction does not require significant modification below the pavement surface. Techniques used to address friction problems include HIR, HR, or an HMA overlay. Temporarily solve friction problems using CM to improve the surface texture. Do not allow aircraft to operate on milled pavement surface due to potential FOD damage to aircraft engines and tires. If it cannot be avoided, vehicular traffic may be allowed on milled roadway pavements for a short duration, with adequate traffic control to reduce safety concerns due to loose aggregate, vehicle damage, and noise.

3-4.2.8 Roughness.

Evaluate roughness from test results and from PCI survey distress data. Correct roughness in the surface layer caused by segregation, raveling and rutting using recycling strategies such as HIR, HR, and CM with an HMA overlay. Roughness from subsurface layers will require more extensive forms of recycling including CM with HMA overlay, HR, CIR, cold central plant recycling (CCPR), and FDR.

3-4.2.9 Drainage.

A drainage survey and evaluation can identify excessive moisture, the sources of moisture, and the affected pavement layers and materials (Grogg et al., 2001). Surface drainage issues are suitable for treatment by recycling strategies that target the surface layer. However, if the effects are deeper in the structure, more extensive recycling or drainage retrofitting may be necessary. Subdrainage improvement may involve installing or replacing longitudinal edge drains and lateral outlets or daylighting a base layer by replacing base material under shoulders with better draining material (Hall et al., 2001).

3-5 STRUCTURAL DESIGN.

Structural design of airfield and roadway pavements is accomplished by engineering analysis of test results and material properties to develop pavement rehabilitation alternatives to support intended traffic over an established design period. Design of flexible and rigid pavements can be accomplished using layered elastic or mechanistic design methods. NDT is conducted to estimate pavement layer and subgrade elastic properties. DCP testing can be used to estimate mechanistic properties such as CBR or k-value. Load transfer efficiency across joints and cracks and the presence of voids under slab corners and edges may assist the designer in developing rigid pavement design alternatives.

Structural pavement design for pavement rehabilitation alternatives using recycling technologies is the same as those for ordinary pavements.

3-5.1 Structural Design for Roads.

The primary structural design tool for DoD roadway pavements is the Pavement-Transportation Computer Assisted Structural Engineering (PCASE) computer program. PCASE performs flexible and rigid pavement design for roads using mechanistic or layered elastic methods. The equivalency factors for use in designing pavements using recycling technologies are provided below.

3-5.2 Structural Design for Airfields.

PCASE is also the primary structural design tool used for DoD airfield pavements. PCASE performs flexible and rigid pavement design for airfields using mechanistic or layered elastic methods. The equivalency factors for use in designing pavements using recycling technologies are provided below.

PCASE Web Site - http://www.pcase.com

PCASE Computer Based Training – http://www.pcase.com/cbt/

Tri-Service Transportation Web Site – http://www.triservicetransportation.com

3-5.3 CBR Design Method.

The CBR design method is detailed in UFC 3-260-02 and UFC 3-250-01. The CBR design method is automated within PCASE. In the CBR method, the thickness and strength of each layer must protect the layers below. PCASE estimates layer thicknesses for conventional flexible pavements. In the case of stabilized layers, modify the layer thickness by using equivalency factors, such as those shown in Table 3-1, which have been developed based on research and field experience.

Design the pavement structure using the equivalency factors shown in Table 3-1 for recycled layers. If the aggregates to be recycled are angular, according to appropriate specifications, then the recycled material can be used for base course. Otherwise, the material can only be used for subbase. Typically, the recycling techniques shown in Table 3-1 are for base material and require a minimum thickness of HMA as a surface course. Low volume roads may use bituminous surface treatment as the wearing surface.

3-5.4 Layered Elastic Design of Airfield Pavements.

The layered elastic design method can be used for the structural design of DoD airfield pavements and is detailed in UFC 3-260-02. The layered elastic design method is automated within PCASE. In this method, failure is defined as excessive tensile strain at the bottom of the HMA layer or excessive compressive strain at the top of the subgrade. Stresses, strains and deflections are computed assuming elastic properties in each pavement layer. The following assumptions apply:

- The pavement is a multilayered structure.
- Each layer is described by its thickness, modulus of elasticity and Poison's ratio.
- The interface between layers is continuous. In other words, the friction resistance between layers is greater than the developed shear force.
- The subgrade is modeled as a homogeneous, isotropic, elastic half-space.
- All loads are static, circular and uniform over the contact area.

Table 3-1 Granular Base Equivalent Factors

Recycling Technique	Equivalency Factor	
	Base	Subbase
HMA (including HR and HIR)	1.15	2.30
Crushed aggregate base	1.00	2.00
Uncrushed aggregate subbase	---	1.00
Pulverized/crushed RAP blended granular base	1.00	2.00
CIR, CCPR, and FDR (asphalt/cement stabilized)	1.00	2.00
Rubblized portland cement concrete	1.00	2.00

3-5.5 Recommendations for Pavement Design.

The following recommendations are for the CBR method of design when using PCASE:

- Use the appropriate equivalency factors shown in Table 3-1.
- Only use uncrushed aggregate as subbase.

3-6 DETAILED DESIGN OF RECYCLING STRATEGIES.

Evaluate feasible recycling strategies by establishing the specific details for each strategy in terms of the pavement cross-section and the engineering properties of the recycled and new surface layers. These details dictate the quantity of material required, the scheduling of work tasks, and the future M&R requirements.

Formulating a detailed design requires considering the needs and constraints of the project. The needs define the service life of the recycled pavement, including the potential levels of future M&R. The constraints pertain to the available funds for the recycling work and to a variety of construction considerations. A discussion of how these items affect the recycling design strategies follows.

3-6.1 Performance Requirements.

Available funding often controls the selected technique and the expected life of a recycling project. The condition of the existing pavement also affects the expected life.

Selecting and designing the recycling strategies to achieve the desired design life follows one of two approaches. In the first, if sufficient performance data exists for a particular recycling strategy and the data are representative of projects with similar conditions (traffic, climatic, etc.), use the data to formulate a design that achieves the design life requirement. In the second approach, make certain assumptions about the strength and durability of the recycled layer and any surface layer. Then, coupled with an understanding of the strength of the underlying subgrade, subbase, and base layers, determine the thickness of the recycled layer and surface layer in relation to climatic properties and the projected design traffic. Utilize as much confirmed engineering data regarding the subgrade and underlying layers as possible.

Although substantial performance data exist for recycled materials on specific projects, predominantly for highway pavements, nationwide performance data is not available.

Recognizing that actual performance largely depends on project conditions, facility type, projected traffic, climate, recycling design details, and the quality of materials and workmanship, the ranges of expected mean service life are as follows (Sullivan, 1996; ARRA, 2001; Grogg et al., 2001; FHWA, 2005):

- HR: 9 to 16 years (HR mix generally accepted as having the same performance as new HMA)
- HIR-I only: 3 to 5 years
- HIR-I with surface layer: 6 to 10 years
- HIR-II only: 7 to 14 years
- HIR-II with surface layer: 7 to 15 years
- HIR-III: 6 to 15 years
- CIR with surface layer: 5 to 15 years
- CCPR with surface layer: 7 to 15 years
- Break/crack-and-seat with HMA overlay: 8 to 12 years
- Rubblization and HMA overlay: 15 to 20+ years
- Recycled concrete aggregate (RCA) PCC: 15 to 20+ years

Mean service life differs from design life. Mean service life represents the timeframe over which a pavement has a 50-percent probability of providing acceptable service under the conditions (traffic, environment) in which it must function. Acceptable service is generally defined as PCI>70 for Primary pavements and PCI>65 for Secondary pavements. Design life represents the timeframe over which a pavement is structurally designed to serve based on a specified degree of reliability (typically, between 80 and 95 percent probability of providing acceptable service). Hence, a 10-year design life using 90-percent reliability will likely yield a mean service life of 12 or more years.

3-6.2 Future M&R Requirements.

Pavement facilities requiring minimal disruption to traffic and thus minimal numbers and durations of M&R require enhanced designs for some recycling strategies. For instance, the addition of chemical additives such as cement, lime, or fly ash and increasing proportions of virgin HMA or aggregate will achieve stronger and more durable recycled asphalt material. Increasing the thickness of surface layers will generally extend the life of the recycling technology.

3-6.3 Pavement Cross-Section.

For HMA pavements, the presence of a concrete layer, stress absorbing membrane interlayer (SAMI), paving fabric, rubber modifier, and other distinct paving layers can dictate the maximum depth of recycling. Likewise, the total thickness of asphalt bound layers and the depth to which distortions such as rutting, depressions, or swells exist in the pavement profile also influences recycling depth. A limited recycling depth may require thick recycled base and surface layers or greater proportions of virgin materials to achieve the intended design life.

For concrete pavements, rubblization requires a thicker HMA overlay compared to crack/break-and-seat. This is due to the fact that rubblization destroys any capability of the PCC to function as a slab and effectively converts the PCC layer into a high-quality aggregate base. Crack/break-and-seat, on the other hand, reduces the length of the slab, but still allows the remaining pieces of PCC to provide structural support to the pavement system.

3-6.4 Construction and Materials Quality.

Variability in the mix properties of recycled HMA may preclude the use of certain recycling techniques such as in-place recycling on high-quality pavements. Variability of recycled HMA may also require thicker base and surface layers or greater proportions of virgin materials to create a durable pavement that will meet the intended design life. For concrete pavements, the extent and severity of D-cracking or ASR may preclude the use of any recycling technique or may require a thick HMA overlay over fractured PCC. Any ASR will preclude the use of RCA techniques on most airfield pavements.

3-6.5 Maintenance.

The presence of previous M&R treatments including chip seal, surface seal, crack/joint sealant, machine patches, or other materials may influence the detailed design of a recycling strategy. Some technologies may require additional work to remove a previously applied surface treatment prior to recycling. In other cases, special design measures may be used to accommodate the mix properties of these treatments.

3-6.6 Project Size and Location.

Occasionally, the size and location of a project provides a cost advantage to one recycling techniques over others. For example, on a significantly large project, the mobilization of in-place recycling equipment or on-site recycling plants may be more cost-effective than a central-plant setup. Do not discard more expensive recycling strategies too quickly; rather, develop detailed designs and perform LCCA to evaluate and compare alternatives.

3-6.7 Project Geometrics.

If vertical alignment is constrained to the existing surface grade, some recycling strategies are not practical. The same is true if overhead clearances severely restrict building up the cross-section and/or if subsurface clearances limit recycling depths. Recycling strategies must account for these types of constraints and satisfy the performance goals.

Slab fracturing techniques, including cracking or breaking and seating, are a cause for concern in situations where buried utilities, like sewer and water lines, are near the surface. The concentrated impact force induced by the drop hammer poses a much greater threat of damage to utilities compared to the distributed impact forces associated with rubblization.

Another consideration for overhead clearances is the ability of recycling equipment and haul trucks to pass under such features and the ability of recycling equipment to effectively operate next to lateral constraints (e.g., buildings, hangars, barrier walls, straight-faced curbs) and around sharp curves or in tight settings (e.g., short perpendicular taxiways, roadway intersections).

3-6.8 Construction Time Requirements.

Pavement facilities with high-type functional uses and/or high levels of traffic often limit the duration of construction activities. Such limitations may preclude certain recycling strategies and influence the adoption of other strategies and their associated operations (e.g., in-place recycling, on-site plants, multiple recycling trains, night work). For instance, because the depth of the recycled layer and the type of asphalt emulsion influences the length of time required for the asphalt emulsion to break, CIR may not be feasible or may require thin recycled layers to meet a compressed schedule. Proprietary “engineered emulsions” offer reduced break/cure time and can be compacted immediately following mixing.

3-6.9 Availability of Local Resources.

The equipment and technology base for most recycling techniques is common throughout the U.S. However, in less populated areas, locally experienced and properly equipped contractors may be limited. Further, the availability of local good-quality aggregates for use in recycled mixes and/or surfacing mixes may also be limited. For projects facing these limitations, eliminate the affected recycling strategies from consideration or properly account for them in the detailed design process.

3-6.10 Structural Capacity.

Recycling often involves removing or reprocessing an existing HMA layer, which may reduce the structural capacity of the pavement system to a low enough level where the remaining layers are no longer able to support construction equipment. Similarly, the remaining layers must provide sufficient platform stiffness during construction to allow the recycled layer to be compacted. The most critical elements in determining the maximum recycling depth and formulating a detailed design are:

(a) Thickness and condition of the non-recycled portion of asphalt bound layers.

(b) Thickness and strength of underlying unbound base and subbase layers.

(c) Subgrade strength.

(d) Anticipated loading characteristics of the construction equipment.

3-6.11 Traffic Accommodation.

In some cases, the project layout is more conducive to certain recycling techniques in terms of accommodating traffic during construction and providing better overall safety.

3-7 SELECTING THE PREFERRED REHABILITATION STRATEGY.

The LCCA procedure described in UFC 3-270-08 represents a traditional approach to life cycle costing. The procedure makes use of the NPW economic formula, an analysis period of between 10 and 30 years, a set discount rate, and a deterministic computational approach. To ensure that alternative pavements are of equal value at the end of the analysis period, compute the cost to rehabilitate the pavement for each alternative. A more commonly used approach to account for value differences in the competing pavement alternatives at the end of the analysis period computes salvage value in terms of the remaining service life of the final pavement structure.

CHAPTER 4 COLD RECYCLING FOR ASPHALT SURFACED PAVEMENTS

4-1 INTRODUCTION.

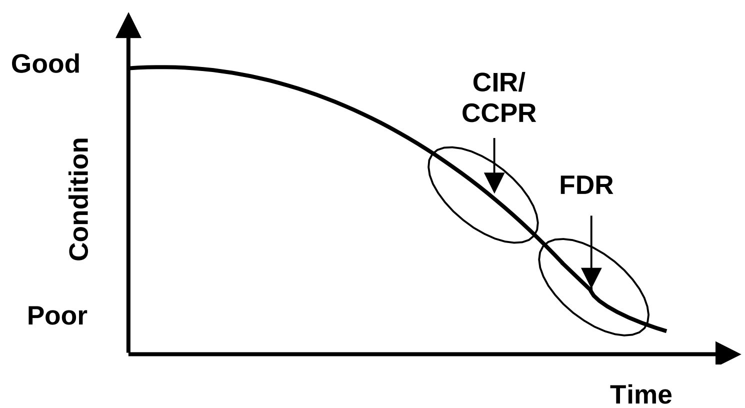
Cold mix recycling involves reusing existing pavement by reprocessing and adding asphalt binder at ambient temperatures. This chapter discusses the application of the three types of recycled cold mix: CIR, CCPR and FDR.

Cold mix recycling takes advantage of chemical additives such as cement, lime or fly ash to increase the early strength and resistance to moisture of the new mixture. Alternative additives include cutback asphalt, foamed asphalt, asphalt emulsion, and a combination of emulsion with cement, fly ash, or lime.

CIR and CCPR are generally used to correct pavements with functional distresses and provide minor strengthening. FDR is appropriate when major structural rehabilitation is required.

Figure 4-1 shows when it is advisable to use CIR/CCPR or FDR in the typical pavement life cycle.

Figure 4-1 Indication of CIR/CCPR or FDR as a Function of Pavement Life



4-2 COLD IN-PLACE RECYCLING.

4-2.1 Introduction.

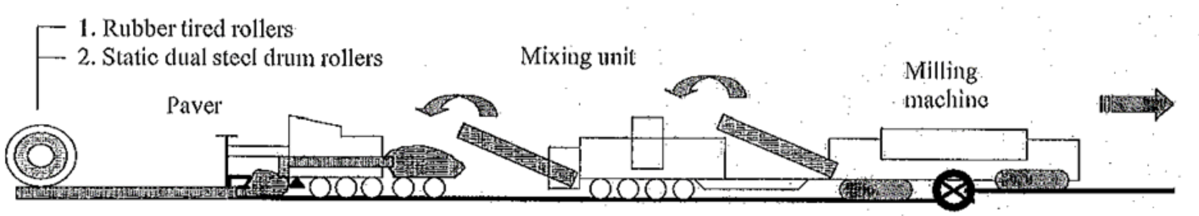
CIR is a partial-depth pavement recycling process. Remove some HMA pavement by milling 2 to 4 inches (50 to 100 mm). CIR creates a layer of material to serve as base course, but it sometimes serves as the surface course on highways with low to medium traffic volume. For example, CIR can be used as the surface for secondary roads if a surface treatment is applied.

CIR is a good technique to rehabilitate thick HMA pavements exhibiting cracks, rutting, shoving, raveling, potholes, bleeding, poor skid resistance, corrugations, fatigue, block cracking, slippage, longitudinal and transverse cracking, reflection cracking, and poor ride quality. However, it requires underlying layers and the drainage system to be in good condition.

CIR can increase pavement strength when placed with an HMA overlay on the recycled material for additional pavement thickness and to provide a higher quality surface.

CIR transforms a distressed pavement into one similar to a new pavement. The CIR process uses special equipment similar to that depicted in Figure 4-2. Ensure the equipment can mill deteriorated pavement and convey the RAP into a unit that crushes the RAP, sizes the RAP, and blends the material into a homogenous mixture. The mixing unit adds asphalt binder and water to the RAP and blends before feeding the mix into the paver hopper. The paver places the recycled mixture at the desired thickness and grade. Vibratory and rubber-tired rollers compact the mix. Cover the CIR with an HMA overlay or surface treatment to provide a smooth riding surface and protect the mixture from water and traffic. When used on airfields, ensure the thickness of the HMA over the CIR meets the minimum HMA thickness required over a crushed granular base course.

Figure 4-2 CIR Recycling Train*



*Source: Hajek et al, 2005.

4-2.2 Past and Current Use.

Mixtures similar to CIR have been used for over 50 years (Bardesi, 2000). Cold recycling has become more common since the 1990s due to technological advances in pavement and material engineering.

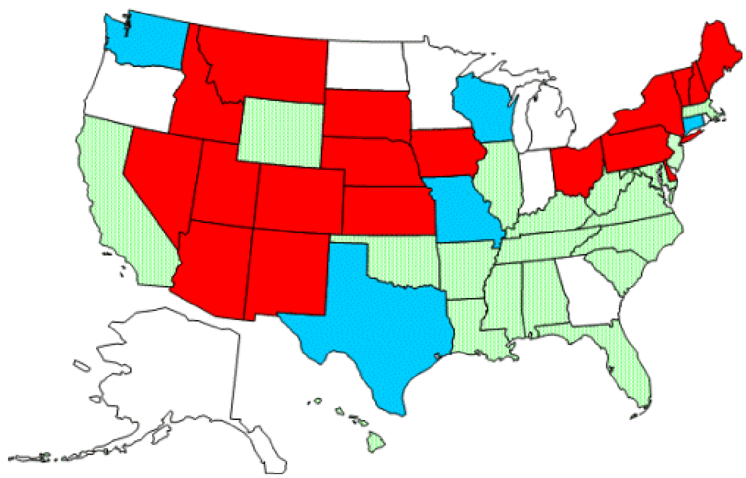
In the past, CIR was used on roads with low to medium traffic volume. Currently, there is no limit to using CIR on high traffic volume roads or as base course material for airfields when properly designed and constructed.

State DOTs have placed millions of square yards of CIR since the 1970s. The main reasons to use of CIR are to correct premature full depth thermal cracking that causes poor ride quality or to address fatigue cracking, rutting, and asphalt stripping problems. A surface treatment or an HMA overlay is used as a surface on most CIR projects.

Asphalt recycling grew rapidly after the early 2000s as highway agencies looked for significant cost savings in highway rehabilitation as well as methods that reduce emissions during construction.

Figure 4-3 shows Federal Highway Administration research on CIR use in the United States (FHWA, 2007). Eighteen states (red) extensively used CIR, five states (blue) reported low use, nineteen states (green) had no use and six states (white) did not respond.

Figure 4-3 Use of CIR in the United States*



*Source: FHWA, 2007.

4-2.3 Guidelines for Use of CIR.

4-2.3.1 Primary Purpose.

CIR is a technology that transforms HMA surfaces into asphalt base material, restores a profile or cross-slope and mitigates surface distresses prior to receiving an HMA overlay or surface treatment. In general, potential projects for CIR are pavements with fatigue cracking, permanent deformation, and surface roughness.

Corrective actions may be necessary for rough or distorted pavement or for flushed pavement. When the pavement is rough, the CIR process may require cold milling (CM) before the CIR operation. When the pavement surface is flushed or is bleeding, adding virgin aggregates may reduce the propensity of the flushing to exist in the CIR mixture.

4-2.3.2 Advantages and Disadvantages.

The main advantages of CIR are as follows:

- Reduced environmental impact due to reduced demand for virgin asphalt binder and aggregates.

- Energy savings compared to other construction techniques.
- Fewer vehicles transporting material at the site. Reduced traffic damage to the pavement when compared to conventional rehabilitation techniques.
- Significant savings compared with conventional rehabilitation techniques.
- Capability to correct surface roughness and reducing cracking.
- Capability to correct surface characteristics such as rutting, potholes, shoving, bleeding and raveling.
- No interference or disturbance of base, subbase and subgrade materials.
- Capability to adjust the mixture by adding virgin aggregates or recycling agent.
- Improved surface ride quality.

The main disadvantages of CIR are as follows:

- Not all materials are economically recycled.
- CIR cannot solve problems associated with layers other than the surface.
- CIR requires a curing period to gain strength and it cannot open immediately to traffic after construction.
- This technology does not apply to projects that require nighttime work in some regions due to temperature limitations and moisture conditions.
- The presence of paving fabric in the existing pavement presents some limitations on the use of CIR.
- CIR is not applicable to pavements with poor drainage or weak base support.

4-2.3.3 Mix Design.

Before starting a mix design, ensure all samples are broken into small particle sizes to simulate RAP during milling operations. Use a small laboratory crusher to crush the RAP in the laboratory to produce a gradation similar to that during actual construction.

There is no nationally accepted cold mix recycling design method. An adaptation of the Marshall Design method (Modified Marshall, Method A) is the method used by most agencies (ARRA, 2001; FHWA, 1997; Asphalt Institute, 2002). Determine the amount of virgin asphalt binder needed in the recycled cold mix by conducting a conventional HMA mix design on the RAP obtained during sampling prior to start of construction.

4-2.3.3.1 Trial Mixes, Curing Time and Job Mix Formula (JMF).

Prior to starting the mix design process, crush the recovered asphalt mix to produce a gradation similar to that expected with the milling machine. Compact the sample at 50 blows per face for low-pressure tires or 75 blows per face for high-pressure tires such as airfields and heavy-duty roads. Equivalent gyratory compaction is permissible.

The main parameters sought are density, stability, flow, voids in the total mixture, and voids filled with asphalt. Plotting these parameters versus asphalt content assists the designer in identifying the optimum asphalt content for the mixture. The optimum additional asphalt is often between 0 and 3%. Do not add additional asphalt if the optimum value is 0% or lower. In this case, only add water to lubricate the mixture so that the expected maximum dry density is achievable in the field. In fact, if the laboratory air voids are too low (below approximately 3 percent), add virgin aggregate to increase the air voids in the mixture to an acceptable level.

In summary, the mix design method consists of:

- Obtain samples of the HMA pavement. Remove samples equal to the depth of milling expected during construction. Crush RAP in the lab to approach the expected gradation of RAP during the milling operation.
- If new aggregate is added, determine the percentage of virgin aggregate to add.
- To determine the percentage of asphalt that provides 3.5 to 4% air voids, design as a hot mix, adding the RAP, virgin aggregate and varying the asphalt emulsion content. The heating process removes the moisture in the mix since this is designed using HMA procedures.
- Once the optimum emulsion content is determined, add the emulsion to the RAP then vary the moisture content in 0.5 percent increments from 0 percent to 2.5 percent. Determine the optimum moisture content by adding moisture in 0.5 percent increments to the cold mix and compacting using 50 blows with the Marshall hammer to determine the optimum additional moisture content to provide maximum dry density. Determine optimum moisture content at room temperature.
- Cure the compacted mixture for 96 hours at 140 ºF (60 ºC).
- Remove the samples from the oven and cool to room temperature. Test the specimens for bulk specific gravity. Then reheat to 140 ºF (60 ºC) and determine Marshall stability and flow.

Table 4-1 shows the mix design parameters recommended by UFGS 32 01 16.70.

Table 4-1 Recommended CIR Mix Parameters[1]

Parameter	**Requirement 50 Blows**
Voids in total mix (%)	3-5
Voids filled with asphalt (%)	75-85

[1]UFGS 32 01 16.70.

4-2.3.3.2 Evaluation of Existing Salvage Material through Lab Analysis of Field Samples.

- RAP Properties: Determine RAP gradation using ASTM C136 *Standard Test Method for Sieve Analysis of Fine and Coarse Aggregate.*
- Extracted Aggregate: Obtain the extracted aggregate after removing the asphalt binder from the mixture using one of the asphalt extraction tests (ASTM D6307 or ASTM D2172).

4-2.3.3.3 Determining Amount of Virgin Aggregate.

Evaluation studies of existing material are very important for determining the adequate amount of virgin aggregate. The gradation of the aggregate recovered from the RAP may be unsatisfactory or the recovered aggregate quality may not be acceptable. This may require adding virgin coarse or fine aggregate. The majority of CIR projects do not add virgin aggregate.

There are two primary cases that require the addition of virgin aggregates: 1) excess asphalt binder content in the RAP or 2) poor aggregate quality of the RAP. In both cases, the addition of virgin aggregate allows minor adjustments to the RAP mixture to address these deficiencies.

4-2.3.3.4 Asphalt Emulsion.

Most projects use asphalt emulsion to introduce additional asphalt binder to a CIR mixture. In this case, the small amount of additional asphalt binder does not significantly modify the properties of the existing asphalt binder, but serves as additional asphalt to fill voids and improve cohesion. On the other hand, a recycling agent tends to mix and soften the oxidized binder to improve the overall binder properties. A potential problem with adding a recycling agent is incomplete mixing with the other components, which results in uneven distribution of the recycling agent in the mix. The result is that one portion of the mix may become too soft and another portion too brittle. Thoroughly blend all mixture components.

Important specifications for asphalt emulsions for cold-mix recycling are ASTM D5297 for anionic asphalt and ASTM D2396 for cationic asphalt emulsions. Most cold mixes use anionic emulsions. Use cationic asphalt emulsions if past experience with cationic emulsions has been successful.

The grades of asphalt emulsion most commonly used are MS, HFMS, and SS.

- Medium-Setting (MS): designed for mixing with open or coarse-graded aggregate. Because they do not break immediately, mixes with medium-setting emulsions keep their workability for a significant amount of time.
- High Float Medium-Setting (HFMS): designed for mixes that work at high temperatures, which allows better aggregate coating and asphalt retention.

- Slow-Setting (SS): these emulsions are generally more stable. Asphalt droplets in a slow-setting asphalt emulsion stay in suspension in the water for a longer period of time and over a wider range of temperatures, which results in fewer construction problems.

4-2.3.3.5 Recycling Agent.

Recycling agents are used in CIR mixes to improve the properties of the asphalt binder. The oxidized asphalt binder in old HMA mixtures benefits from the use of recycling agents. The recycling agent tends to soften the asphalt binder, resulting in improved properties. If experience shows success with the recycling agents, use it in place of asphalt emulsion. Specify asphalt recycling agents using ASTM D5505.

4-2.3.3.6 Moisture in Mix.

Moisture is necessary to facilitate mixing, handling, and the compaction process. RAP may contain enough free moisture so that adding water is unnecessary. Add water before adding recycling additives to lubricate and promote cooling of the cutting head. If using a pugmill, add water simultaneously with the recycling additive. Slow-setting asphalt emulsions and the anionic grades of medium-setting asphalt emulsions require moisture to promote adequate coating during mixing process. High float emulsions and cationic medium-setting asphalt emulsions may contain petroleum distillates and require less moisture to provide good workability and compaction.

Conduct coating tests for any type of asphalt binder additive used to verify if the mixing water is adequate to disperse the additive. It is a very simple test that requires 2.2 pounds (1000 g) of RAP with the estimated initial amount of recycling additive. Test different samples with 0.5% increments of water. Add water and mix briefly (maximum of 30 seconds) to humidify the RAP. Incorporate the recycling additive and blend the mixture for 2 additional minutes. Perform this test manually, because it is easier to observe mix workability and coating. Visually evaluate and select the dispersion and the lowest moisture content that results in no additional increase in coating. The total liquid content (sum of the mix water content + recycling additive + moisture of the RAP) is different for each project and is determined during the mix design.

4-2.3.4 Structural Design.

Chapter 3 provides a general overview of structural design and its application to pavement recycling. One concern in the structural design of a pavement using CIR mixtures is the difficulty in characterizing the mixture sufficiently for use in the CBR method or layered elastic design method. Information required for design includes the equivalency factor for CIR and the modulus and thickness of the CIR layers. Chapter 3 provides this information.

4-2.3.5 Construction.

4-2.3.5.1 Types of Equipment.

The CIR train consists of a cold milling machine capable of reclaiming old asphalt pavement to depths of 2 to 6 inches (50 to 150 mm). The equipment for CIR is available in different configurations: single machine (single-unit train), two-unit train and multi-unit train. Use the same compaction equipment as used for HMA.

4-2.3.5.2 Single Machine (Single-Unit Train).

The milling machine of the single-unit train cuts the old pavement to a specified depth, providing the desired profile grade and transverse slope. The equipment separates the RAP into sizes and mixes the RAP with asphalt emulsion or recycling agent. Figure 4-4 shows one example of these machines.

Figure 4-4 Single Machine*

*Source: Roadtec, https://www.roadtec.com/

- Simple operation.
- High production capacity.
- Good for operation in urban areas and roads with small turning radius.

One disadvantage of the single machine is its lack of control of oversize RAP aggregate. The operator is unable to control the exact amount of material and is unable to control minimal mix times. Since the single-unit train lacks screening and crushing units, the operator likely will have difficulty controlling the maximum particle size. Old pavement with serious fatigue cracking exacerbates this limitation. Do not use the single unit train for pavements that present edge drop-off and severe distortion caused by rut depth because the application rate of recycling additive cannot be controlled. Base the amount of additive on the volume of material considered and it depends on the cutting depths and widths as well as the previously estimated speed for the machine operation.

If the mix design recommends incorporating aggregates or dry additives, such as lime or cement, spread the additives on the pavement prior to milling.

4-2.3.5.3 Two-Unit Train.

The two-unit train has an advantage when compared to the single machine, namely, it allows precise control of liquid additives in the RAP. Control of liquid additives is based on weight rather than the volume of material or speed.

The two-unit train incorporates pugmill mix pavers in the system and is able to mill a full lane wide. An example of this machine is in Figure 4-5.

Like the single-unit train, the two-unit train is able to work in urban areas and on roads with short turning radii. The primary disadvantage is its lack of crushing and screening units which means this type of equipment is not able to control aggregate oversize. Simple operation and high production capacity are the main advantages when compared with the multi-unit train.

The two-unit train removes the RAP with the milling machine and deposits the mix into the pugmill of the mix paver. The pugmill has a feeder belt with a scale and a computer system estimates the weight of the liquid recycling additive to incorporate into the mix.

CIR is a process of milling a portion of existing pavement to a specified depth, screening and crushing the reclaimed material to comply with specifications, incorporating aggregates, mixing additives and water, spreading and compacting the mixture. Typically, the maximum particle size ranges from 1 to 1.5 inches (25 to 37.5 mm) (Hajek et al, 2005).

Do not operate during rainfall. In addition, ensure the ambient temperature is at least 50 ºF (10 ºC) and freezing temperatures are not expected for at least 5 days. In general, the warmer the weather, the better the final properties of the CIR mixture.

Figure 4-5 Two-Unit Train*

*Source: Lee and Kim, 2007.

4-2.3.5.4 Multiple-Unit Train.

The multiple-unit train, as indicated in Figure 4-6, has the highest degree of quality control and productivity of CIR. The multi-unit train produces as much as 2 lane miles/day (3.2 lane km/day). The sequence of the multi-unit train operation is as follows (ARRA, 2015):

- Mill the pavement to the design depth and slope with a milling machine.
- The milling machine can work with the “down cutting mode”, which produces finer RAP aggregates or with the “up cutting mode”, which allows higher working capacity. The down cutting mode should reduce the chance for scabbing during the milling operation.
- The RAP is screened and oversized material is sent to a crushing unit.
- The crushed material is sent back to the screening unit.
- An aperture below the screens controls the maximum RAP size.
- After passing through the screening and crushing unit the RAP goes to the pugmill mixer.
- The belt that transports the RAP has a scale that controls the weight of the RAP that goes into the pugmill.
- A computerized system controls the amount of liquid recycling additive, based on the weight of the material estimated by the belt scale.
- A pump equipped with a meter device indicates the flow rate and the amount of liquid recycling additive incorporated in the pugmill
- The pugmill thoroughly mixes the RAP with liquid recycling additive or asphalt emulsion.
- The mixture is conveyed to a windrow or paver hopper.
- A windrow elevator takes the mix from the windrow and feeds it to a conventional HMA paving machine.

Figure 4-6 Multiple-Unit Train*

*Source: Ken, 2008.

The main advantages of the multi-unit train are:

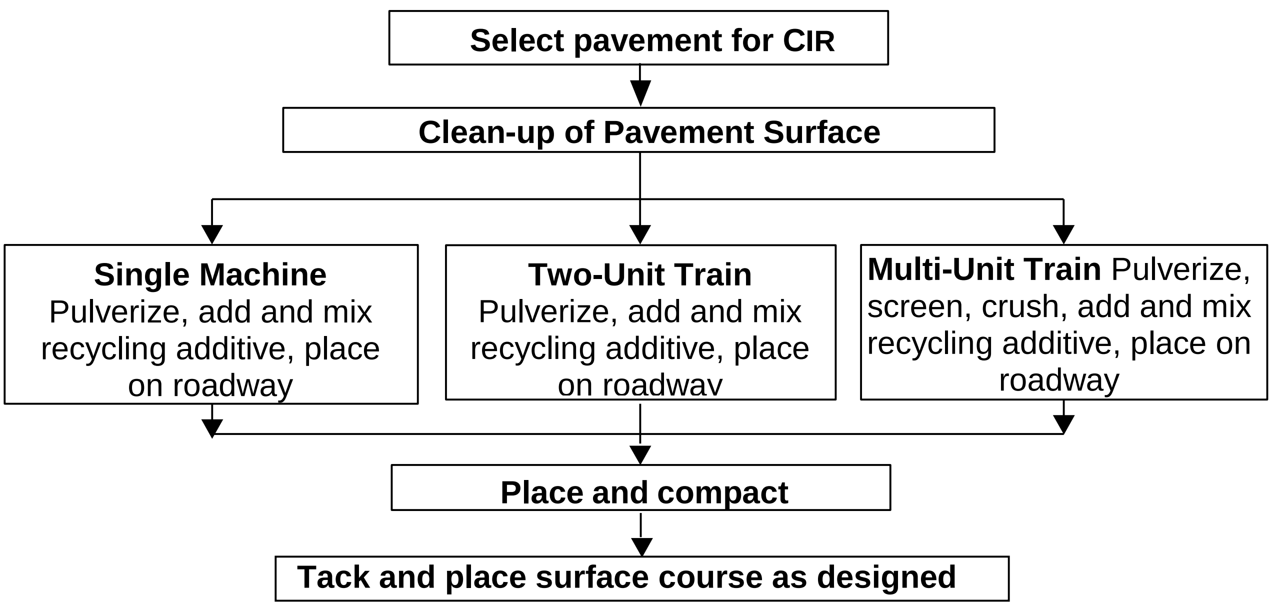
- high productivity.
- high quality control process.

The main disadvantages are:

- length of the train.
- It is not suited for urban areas or roads that have no room for maneuvering.

Figure 4-7 presents an abbreviated summary of the CIR construction process for the three types of equipment configurations.

Figure 4-7 CIR Construction Process*



*Source: ARRA, 2001.

4-2.3.5.5 Technical Aspects on CIR Construction.

Some additional technical aspects are necessary during CIR construction.

a. Clean-Up of Pavement Surface. Inspect the pavement surface before recycling operations begin to clear vegetation and debris across the pavement and shoulders.

b. Cold Milling Process. Mill existing pavement to a pre-defined depth and width in one pass. The cold-milling machine removes a portion of the existing HMA layer, typically between 2 and 6 inches (50 and 150 mm) deep, always leaving at least 1 inch (25 mm) of HMA in place.

Generally, the particle size of the removed material is satisfactory for recycling and no further crushing is necessary.

c. Placement of the Recycled Material. Place and finish recycled material in one continuous pass, without segregation. Compact material in minimum 2 inches (50 mm) thick and no more than 4 inches (100 mm) thick. Increase the upper limit to 6 inches (150 mm) when required to place more than 4 inches in one pass, but only if the contractor has suitable equipment to place and compact this thicker layer.

Begin by spreading the material along the centerline of areas paved on a crowned section or on the high side of areas with one-way slope, always in the primary direction of traffic flow. Pavements surrounding curbs, manholes and other structures may need special attention.

d. Field Adjustments of the Mix. Adjust the job mix formula (JMF)in the field to take into consideration the gradation of the RAP. Modification of the percentage of additives and water may improve the aggregate coating and mix workability. Determine the optimum amount of water. Excessive water content may flush the asphalt to the surface during the placement and compaction process. Lack of adequate water may cause mix segregation, loss of workability, raveling and poor density.

Excess asphalt emulsion or rejuvenating agent may lead to an unstable mix. On the other hand, an insufficient asphalt emulsion may cause mix raveling due to low asphalt content. A practical rule is to adjust the asphalt content by 0.2% increments. However, only an experienced technician should make adjustments to the mixture.

e. Curing. Cold mix recycled mixtures gain strength and stability with time as they cure. Factors that affect the cure time are:

- Type of emulsified asphalt
- Mix water content
- Gradation
- Layer thickness
- Ambient and mixture temperatures
- Wind velocity
- Humidity

When multiple lifts are required, allow 2 to 5 days cure time between them depending on the amount of moisture and porosity of the mixture. Ensure the water content of the recycled mixture is less than 1.5% prior to placing additional layers.

The final curing time is typically between 7 and 14 days. In general, depending on the climatic conditions, the cure period is about 2 days for each 1 inch (25 mm) of lift thickness.

f. Compaction. The objective of compaction is to achieve the desired mat density. Start compaction as soon as the emulsified asphalt breaks or when the mixture is adequately aerated. Usually the mixture starts to break between 30 minutes to 2 hours depending on ambient conditions such as temperature, wind speed, and humidity. However, if portland cement, lime or fly ash are used as recycling additives, begin rolling immediately after placement. Ensure the minimum layer thickness is no less than twice the size of the maximum aggregate particle of the RAP or aggregate. The compaction process encompasses three phases:

- Carry out breakdown rolling with vibratory roller(s). If the mix is tender and moves excessively underneath the vibratory roller, use a pneumatic tire roller. This phase of rolling continues until obtaining a tight, smooth, stable surface.
- Conduct intermediate rolling with at least 12-ton double drum vibratory steel-wheeled or pneumatic rollers preferably weighing approximately 20 tons. Achieve adequate density before completing intermediate rolling.
- Carry out finish rolling with steel-wheeled static or double-drum vibrating rollers operating in static mode to eliminate roller marks.

Use the theoretical maximum density in accordance with ASTM D2041 to establish field density and control compaction. Theoretical maximum density is the density which corresponds to zero air voids in the mixture.

Construct a test section to evaluate various combinations of rollers and monitor the process step-by-step with a density gauge to determine the relative increase in density with roller passes. Set the number of passes required to provide a density equal to or exceeding the minimum density requirements.

g. Field Density Measurements. It is very difficult to cut and remove undamaged cores from completed CIR mixtures. The longer the mixture has cured, the easier it will be to obtain good cores without damage. Alternatives to obtain samples of in-place pavement within 24 hours include:

- Ice placed on the sample locations for 1 to 2 hours before coring samples will cool the material during the coring operation, reducing the damage caused by the heat developed during this process.
- Use a concrete saw to cut small cubes from the pavement.
- Use density gages as an indication of the densities. This device does not eliminate the need to take actual pavement cores for testing later, but it will provide a reasonably good first estimate of the in-place density.

Modify rolling procedures to improve the compaction and meet the specified density requirements.

4-2.3.5.6 Surface Course.

Since CIR contains high voids in the total mix, do not use it as a wearing course. For low volume roads, use single or double bituminous surface treatment to cover the CIR. For roads with high volume traffic and for airfields, cover the CIR with an HMA overlay having thickness equal to or exceeding the minimum thickness required for HMA placed over granular base course.

4-2.4 Specifications, Quality Control, Inspection and Acceptance.

4-2.4.1 Specifications.

The specification for cold mix recycling is UFGS 32 01 16.70. This specification includes the in-place mixture and compaction requirements as well as the plant mixed cold recycling processes. It includes requirements for using asphalt emulsions as well as requirements for using asphalt recycling agents.

4-2.4.2 Quality Control/Quality Assurance.

A good QC/QA plan is a key factor for the success of a cold in-place recycling project.

Old pavement sections present great variability in aggregate gradation, asphalt content, and areas subjected to different maintenance types, etc. As a result, during the CIR process, small changes may be necessary in the rolling patterns, aggregate gradations, moisture and recycling agent content to improve performance of the resurfaced pavement. QC personnel should prepare a QC plan that accommodates changes without needing to redesign the mixture.

Follow testing requirements identified in UFGS 32 01 16.70 for the contractor QC plan. Inspect work continuously and identify any deviations from the specifications or from good standard construction practices.

4-2.4.3 Inspection and Acceptance.

4-2.4.3.1 Inspection is one of the most important steps for CIR construction. Inspection must identify problems early so that the construction process can change to correct the problem before too much CIR is constructed. Identifying problems early allows prompt resolution of construction deficiencies with less effort. However, missed problems are a bigger problem to correct later in the paving process.

4-2.4.3.2 Conduct both inspection and acceptance in accordance with specification requirements. While the specifications identify many items related to inspection, many other important items that may not be in the specifications are presented and discussed in the following paragraphs.

4-2.4.3.3 Regular meetings during construction ensure compliance with all aspects of the specifications and ensure timely implementation of necessary adjustments. Identify problems early and take steps to correct these problems before performing a large quantity of unacceptable work. Meetings are a good place to identify problems and the necessary steps to correct them.

4-2.4.3.4 On some projects, traffic flow is a concern. Develop plans to control traffic flow and inspections to minimize traffic problems. At times the completed layer may temporarily serve as a riding surface for traffic. Temporary pavement markings are a part of the project.

4-2.4.3.5 Control the materials used for the project to ensure acceptable quality and that the quantity of material is sufficient. Control aggregate quality at delivery and perform aggregate handling in a manner that avoids segregation. Supply the specified asphalt emulsion or recycling agent and provide test certificates.

4-2.4.3.6 Specific equipment requirements are minimal. Ensure that the contractor has the flexibility to select equipment necessary to produce the mixture according to the specifications and to ensure compaction requirements are met. However, maintain all equipment in good working condition.

4-2.4.3.7 Remove isolated locations of unsuitable material as part of the project. Identify and discard this material and ensure that no discarded material is used in the project.

4-2.4.3.8 The mix design identifies the materials and proportions used in the project. Only an authorized government official can approve changes to the mix design. Supply issues or changes in quality may require a change in the mix design.

4-3 COLD CENTRAL-PLANT RECYCLING.

4-3.1 Introduction.

CCPR recycles RAP in a central plant to produce recycled mixes. Two conditions make CCPR a feasible technique: (a) availability of stockpiles of high quality and uniform RAP and (b) inability to use CIR process.

The general process is that the RAP is hauled to a plant site or stockpiled. The plant crushes, screens, and mixes in additives prior to the mix being transported to a job site. The mix is then placed and compacted in accordance with specifications. In some circumstances, it is also possible to use a portable unit to process the RAP at the stockpile area.

Use CCPR as stabilized base course with an HMA overlay for roads with higher traffic volume as well as for airfields. For low traffic roads, it can be used along with a single or double bituminous seal coat to seal and protect the surface.

4-3.2 Past and Current Use.

The U.S. does not use a large amount of CCPR; however, its use is significant in several other countries. The use of CCPR has decreased in the U.S. due to improvements in CIR and FDR and the cost effectiveness of these processes. CIR methods are less expensive and less likely to cause traffic problems when transporting materials from the plant to the project site.

4-3.3 Guidelines for Use of CCPR.

The guidelines established to use CIR and FDR are applicable to CCPR. When better control is required, use CCPR over a CIR approach.

4-3.3.1 Primary Purpose.

CCPR is an adequate technique when a pavement cannot be in-place recycled and the HMA layer must be removed to allow for treatment of underlying layers. In other words, CCPR is a good solution for pavements that present problems in underlying layers such as lower HMA lifts or aggregate base layers. Successful CCPR projects should only be used in areas having no major problems with realignment, drainage, or frost heave.

The ability to control aggregate gradation, percentage of water, recycling additives and stabilizers makes CCPR an attractive alternative for some special cases. Use the CCPR process when additional aggregate is required to correct pavement cross slope and when there are restrictions for CIR equipment in the work area.

4-3.3.2 Advantages and Disadvantages.

The main advantages of using CCPR are similar to those advantages for CIR and FDR. Other complementary advantages are: 1) stockpiled RAP is cleaner than in-place recycled material, 2) crushing RAP allows gradation requirements to be met, 3) RAP is mixed with asphalt emulsion in a central plant allowing better control, and 4) multiple feed bins provide an opportunity for better control of aggregate gradations.

The primary disadvantages of using CCPR are higher cost and increased material handling required to move materials from the job site to the plant, feed materials into the plant, and haul the completed mixture back to the job site.

4-3.3.3 Performance and Costs.

Similar to CIR and FDR, the performance of CCPR depends on several aspects such as local conditions, climate, traffic, types of material, quality of construction, specifications, and QC/QA. The estimated life of a CCPR mix with surface treatment is between 6 and 8 years and with HMA overlay is between 12 and 15 years (ARRA, 2015).

4-3.3.4 Mix Design.

The discussion carried out for mix design of CIR applies to CCPR. Removing materials from the project site prior to producing CCPR mixture provides time to take samples of materials and conduct mix design. Take core samples prior to starting work. However, the mix design based on these samples is not as reliable as samples taken from the milled material.

4-3.3.5 Structural Design.

All the considerations for structural design for CIR apply to CCPR.

4-3.4 Construction.

As pointed out before, transport the RAP to a special location for crushing, screening and blending with recycling aggregates. Process in a central mixing plant. Another option is to process the RAP at the project location using a mobile mixing plant located at or near the job site. In both situations, use a pugmill mixer.

Store RAP as any other aggregate. Be aware of the variability inherent in different sources of RAP. Contractors typically have sources of RAP to produce the CCPR or the specifications may require that only RAP from the existing project be used. If using RAP from other sources, evaluate this RAP to ensure it is satisfactory for the existing project. The most common problem that may occur is the RAP source may contain aggregates with unsatisfactory aggregate properties. In any case, manage the stockpiles to minimize segregation of materials.

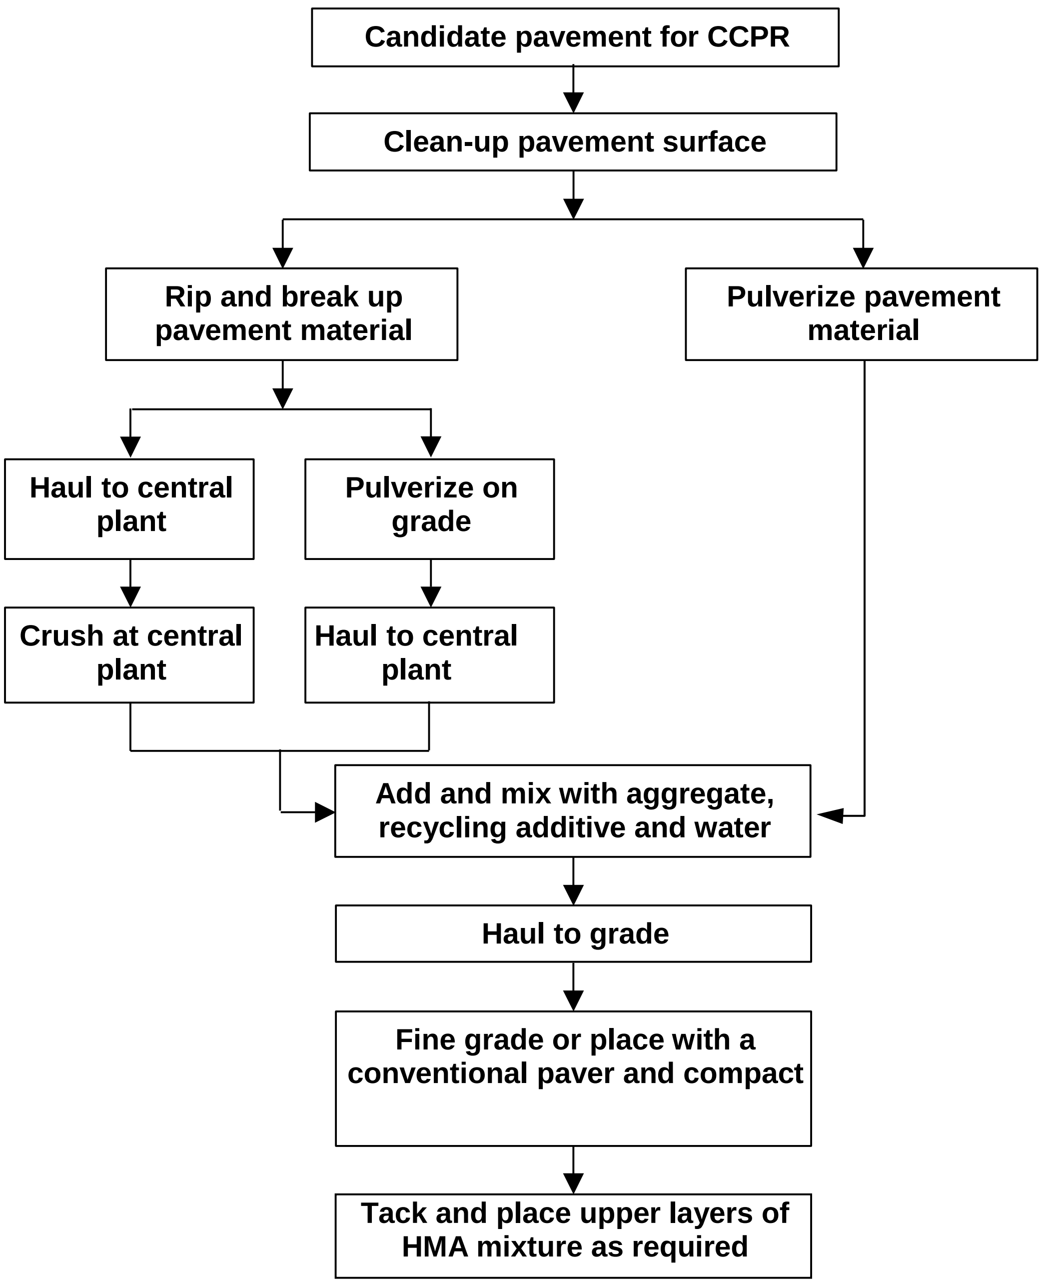
4-3.4.1 Types of Equipment.

Process equipment produces RAP by milling, ripping, breaking, crushing or pulverizing old HMA layers. Other equipment transports the RAP to the plant and handles the RAP at the plant. The central plant is similar to an HMA plant and should have the following parts:

- Screening and crushing units to keep the maximum size of the RAP under control. Alternatively, it can use a scalping screen to remove oversize particles in the RAP.
- RAP feed hopper.
- Conveyor belts with a belt scale.
- A computerized system, connected to the belt scale, controls the amount of liquid recycling additive and water added to the pugmill, based on the weight of the RAP estimated by the belt scale.

Figure 4-8 shows the steps in the CCPR process.

Figure 4-8 CCPR Construction Process*



*Source: ARRA, 2015.

4-3.4.2 Technical Aspects on CCPR Construction.

Additional technical aspects to consider during work at the central plant:

- Complete coarse aggregate coating is not required during the mixing process. Additional coating will occur during the hauling, spreading, and rolling of the mix.
- Ensure the mixing time is sufficient to obtain good mixing of all materials. Excessive mixing causes excessive breakdown of the material and may adversely affect the coating. Under-mixing results in lack of good coating of materials.

4-3.4.2.2 Clean Up Pavement Surface.

It is a good practice to inspect the pavement surface before the recycling operation to clear vegetation and debris across the pavement and shoulders.

4-3.4.2.3 Cold Milling Process.

Conduct cold milling and pulverization of asphalt pavement layers according to the required depth and maximum RAP size specified for the project.

4-3.4.2.4 Placement of the Recycled Material.

Haul the mixed material to the project site and laydown the recycled material with an asphalt paver. A paver works better than other equipment to place the recycled mixture in a uniform manner to the desired grade. The paver provides some initial compaction.

Aeration may be necessary to decrease water and/or volatile content before the compaction process. Perform placement in several lifts as required by the project. Maximum lift thickness is limited to 4 inches (100 mm) when compacted.

Inspect the placement of the CCPR to minimize segregation. When segregation occurs, stop the project until the causes of segregation are identified and corrected.

4-3.4.2.5 Field Adjustments of the Mix.

Perform field adjustments of the mix during construction of the test section as discussed in UFGS 32 01 16.70. Consider using a variety of roller combinations during construction of the test section. Monitor changes step-by-step with a density meter to understand the relative increase in density with roller passes. Ensure the test section has a minimum length of 150 ft (15 m) and is the width of two pavers. Place the test section and compact to the thickness required for the project. All CCPR projects require compliance with performance specifications.

4-3.4.2.6 Curing, Compaction, and Field Density.

See the discussion for CIR.

4-3.4.3 Surface Course.

Since CCPR contains high voids in the total mix, do not use as a wearing course. For low volume roads, use single or double bituminous surface treatment to cover the CCPR. For roads with high volume traffic and for airfields, keep the thickness of HMA equal to or greater than the minimum requirements for thickness of HMA placed over a granular base course.

4-3.5 Specifications, Quality Control, Inspection and Acceptance.

4-3.5.1 Specifications.

The specification used for CCPR are UFGS 32 01 16.70. In addition to the specifications for CIR, define the spreading depth because it only applies to CCPR. Monitor this feature to avoid inadequate thickness and to assure compliance with the design requirements.

4-3.5.2 Quality Control/Quality Assurance and Inspection and Acceptance.

See comments for CIR.

4-4 FULL-DEPTH RECLAMATION.

4-4.1 Introduction.

Full-depth reclamation rehabilitates flexible pavements with significant deterioration. For example, a pavement with base failure is an excellent candidate for FDR. The process can involve modification to the HMA layers and possibly underlying granular layers. The technique consists of uniformly breaking up the material to a specified depth between 4 and 12 inches (100 and 300 mm), pulverization, incorporation of a stabilizing agent, blending, shaping and compaction of the reclaimed mixture as a base layer. Mechanically stabilize the material if the pavement is for low and medium traffic. For pavements with higher traffic or higher load capacity, including high volume roads and airfields, chemically stabilize the FDR material by introducing and blending additives such as cement, fly ash, lime, foamed asphalt, and asphalt emulsions.

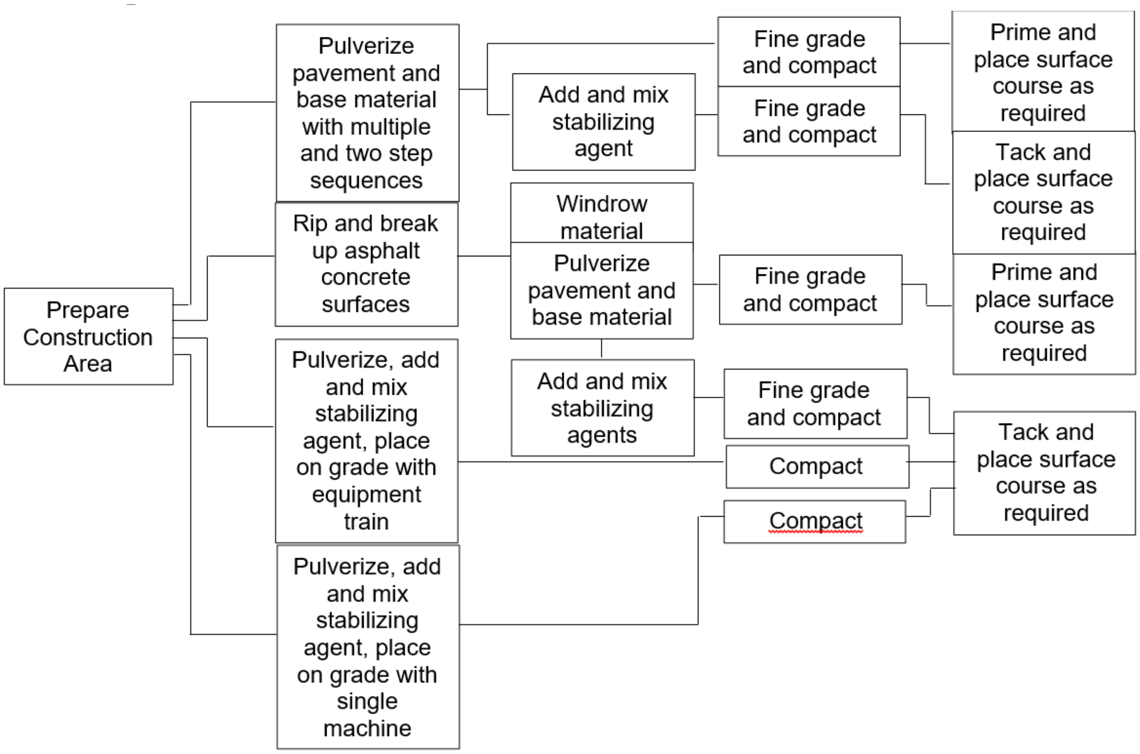
Pavements that do not have structural capacity to support CIR equipment are also good candidates for treatment with FDR. This is usually a pavement with less than 3.5 inches (90 mm) of HMA and a weak subgrade with a resilient modulus less than 5000 psi (34.5 MPa) (PIARC, 2003).

Figures 4-9 and 4-10 show examples of recycled material and a schematic of the FDR process, respectively.

Figure 4-9 Recycled Material*

*Source: https://cdn.ymaws.com/arra.site-ym.com/resource/resmgr/files/ARRA_Full_Depth_Reclamation_.pdf

Figure 4-10 Full Depth Reclamation*



*Source: Kandhal and Mallick, 1997; https://cdn.ymaws.com/arra.site-ym.com/resource/resmgr/files/ARRA_Full_Depth_Reclamation_.pdf

4-4.2 Past and Current Use.

Full-depth recycling is not new and was first competed in the early 1900s (Kandhal and Mallick, 1997; Sullivan, 1996). Several state DOTs have experience with FDR.

FDR technology applies to airfields. One example is an airport that used FDR with cement stabilization to rebuild a runway pavement. The construction period was only 30 days and they estimated that they saved approximately $1 million by using FDR compared with other paving options (Arroyo, 2007).

Since the 2000s one state DOT implemented a large FDR program with stabilized base. One project saved $200,000 on a $3 million project to reconstruct a 6-mile section of roadway. This state DOT stabilized projects with cement and fly ash (Terra, 2008).

One city in Canada began to use FDR with foamed asphalt in 2000. Since then, they have successfully constructed more than 30 million sq yd (25 million sq m) of FDR, much of which was stabilized with foamed asphalt.

4-4.3 Guidelines for Use of FDR.

Most of the guidelines suggested for CIR are applicable to FDR. There is no UFGS specification for FDR. Hence, DoD projects must use local state DOT specifications for FDR. The following sections discuss some aspects unique to FDR.

4-4.3.1 Primary Purpose.

FDR is suitable for pavements with structural problems such as deteriorated HMA and base layers. Figure 4-11 shows good candidates for FDR where there are significant problems with the HMA mixture and likely with underlying granular layers and subgrade.

Under the correct conditions, FDR allows:

- Adjustment of the profile and cross slope of the pavement
- Accommodation of pavement widening, if necessary
- Ability to improve quality of underlying pavement layers

4-4.3.2 Advantages and Disadvantages.

4-4.3.2.1 Advantages.

FDR has advantages similar to CIR to include:

- Crown and cross-slope are easily restored.
- Reflective cracks are eliminated or reduced.
- FDR is cost effective in the long-term since FDR can eliminate problems with an inadequate base course.

- FDR offers a low environmental impact, because materials are not transported back and forth.
- Reduction in future maintenance costs due to the long-term correction of structural and other problems.
- The typical FDR depth is between 6 and 9 inches (150 and 225 mm). However, the literature indicates the possibility of depths over 12 inches (300 mm).
- With good quality control during construction, pulverizing base and HMA layers and mixing with stabilizing additives increases the structural capacity of the pavement.

Figure 4-11 Good Pavement Candidates for FDR*

*Source: ARRA, "Full Depth Reclamation."

4-4.3.2.2 Disadvantages.

The main disadvantages of using FDR are:

- The mixing and uniformity of mixture are not as well controlled for FDR compared to CCPR or CIR.
- Any construction problem at the longitudinal joints in between adjacent strips may cause longitudinal cracks.
- Usually FDR requires more time than required to construct an HMA overlay.

4-4.3.3 Performance and Cost.

The performance of FDR depends on several aspects such as local conditions, climate, traffic, type of material, quality of construction, specifications, and QC/QA. Several states in the US have good experience with FDR and excellent results.

Shuler and Schmidt (2008) evaluated the performance of a number of recycling methods. The research concluded that it generally took 6 to 8 years for the recycled pavement to reach the condition of the original pavement prior to application of the recycling technologies. This was true for every distress except roughness. It took an average of 14 years to reach the same level of roughness.

4-4.3.4 Mix Design.

The CIR mix design concepts apply to the mix design of FDR. The following sections discuss other details concerning FDR mix design.

4-4.3.4.1 Trial Mixes, Curing Time, and Job Mix Formula.

Most of the information concerning CIR mix design applies to FDR. Additional aspects to consider due to the variability of stabilization methods available for FDR are:

- Mechanical Stabilization - use one or more of the following options:
  - crushed virgin aggregate.
  - reclaimed asphalt pavement.
  - crushed concrete, etc.
- Chemical Stabilization – use one or more of the following options:
  - Portland cement (dry or slurry).
  - lime applied dry or in a slurry.
  - fly ash.
  - calcium chloride.
- Asphalt Stabilization – use the following options:
  - emulsified asphalt.
  - foamed asphalt.

Apply cementitious and pozzolanic materials as dry powder in front of the reclaimer, in slurry form together with the pre-pulverized material, or in suspension by using a spray bar. Pavements with severe deterioration and high deflections are excellent candidates for FDR with cement.

Apply liquid stabilizing/additives like calcium chloride ahead of the reclaimer, together with the pre-pulverized material, or by injection with the reclaimer additive system**.**

Asphalt stabilization reduces the effects of moisture and improves the strength of the reclaimed material. When compared with other chemical stabilizers it creates a more flexible base which is more resistant to fatigue. Asphalt can stabilize 100% RAP or a mix of RAP and granular base and subbase. Require that the fine materials have a plasticity index of no more than 6%.

The same considerations carried out for CIR apply to FDR. Table 4-2 provides general guidelines to select stabilizers for FDR (lab testing).

Table 4-2 General Guidelines for Selecting Stabilizers for FDR

	Characteristics of Reclaimed Pavement Materials
Hydrated lime or quicklime (2 to 6% by weight)	RAP having some amount of silty clay soil from subgrade with a plasticity index greater than 10.
Class C fly ash (8 to 14% by weight)	Materials consisting of 100% RAP or blends of RAP and underlying granular base or soil. The soil fraction can have plasticity or be similar to soils acceptable for lime treatment.
Portland cement (3 to 6% by weight). The maximum limit of Portland cement for airfields is 4%.	Materials consisting of 100% RAP, or blends of RAP and underlying granular base, or nonplastic or low plasticity soils. Sufficient fines are necessary to create an acceptable aggregate matrix for the cement treated base (CTB) (not less than 45% passing the 4.75 mm or No. 4 sieve preferred).
Emulsified or foamed asphalt (1 to 3% by weight)	Materials consisting of 100% RAP, or blends of RAP and underlying granular base, or nonplastic or low plasticity soils. Limit the maximum percent passing the 75 µm (No. 200) sieve to 25%. Limit the plasticity index to 6%. Limit the sand equivalent 30 or greater or the product of multiplying the P4 and the percent passing the 75 µm (No. 200) less than 72.
Calcium chloride (1% by weight)	Materials consisting of a blend of RAP and nonplastic base soil with 8 to 12% minus 75 µm (No. 200) material. Small amounts of clay (3 to 5%) are also beneficial.

4-4.3.4.2 Mechanical Stabilization.

Mechanical stabilization is simple and sometimes requires imported material such as virgin granular materials to improve the gradation of the reclaimed material. This increases the structural stability of the mixture and the excess bituminous material has more surface area to coat. In other cases, additional granular material is necessary to reach the specified thickness of the material.

4-4.3.4.3 Chemical Stabilization.

Portland cement is the most common additive used for chemical stabilization. The following sections discuss the main steps to stabilize FDR with cement.

a. Gradation. To achieve a suitable gradation, determine whether to add new material to the mixture. It is desirable to achieve a gradation similar to the Talbot's curve shown below:

$$y = 100 \times (d/D)^{0.4}$$

Where:
y = percentage passing sieve "d"
d = sieve size in mm (inch)
D = maximum aggregate size in mm (inch)

b. Water Content. Obtain the optimum water content of the reclaimed pavement material mixed with cement as the peak of the moisture-density tests. Use modified Proctor procedures for compaction (ASTM D1557).

c. Mix Density. Ensure that the mix density is at least 97% of the Modified Proctor laboratory density.

d. Optimum Cement Content. Ensure that the cement content provides the specified strength, is economically feasible, and keeps shrinkage cracks as fine as possible. On airfields limit the cement content to 4%.

Obtain the optimum cement content by running moisture-density tests. Prepare at least three sets of specimens with material obtained from the pavement incorporating imported material, as necessary, and compact to the minimum density expected. Test specimens to obtain the axial compression strength at 7 days.

Subsequently, prepare specimens by varying the initial amount of cement ± 2%. This approach guarantees that the amount of cement will include the target value. For larger projects, test the compressive and indirect tensile strengths at 28 and 90.

e. Types of Cement. Cements with a high percentage of pozzolans are best suited for FDR and for roller compacted cement treated materials.

The density and cement content are more important than limiting the type of cement. Review the available types of cement in the market. Test to ensure that the cement produces the required characteristics in terms of strength, workability, and mix homogeneity. Using high-strength cements can produce a very low cement content of 2 to 2.5% by weight of dry material.

Note: It is possible to meet strength requirements and lack adequate homogeneity. Other classes of cement may produce a mix with a cement content as high as 3 to 6%. In this case, recycled material incorporated into the mix design has fewer homogeneity and workability problems.

f. Workability Time. Evaluate the impact of a limited workability period, or setting time, for cement treated material carefully. Air temperature and humidity interfere with the period of workability. When cement starts hydrating, it binds the aggregates and the compaction may break these links. Complete compaction before the cement begins to set and bind the aggregate.

Check the workability time by verifying the decrease in sample density when compacted at increasing times. For practical purposes, the workability period ends when the density drops to 98% of the density obtained for specimens compacted immediately after mixing.

4-4.3.4.4 Determining the Proper Amounts of Virgin Aggregate to Add.

Apply the same steps described for CIR for FDR. As discussed above, obtain additional information when stabilizing with cement.

4-4.3.4.5 Requirements for Aggregates.

The requirements for aggregates are similar to those for granular base, soil-cement, and cement treated base.

4-4.3.4.6 Recycling Additives.

Recycling additives are the same as for CIR and as discussed in this section for FDR.

4-4.3.5 Structural Design.

Follow the discussion in Chapter 3 for structural design.

4-4.4 Construction.

The construction considerations for CIR apply to FDR principally regarding the use of asphalt materials as a stabilizer. Some additional considerations are necessary when cement is the additive. The following sections discuss important considerations when cement is the additive.

4-4.4.1 Types of Equipment.

In general, use the same equipment described for CIR for FDR. However, each project has unique equipment requirements. Tables 4-3 and 4-4 present the necessary equipment and operational steps for FDR stabilization with cement for low and medium/high volume roads.

Table 4-3 Steps for Recycling Low Volume Roads[2]

		Typical Equipment
Pavement scarification[1]	Loosen the existing pavement	• Front loader with ripper • Bulldozer with ripper • Recycler
Eliminating large particles	Eliminating large particles over 80 mm (3.2 inches): • By crushing • By removal	• Stationary or mobile crushing unit • Manual work • Agricultural equipment
Leveling	Distribution of milled material	• Motor grader
Adding imported aggregate (if needed)	• Improvement of aggregate gradation • Cross slope correction • Increasing treated surface thickness	• Aggregate spreader • Bituminous mix paver • Motor grader
Moistening[2]	Achieve optimum moisture content according to moisture- density test (Modified Proctor)	• Water tanker with spraying bar • Water tanker connected to recycler • Slurry mixer
Binder distribution	Introduction of binder in proportion to site requirements and working depth	• Manual spreading (grid of cement bags) • Binder spreader (cement as powder is spread ahead of mixing plant) • Slurry mixer (cement and water are mixed and introduced as slurry into the recycler)
Mixing	Homogeneous mix of loosened pavement material with binder, water and any additives	• Rotary plough • Pulvimixer with horizontal mixing rotor • Recycler
Trimming	Eliminating surplus material to achieve final level	• Grader
Transverse joint cutting	Prevention of reflective cracking	• Mechanically driven machines • Hand driven device (vibrating plate or roller with welded knife)
Compacting	Achieving required density	• Vibratory roller
Curing and protection seal	• Curing of recycled surface • Protection of applied seal	• Water tanker[3] • Emulsion spreader • Chip or sand spreader + pneumatic tire roller
(1) When using a recycler, if it is not necessary to eliminate large particles, perform this step after distributing the binder (or at the same time). (2) Allow excessively moist milled material to dry before incorporating the binder and any imported material. (3) During warm and dry weather conditions, have a water tanker readily available to moisten the surface before spraying the curing seal.		

[2]PIARC, 2003.

Table 4-4 Steps for Recycling of Medium and High-Volume Roads[3]

		Typical Equipment
Adding imported aggregate (if needed)	• Improvement of aggregate gradation • Cross slope correction • Increasing treated surface thickness	• Aggregate spreader • Bituminous mix paver • Motor grader
Moistening[1]	Achieve optimum moisture content according to moisture-density test (Modified Proctor, AASHTO 1557)	• Water tanker with spraying bar • Water tanker vehicle connected to recycler • Emulsion spreader
Binder distribution	Introduction of binder in proportion to site requirements and working depth	• Binder spreader (cement as powder spread ahead of mixing plant) • Slurry mixer (cement and water are mixed and introduced as slurry into the recycler)
Pavement scarification[2]	Loosen the existing pavement	• Recycler
Mixing	Homogeneous mix of loosened pavement material with binder, water and any additives	• Recycler
Transverse joint cutting	Prevention of reflective cracking	• Mechanically driven machines • Hand driven device (vibrating plate or roller with welded knife)
Initial compaction	Achieving 90-92% of reference density	• Vibratory roller
Trimming	• Eliminating surplus material to achieve final elevation • Improvement of surface evenness	• Grader
Final compaction	Achieving required density	• Vibratory roller + pneumatic-tire roller[3]
Curing and protection seal[4]	• Curing of recycled surface • Protection of applied seal	• Emulsion spreader • Chip or sand spreader + pneumatic tire roller

[1] Allow excessively moist milled material to dry before adding the binder and any imported material.
[2] In recycled pavement layers, crush or remove particles larger than 3.2 inches (80 mm),
[3] Or two vibratory rollers.
[4] During warm and dry weather conditions, have a water tanker readily available to moisten the surface before spraying the curing seal.

[3]PIARC, 2003.

4-4.4.2 Technical Aspects on FDR Construction.

In general, the process of laydown, compaction and overlaying the in-place cold recycling is the same as that for conventional stabilization operations. However, consider the uniqueness of each problem, type of additives, proposed technique and the variability found in FDR techniques.

Focus special attention on the variability of the strength of reclaimed pavement stabilized with cement. Research indicates that the tensile strength obtained from cores of cement-recycled pavements after 1 to 2 years was between 60 and 290 psi (0.4 and 2 MPa). The respective moduli of elasticity were between 508,000 and 5,438,000 psi (3,500 to 37,500 MPa) (PIARC, 2003). These are very highly variable results and the selected specifications, testing procedures and performance requirements must account for the possibility of highly variable results while using similar materials under the same environmental conditions.

4-4.4.2.1 Pavement Surface Cleanup.

See CIR section.

4-4.4.2.2 Cold Milling Process.

See CIR section.

4-4.4.2.3 Placing Recycled Material.

See CIR section.

4-4.4.2.4 Field Adjusting the Mix.

See CIR section.

4-4.4.2.5 Curing.

See CIR section.

4-4.4.2.6 Compaction.

Compact each strip within the workability timeframe prior to starting on a subsequent strip. When the time for compaction is within the workability time, the rollers will not damage the previous strip and form cold joints. Complete any trimming prior to starting the compaction process.

Ensure that cement recycled layers are no less than 8 inches (200 mm) and no more than 14 inches (350 mm) thick. The minimum thickness requirement avoids areas with insufficient thickness that leads to premature fatigue. The capacity of recyclers and compaction equipment limits the maximum layer thickness. Figure 4-12 shows an example of incorporating and spreading granular material on the top of old pavement to achieve the necessary compacted thickness.

Figure 4-12 Granular Material Added to Achieve Compacted Thickness*

*Source: PIARC, 2003.

4-4.4.2.7 Field Density.

Refer to the CIR section. However, the minimum field density suggested for FDR stabilized with cement is 97% of the maximum laboratory density obtained when compacted in accordance with Modified Proctor (ASTM D1557).

4-4.4.2.8 Surface Course.

The same considerations carried out for CIR are valid for FDR.

4-4.5 Specifications, Quality Control, Inspection and Acceptance.

See CIR section.

4-4.5.1 Specifications.

See CIR section. The UFGS specifications related to FDR are:

- UFGS 32 11 26.19, *Bituminous Stabilized Base and Subbase Courses*
- UFGS 32 01 16.70
- UFGS 32 11 36.13

4-4.5.2 Quality Control/Quality Assurance.

The QC/QA procedures for CIR apply to FDR. Because other stabilizers were included for FDR, Table 4-5 summarizes the methods for evaluating stabilized materials.

Table 4-5 Testing Methods for Evaluation of Stabilized Materials

	Applicable Testing Procedures
Hydrated lime or quicklime	Liquid Limit, Plastic Limit and Plasticity Index of Soils (ASTM D4318) Moisture Density Relations of Soils and Soil-Aggregate Mixtures (ASTM D698 or D1557) Unconfined Compressive Strength of Compacted Lime Mixtures (ASTM D5101, Procedure B)
Class C fly ash or cement	Moisture-Density Relations of Soil-Cement Mixtures (ASTM D558, Method B) Compressive Strength of Molded Soil-Cement Cylinders (ASTM D3633) Wetting and Drying Compacted Soil-Cement Mixtures (ASTM D559, Test Method B)
Asphalt emulsion or foamed asphalt	Percent Air Voids in Compacted Dense and Open Bituminous Paving Mixtures (ASTM D3203) Effect of Moisture on Asphalt Concrete Paving Mixtures (ASTM D4867) Indirect Tension Test for Resilient Modulus Bituminous Mixtures (ASTM D4123)
Calcium chloride	Liquid Limit, Plastic Limit and Plasticity Index of Soils (ASTM D4318) Moisture-Density Relations of Soils and Soil-Aggregate Mixtures (ASTM D1557)

4-4.5.3 Inspection and Acceptance.

Apply the requirements for inspection and acceptance formulated for CIR to FDR and are supplement with the appropriate UFGS requirements.

CHAPTER 5 HOT RECYCLING FOR ASPHALT SURFACED PAVEMENTS

5-1 INTRODUCTION.

There are two basic methods of hot mix recycling: HR and HIR. HIR includes three sub-categories: The HIR Type I, Surface Recycling, HIR Type II, Remixing, and HIR Type III, Repaving. Table 5-1 presents the advantages and disadvantages of using HR and HIR Types I, II and III.

Hot mix recycling uses heated materials that combine RAP with virgin aggregates and, if necessary, new asphalt binder and recycling agents. HR and HIR mixes serve as base, intermediate and surface layer materials in all types of roadway pavements, but only as base or intermediate courses in airfield pavements. RCA may serve as a portion of the aggregate in HMA for some road and airfield specifications.

5-2 OVERVIEW OF HOT RECYCLING METHODS.

5-2.1 Hot Central Plant Recycling (HR).

HR combines RAP with new aggregates, new asphalt binder, and recycling agents, in a plant to produce recycled HMA. The process removes existing pavement, crushes the reclaimed mix, mixes the reclaimed mix with virgin aggregate, and virgin asphalt in a conventional asphalt plant, places and compacts the recycled mix using the same procedures and equipment as for a virgin mix. Figures 5-1 and 5-2 show schematics for two general types of asphalt plants used for HR.

HR is allowed for all pavement layers other than surface layers on airfields. HR is an excellent option for roadway pavements with high traffic volume. However, never use HR as the wearing surface for airfield pavements subjected to traffic. For airfields, HR mixes are allowed for shoulders and underlying layers in trafficked areas. HR is applicable to all levels of traffic and can use RAP from pavements with a range of asphalt mixture issues as long as the quality of the aggregate and asphalt binder is reasonable. Compared with other recycling processes, HR produces the highest quality pavement material because it provides uniform mix production and presents the lowest construction variability (Kandhal and Mallick, 1997).

5-2.1.1 Past and Current Use.

Currently, hot recycling of RAP in an asphalt plant is the most used asphalt recycling method. Prior to use of RAP many RAP stockpiles throughout the U.S. contained a large percentage of material that had to be wasted or utilized for other than HMA applications.

Table 5-1 Asphalt Recycling Technique Advantages and Disadvantages[4]

Technique	Advantages	Disadvantages
Applied to HIR in General	• Conservation of non-renewable resources. • Energy savings. • Less truck hauling at the work site. • No need for material removal. • Work the entire lane width at once. • Maintenance of curb height and overhead clearance. • Correction of aggregate and/or asphalt binder problems. • Remixing and recoating of aggregates with stripping problems. • Reduction of traffic disruptions and user nuisance. • Possibility of roadway opening to traffic at end of day. • Considerable economic savings.	• Does not improve load carrying capacity of pavement. • Not applicable to pavements with base failures and drainage problems. • Existing pavement surfaces should be at least 3 in (75 mm) thick. • Process does not correct large surface wavelengths or large changes in grades. • Difficult to use on narrow roads due to the width of the equipment. • Process not suited to streets with many utilities such as manholes, access covers, etc. • Cold weather can require more time for heating the pavement. • Surface treatments, like multiple chip seals affect pavement re-heating time. • Limitation for pavements with aggregate larger than 1 in (25 mm) diameter. • The heating process must be highly controlled to avoid creating air quality problems or overheating and damaging the asphalt binder.
Surface (HIR-I)	• Reduces frequency of reflection cracking. • Promotes bond between old pavement and thin overlay. • Provides a transition between new overlay and existing gutter, bridge, and/or pavement that is resistant to raveling (eliminates feathering). • Reduces localized roughness. • Treats a variety of low level pavement distresses (raveling, flushing, corrugations, rutting, oxidized pavement, faulting) at a reasonable initial cost. • Improves skid resistance.	• Provides limited structural improvement. • Heater-scarification and heater-planing have limited effectiveness on rough pavement without multiple passes of equipment. • Limited repair of flushed or unstable pavements. • Some air quality problems. • May damage vegetation close to the roadway. • Some equipment cannot treat mixtures with maximum aggregate sizes greater than 1 in (25 mm).

Technique	Advantages	Disadvantages
Remix and Repave (HIR-II and HIR-III)	• Provides structural improvement. • Treats all types of pavement distress. • Can reduce reflection cracking. • May reduce frost susceptibility. • Improves ride quality. • Improves skid resistance. • Minimizes hauling.	• Quality control not as good as central plant. • Traffic disruption. • PCC pavements cannot be recycled in-place. • Curing often required for strength gain.
Central (HR)	• Conservation of non-renewable resources. • Energy savings. • Provides significant structural improvements. • Treats all types and degrees of pavement distress. • Can eliminate reflection cracking if removing a sufficient depth of asphalt. • Improves skid resistance. • May reduce frost susceptibility. • More easily alters geometrics. • Improves ride quality.	• Traffic interruption. • Additional costs for transporting materials. • The recycled mix uses less than 100 percent RAP, so virgin aggregate and virgin binder are required. Typically up to approximately 20% RAP is used in recycled mixture.

The maximum amount of RAP allowed on DoD airfields projects is such that the asphalt binder from RAP cannot exceed 20 percent of the total asphalt content. RAP is not allowed in the surface course of airfield pavements. Other current requirements for use of RAP are in HMA on DoD airfield pavements is provided in UFGS 32 12 15.13.

The maximum amount of RAP allowed on DoD road and parking lot projects is such that the asphalt binder from RAP cannot exceed 30 percent of the total asphalt content. Other current requirements for use of RAP are in HMA on DoD roadway pavements is provided in UFGS 32 12 16.16.

Successfully using HR requires a good evaluation of the RAP, an adequate mix design, a rigorous QC/QA program and good construction practices (ARRA, 2001).

- When feeding RAP into the plant, ensure the maximum RAP chunk size does not exceed 2 inches (50 mm).
- Ensure the individual aggregates in a RAP chunk does not exceed the maximum size aggregate of the specified gradation.
- Use the procedures described in the Mix Design section of the UFGS cited in the paragraphs above to design recycled HMA

Many DOTs use Reclaimed Asphalt Shingles (RAS) to offset the cost of asphalt mixtures and utilize waste shingles that typically contain approximately 20 percent asphalt binder. RAS is not allowed on DoD airfield or roadway projects.

5-2.2 Hot In-place Recycling (HIR).

HIR can rehabilitate existing HMA pavements with distresses such as bleeding, shoving, raveling/segregation, corrugation, slippage, potholes, rutting, poor surface friction and cracking. HIR reprocesses existing HMA materials in-place at temperatures similar to conventional HMA by softening with heat, scarifying to depths of 3/4 to 2½ inches (20 to 60 mm), mixing new aggregate and binder, as required, placing and compacting (ARRA, 2001; Kandhal and Mallick, 1997; Hajek et al, 2005). The differences in the construction process and treatment of pavement distresses defines the three subcategories of HIR (Surface Recycling, Remixing, and Repaving).

HIR rejuvenates the surface of existing pavements having generally good structural capacity but that contain distresses in the surface layer. Conduct a comprehensive pavement evaluation prior to selection of HIR techniques to determine the asphalt concrete properties, the need for rejuvenators, and/or fine or coarse aggregates. Surface recycling is applicable for pavements that have no major distresses or deterioration and, hence, do not require additional material. Since repaving (HIR-III) is a combination of surface recycling or remixing with HMA overlay, it is applicable to high volume roads and airfield pavements.

Pavements without structural problems are ideal candidates for HIR. The type, extent, and severity of distress determines the applicable HIR type. Table 2-1 presents suggestions for selecting different HIR processes as a function of the pavement distress (ARRA, 2001).

5-2.2.1 Hot In-place Surface Recycling (HIR-I).

Surface recycling is the oldest HIR process. Formerly known by several names including heater-scarification, heater-planing, reforming, and resurfacing. It consists of heating, scarifying, adding asphalt binder or rejuvenator, leveling, reprofiling and compacting of the existing HMA mixture. The HIR-I process adds no new aggregates or new HMA. Treatment depth ranges between 3/4 to 1½ inches (20 to 40 mm).

Surface recycling prepares pavement for subsequent HMA overlay or chip seal. Steps in surface recycling are:

1. Dry and heat the upper HMA layers of the existing pavement such that surface temperatures range from 230 to 300 ºF (110 to 150 ºC) when at least two heaters are used in tandem.
2. Scarify the heated and softened HMA pavement.
3. Add a recycling agent if the mix design and JMF require.
4. Mix the loosened recycled mix.
5. Spread and place the recycled mix.
6. Compact the recycled mix using conventional HMA rollers and procedures.

5-2.2.2 Remixing (HIR-II).

Remixing consists of heating, softening and scarifying existing HMA pavement, adding virgin aggregate, new asphalt binder, recycling agent and new HMA, if necessary, followed by final mixing. HIR-II rehabilitates pavements that need an additional thickness of asphalt. The recycled mix acts as the wearing surface, but can be covered with a chip seal or overlaid with new HMA or HR to provide an improved surface that better resists traffic and environmental effects.

Perform remixing using a single or multi-stage approach. The single-stage approach successively heats and softens pavement to a specified full treatment depth followed by full material scarification. Multi-stage remixing heats thin layers of the pavement (normally between two to four layers), softens and scarifies them until achieving the desired full treatment depth. The scarified material is accumulated in a windrow to allow continued heating and scarification of underlying layers. The treatment depths for single-stage and multiple-stage are 1 to 2 inches (25 to 50 mm) and 1 ½ to 3 inches (40 to 75 mm), respectively (ARRA, 2001; Federation of Canadian Municipalities, 2005; Kandhal and Mallick, 1997).

5-2.2.3 Repaving (HIR-III)

Repaving combines surface recycling or remix with an HMA overlay and is frequently called the Cutler process. The surface recycled mix works like a leveling course and the new HMA as a wearing course. The thickness of the HMA overlay depends on the maximum aggregate size of the mix and varies between 3/4 inch (20 mm) and 3 inches (75 mm). The repaving process can significantly increase the pavement thickness (ARRA, 2001; Federation of Canadian Municipalities, 2005; Kandhal and Mallick, 1997).

Repaving is carried out by one unit equipped with several separate pieces of equipment including heaters, scarifiers, hot milling machines, pavers, and two screeds. The unit scarifies the heated and softened pavement at a temperature of approximately 375 ºF (190 ºC), adds the necessary quantity of recycling agent and mixes the recycled mix before the first screed. The screed levels and shapes the recycled material. Another screed on top of the recycled layer adds and spreads a new HMA layer. Rubber-tired and vibrating steel drum rollers compact the two layers as a single layer. The repaving process steps are:

1. Heat
2. Scarify using teeth or a rotary mill
3. Add recycling agent
4. Mix the recycling agent and loosened mixture
5. Spread and screed the recycled mixture
6. Place a new HMA overlay
7. Compact the two layers as a single layer

HIR-III recycling is only suitable for secondary or tertiary roads. Do not use this type of construction on airfields or parking areas subjected to heavy concentrated loads such as cargo yards, munitions haul roads, or similar critical roadways. For roads receiving HIR-III recycling, use the recycled layer as a base and determine the thickness of the new surface with the appropriate design analysis.

5-2.2.4 Past and Current Use.

Resistance to using HIR remains for the following reasons: (a) greater confidence in the conventional HMA overlay (b) lack of knowledge or appreciation of the new HIR technology, and (c) lack of appreciation of the quality of the pavement achieved with this technology. The quantity of the three types of HIR used in the United States is approximately the same (Emery, 2007; Kandhal and Mallick, 1997).

HR has been widely used in the US since the early 1980s. Most projects incorporate approximately 20 to 25 percent RAP or less.

5-2.3 Mix Design.

Follow the basic steps below for mix design for HIR/HR mixes.

1. Conduct analysis of existing pavement structure and surface condition.
2. Evaluate existing in-situ materials.
3. Sample the asphalt mixture selected for recycling by coring, sawing, or milling the pavement surface. Normally for HR, the contractor maintains RAP stockpiles as the RAP source.
4. Conduct either Marshall or Superpave mix design.

HIR is not normally recommended for airfield use, but has been used in conjunction with an HMA overlay. For roads, perform mix design with Marshall or Superpave mix design methods as specified in UFGS 32 12 16.16. For airfield pavements, perform mix design with Marshall or Superpave methods as specified in UFGS 32 12 15.13. Take samples of the surface pavement to be recycled, crush, and mix with asphalt binder or asphalt rejuvenator to determine the optimum asphalt content. Mix samples with various amounts of asphalt binder or rejuvenator and compact with a Marshall hammer or Superpave gyratory compactor. Select the asphalt content that provides approximately 4 percent air voids.

Design HR using the procedures addressed in Chapter 3. Use the two UFGS specifications (UFGS 32 12 15.13 and 32 12 16.16) to ensure production of a quality mix and successful placing and compaction.

5-2.3.1 Analysis of Existing Pavement Structure and Conditions.

Ideally, conduct a FWD evaluation and analysis prior to designing the pavement structure. If the structure is satisfactory or it needs only 1 or 2 inches (25 or 50 mm) of additional asphalt mixture, then HIR methods are suitable. If structural problems exist, or if the traffic volume or weight will increase, perform a structural analysis and design. See a description of design considerations above.

5-2.3.2 Samples.

See discussion on CIR and the following additional guidelines (NCHRP, 2001):

- For samples taken from a stockpile, take approximately 10 random samples from throughout the stockpile.
- For the samples taken from haul trucks, take samples from approximately three locations along the center of the truck bed. Take a sample approximately ¼ the way from front to back of the truck, approximately ½ the way from front to back, and about ¾ of the way from front to back. Samples should be taken underneath the surface by removing surface material with a shovel. All samples should be combined to obtain a representative sample of the truck.
- If the samples are for mix design, obtain at least 55 lbs. (25 kg) of RAP.
- If the samples are for gradation and asphalt content for QC testing, the sample size is approximately 22 lb (10 kg).

5-2.3.3 Identification of Distress Causes.

See Chapter 3 for common distresses and potential recycling methods that address distresses.

5-2.3.4 Analysis of Road Profile and Geometric Assessment.

Evaluating the existing pavement profile and cross slope can determine if a project is suitable for HR or HIR. A pavement that needs major realignments, drainage corrections or frost heave mitigation repairs, could use HR. In general, one of the three types of HIR can correct small problems with longitudinal or transverse profiles. In other circumstances, consider the following alternatives:

- Prior to overlay correct profile deficiencies by milling if the asphalt layer has sufficient thickness.
- Add granular material and new HMA or RAP to correct the profile. In this case, the options are Remix (HIR-II) or Repave (HIR-III).
- Correct what is possible during the HIR process and add HMA leveling or wearing course.
- If the HIR processes cannot correct the profile, then HR is a viable alternative.

5-2.3.5 Analysis of the Drainage Systems and Base Problems.

Thoroughly evaluate the drainage system to remove surface and subsurface water from the pavement structure. Solve drainage problems as part of any rehabilitation process. Otherwise, the problems will reoccur and significantly reduce the pavement life.

5-2.3.6 Selection of Materials and Methods.

Select satisfactory materials for use in HIR and HR. These include virgin aggregates to mix with existing materials to provide a satisfactory aggregate gradation. Select an appropriate asphalt binder so that when added to the RAP binder it produces satisfactory binder properties. With HIR, only limited additional materials can be used. Hence, improvement in the mix is limited.

5-2.3.7 Marshall and Superpave Mix Design Procedure.

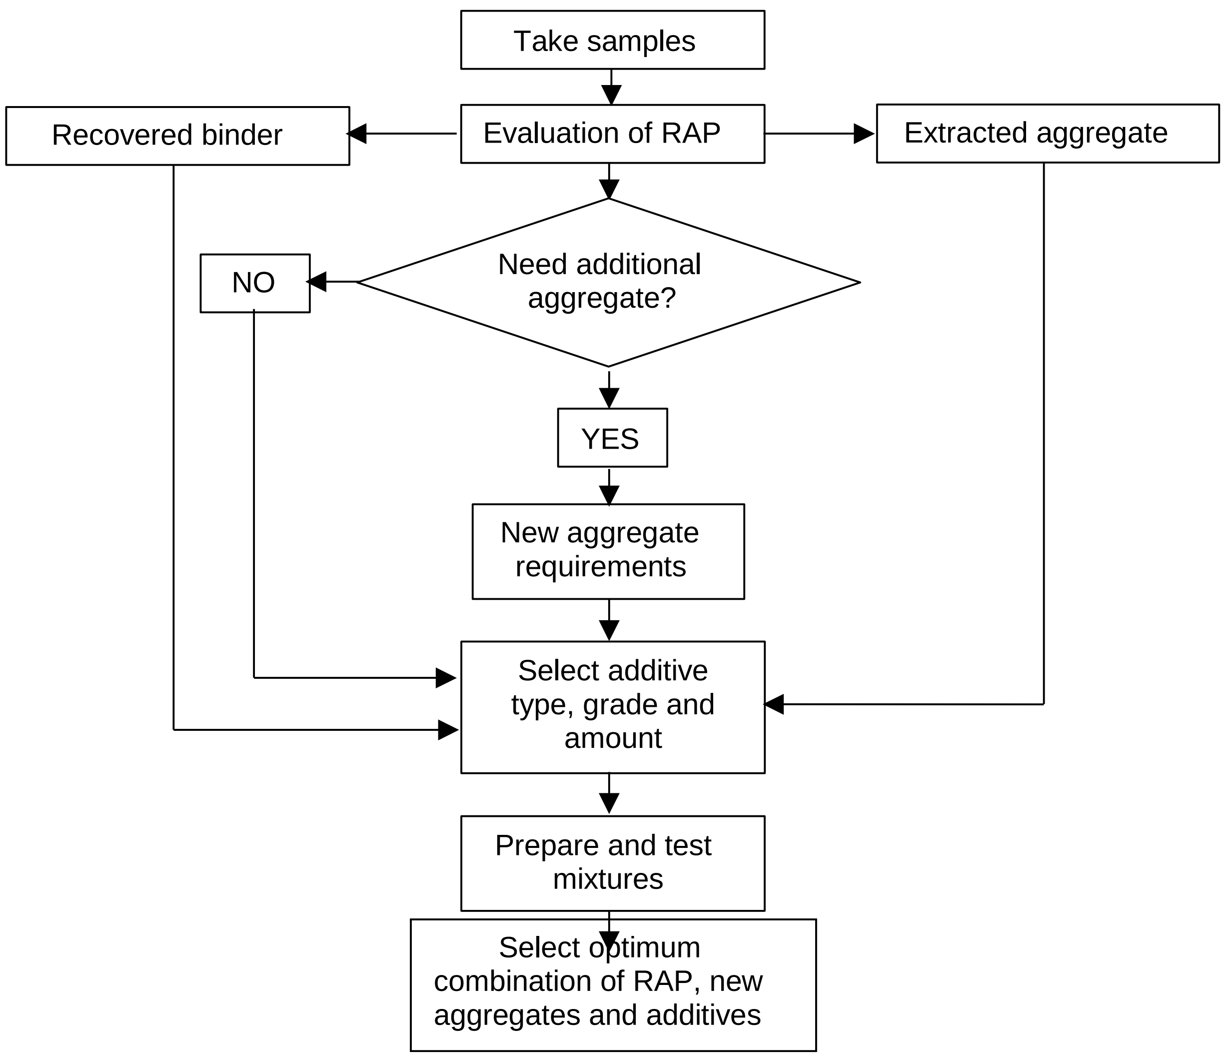
Perform a mix design to determine the percentages of RAP, new aggregate, recycling agent, and asphalt binder to use in the mixture. Base the amount of RAP used in a recycled mixture on the amount of the available reclaimed materials, the quality of the RAP, the desired properties of the recycled mix, aggregate gradation requirements, and economic considerations.

Figure 5-3 is a flowchart for the mix design procedure for the hot recycled mixtures. HIR adds very little or no additional virgin aggregates to the mixture, whereas, with HR there is at least 80% virgin aggregates in the mixture.

Compact samples of the recycled mixtures at various asphalt contents. Add the amount of new asphalt or recycling agent in 0.5 percent increments from 0 percent to 1.0 percent beyond the estimated optimum asphalt content. Compact the samples at the required effort, either 50 blows with a Marshall hammer (or 50 Superpave gyrations) for low-pressure tires (<100 psi or 6.9 kPa) or 75 blows with a Marshall hammer (or 75 Superpave gyrations) for high-pressure tires (>100 psi or 6.9 kPa), and determine the density, stability, flow, voids total mixture, and voids filled with asphalt. Only determine stability and flow with samples compacted with the Marshall hammer. Plot these determinations and draw curves to select the optimum asphalt content.

Determine the optimum asphalt content by selecting the virgin asphalt content equal to the amount that provides 3.5 percent air voids for HIR and 4.0 percent air voids for HR. The optimum additional asphalt binder is often between 0 and 1 percent for HIR mixtures. When the selected optimum additional asphalt is 0 percent or less, add no additional asphalt binder, since it may cause low voids in the asphalt mixture resulting in an asphalt mix that tends to bleed, rut, or shove under traffic. When the optimum asphalt content is very low use a recycling agent instead of asphalt binder.

Figure 5-3 Mix Design Procedure for Hot Recycled Mixtures



5-2.3.8 Evaluation of Existing Materials.

When evaluating existing materials, determine the properties of the RAP, extracted aggregate and recovered binder. Test samples of RAP, taken from stockpiles or directly from the existing pavement, in the laboratory. If performing a 5-point Marshall mix design, obtain a total of 18 to 20 cores, 2 inches (50 mm) thick and 6 inches (150 mm) in diameter or approximately 90 pounds (40 kilograms) of material.

5-2.3.8.1 RAP Properties.

Evaluate RAP properties to identify deficiencies to improve by adding rejuvenators, asphalt binder, fine and/or coarse aggregate or new hot mix for HIR. Determine the gradation of the RAP aggregate after solvent extraction (ASTM D2172) or ignition test (ASTM D6307) to remove asphalt binder. Determine the aggregate gradation using ASTM C136, the fractured faces by ASTM D5821, and flat and elongated particles by ASTM D4791. Properties of the combined aggregate from RAP and new aggregate sources must meet the same requirements as virgin aggregates in conventional HMA. It is difficult to recover enough aggregate from the RAP to conduct all of the required aggregate tests. Hence, the typical aggregate tests conducted are gradation, fractured faces, and fine aggregate angularity.

Determine the asphalt binder content of the asphalt mixture.

5-2.3.8.2 Virgin Aggregates.

a. Without adding significant amounts of new aggregate when producing HR, air pollution during mix production for most plants would exceed allowable levels. Adding new aggregate in a drum mix plant creates an aggregate shield preventing the flame from directly contacting the RAP and thereby burning the asphalt binder in the reclaimed asphalt pavement. Burning asphalt binder is the main source of air pollution during HR production.

b. Improve RAP aggregate gradation when using HR or HIR by adding virgin aggregates. Many times existing pavements do not contain the desired aggregate gradation. If they do contain a satisfactory gradation, this gradation may change during milling or crushing. Therefore, adding new aggregate modifies the recycled mix gradation to an acceptable level.

c. Often, the quality of the aggregates in an existing mix is not acceptable, even though the gradation is satisfactory. One cause of poor quality in an aggregate blend is an excessive amount of natural sand. Natural sand is a poor aggregate for asphalt mixtures, but because of its abundance and low cost, asphalt mix designs often use it in excess. The maximum amount of natural sand allowed by the airfield specifications is 15 percent, but many RAP stockpiles contain significantly more natural sand. Adding crushed stone decreases the relative percentage of natural sand in the mixture and improves the RAP aggregate quality.

d. Existing HMA pavements may contain filler (material passing the No.200 sieve) significantly higher than the 6 percent maximum allowed for HMA mixtures. Milling and crushing RAP generates up to 1 to 3 percent additional filler due aggregate breakdown. To control the filler use new aggregates with minimal filler content. In some cases, wash the virgin aggregates to minimize the filler material or screen the RAP into coarse and fine RAP stockpiles. The coarse RAP stockpile will have significantly less filler than the fine aggregate stockpile and thus less effect on the total amount of filler.

5-2.3.8.3 Recycling Additive.

a. The oxidized asphalt binder in existing HMA pavement requires some modification during recycling to produce an asphalt binder with acceptable binder properties. Ensure the mixture of old and new HMA material meet the specifications for the asphalt mixture using virgin materials. If not adding new aggregate to the mix, such as in HIR, adding asphalt or recycling agent to produce satisfactory asphalt binder properties may generate a rich mixture. The asphalt binder content of an existing pavement mixture is generally near the optimum asphalt content; thus, adding more asphalt binder or recycling agent for HIR mixtures generates excessive asphalt content. Not modifying the existing asphalt binder with low viscosity asphalt or recycling agent produces a brittle mixture. Using RAP in a mix such as for HR mixtures allows significant modification of the RAP aggregate quality and binder properties since there is significantly more virgin materials in the mixture. However, for HIR mixtures, most aggregate comes from the RAP, so this quality is much more important.

b. Restoring the existing asphalt binder is important for the success of a recycled mixture. Using a high amount of RAP in a mixture, such as for HIR, it is difficult to control the properties of combined binder as the amount of reclaimed asphalt binder likely exceeds the amount of virgin asphalt binder. For HIR, determine the amount and type of new asphalt binder required using the mix design process and to obtain the desired total binder properties. Recommendations for recycling additives for HIR are (ARRA, 2001):

- Use a recycling agent only to restore or rejuvenate the existing asphalt binder properties. Assume that the recycling agent thoroughly mixes with the aged asphalt binder during plant or in-place mixing.
- Use a performance grade (PG) binder with reduced high temperature grade as the new asphalt binder instead of a recycling agent. The assumption is that a new asphalt binder of lower PG grade will effectively combine with the aged binder resulting in an acceptable combined asphalt binder.
- Use a recycling agent and a soft new asphalt binder combined to rejuvenate the aged asphalt binder.

- Select asphalt binders according to the following standards (UFGS 32 12 15.13, UFGS 32 12 16.16):
  - ASTM D6373 for performance grade
  - ASTM D946 for penetration grade (penetration grading is used in some areas outside the U.S.)

c. When selecting PG asphalt binders in the U.S., consider adopting local DOT requirements for binder selection. Tweak the identified grades to meet mission needs. This makes it easier to obtain sources for asphalt binder and reduces the cost.

d. Typically, rutting is not a major problem on most airfield runways. However, for high traffic volumes on taxiways and at the end of runways, pavement rutting may occur under slow moving traffic with high tire pressures. High tire pressures exceeding 200 psi (1.4 MPa) may contribute to rutting. Some aircraft tire pressures exceed 300 psi and these high pressures can produce rutting in an asphalt mixture.

e. Use PG graded asphalts in HR mixture. Use recycling agents in HIR mixtures. Since a small amount of recycling agent will modify the RAP binder, ensure it contains an optimum residual asphalt content. Use the recycling additive to achieve the desired asphalt binder physical properties. Compare the physical properties of the combined asphalt binder (new recycling additive plus aged asphalt binder) with those of the original aged asphalt binder to establish the amount of recycling additive necessary.

f. In general, use softer recycling agents and lower new binder contents for HIR recycling methods (FHWA, 1997). Select the appropriate tests to ensure grade conformance of new asphalt specified, using the following guidance.

- If using a PG asphalt, use the dynamic shear rheometer and bending beam tests.
- If specifying a penetration grade asphalt, use a penetration test.

g. Ensure the new asphalt binder added to the HR mix has a grade that is no more than two PG grades different from that specified in paragraph ASPHALT CEMENT BINDER of the UFGS 32 12 15.13 or UFGS 32 12 16.16 specifications. Ensure the temperature of unmodified asphalts is no more than 325 ºF (160 ºC) when added to the aggregates and the temperature of modified asphalts is no more than 350 ºF (175 ºC) when added to aggregates.

5-2.3.8.4 Mix Properties.

Ensure the HR mix properties comply with the requirements indicated in Table 5-1 for airfields (UFGS 32 12 15.13) and Table 5-2 for roads (UFGS 32 12 16.16).

Table 5-2 Hot Mixed Recycled Properties for Airfields[5]

Parameter	Requirement	
	75 blows 75 gyrations	50 blows 50 gyrations
Minimum stability[4], pounds	2150	1350
Flow, 0.01 inch	8-16[1]	8-18[1]
Air voids, percent	4	4
Minimum percent voids in mineral aggregate	---[2]	---[2]
Dust proportion[3]	08-1.2	0.8-1.2
TSR, minimum percent	75	75

[1]The flow requirement is not applicable for polymer modified asphalts. Do not use flow with Superpave gyratory compactor.

[2]Aggregate gradation 1, minimum VMA = 13 percent; aggregate gradation 2, minimum VMA = 14 percent; aggregate gradation 3, minimum VMA = 15 % (see UFGS 32 12 15.13).

[3] Calculate dust proportion as the aggregate content, expressed as a percent of weight, passing the No. 200 sieve, divided by the effective asphalt content, in percent of total weight of the mixture.

[4]The stability requirement is not applicable when Superpave gyratory compactor is used.

Table 5-3 Recycled Asphalt Mix Properties for Roads[6]

Parameter	Requirement	
	75 blows 75 gyrations	50 blows 50 gyrations
Minimum stability[2], pounds	1800	1000
Flow[2], 0.01 inch	8-16	8-18
Air voids, percent	3-5	3-5
Minimum percent voids in mineral	---[1]	---[1]
TSR, minimum percent	75	75

[1] Aggregate gradation 1, minimum VMA = 13 percent; aggregate gradation 2, minimum VMA = 14 percent; aggregate gradation 3, minimum VMA = 15 % (See UFGS 32 12 16.16)

UFC 3-250-03 presents additional information on mix properties and complete description on mix design.

[5]UFGS 32 12 15.13.

[6]UFGS 32 12 16.16.

5-2.3.9 Structural Design.

See guidance on structural design above.

The structural design of road and airfield pavements with hot recycled asphalt mixes (HR, HIR) follows the same criteria and procedure as for the conventional design for flexible pavements for roads and airfields. HIR and HR mixes perform the same as virgin asphalt mixtures. Use the same thickness design requirements for HIR and HR for conventional asphalt pavement design. For CBR design, the equivalency factors for HIR and HR are the same as for conventional asphalt mixture.

5-3 CONSTRUCTION.

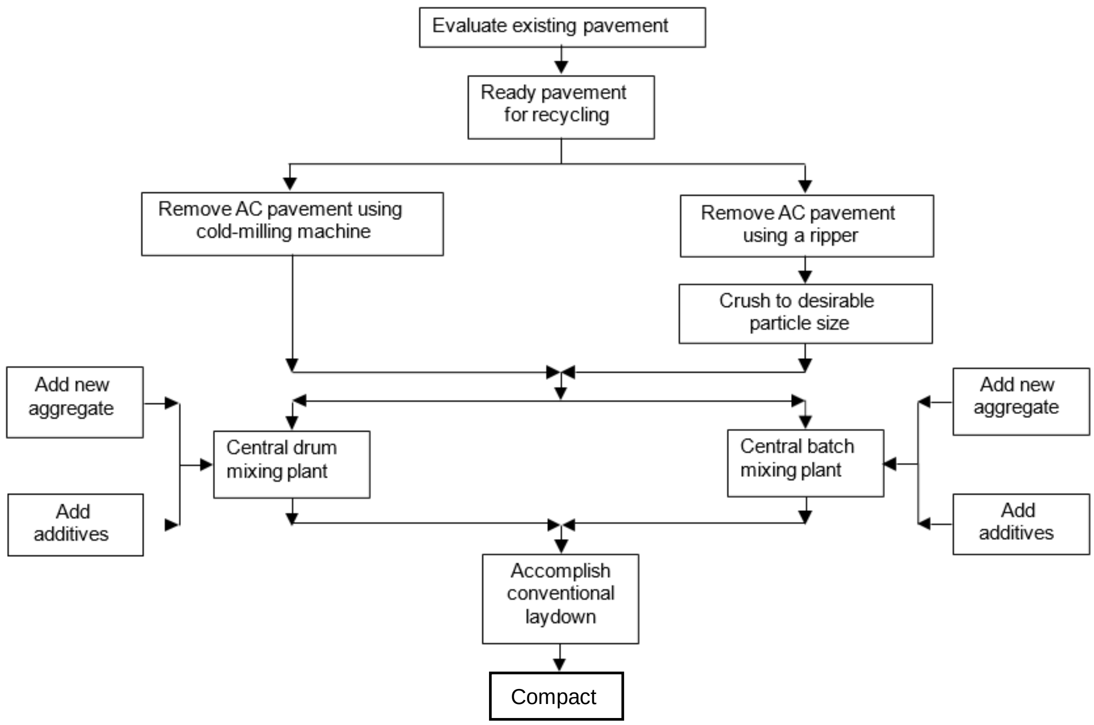
5-3.1 HR.

The HR process encompasses six basic construction steps (ARRA, 2001):

1. Remove the existing pavement materials to the desired depth.
2. Prepare the RAP for recycling (stockpiling and crushing).
3. Utilize RAP as available from other projects.
4. Blend old and new materials in a HMA production facility.
5. Mix the components in the proper proportions per the mix design.
6. Place the mixture and compact.

Figure 5-4 depicts these processes below.

Figure 5-4 Hot-Central Plant HR Recycling Process



HR mixture is a commonly used HMA mixture. In fact, most HMA mixtures now contain some amount of RAP in the mix. Asphalt mixtures on average among the various state DOTs contain approximately 20 percent RAP. The procedures used to produce and construct HR mixtures are essentially the same as used to construct HMA without RAP.

The construction equipment include: 1) equipment to remove existing material, 2) equipment for crushing RAP, 3) equipment for mixing and placing the HR, and 4) equipment for field compaction. The following sections discuss this equipment.

Transport HMA from the mixing plant to the site in clean, tight truck beds. Schedule deliveries for uniform placement and compaction of the mixture with minimum paver stopping and starting. Provide adequate artificial lighting for night placement. Do not permit hauling over freshly placed material until the material is compacted and allowed to cool to 140 ºF (60 ºC).

5-3.1.1 Removing and Processing Existing Material.

Remove asphalt mixtures with a milling machine to the desired depth. On some projects, a ripper tooth removes the asphalt mixture, but this requires crushing prior to re-use and is reserved for small jobs where full depth removal is required. A milling machine can remove up to 4 inches (100 mm) of HMA in one pass. It uses sensors that follow a grade reference and/or slope control to establish the finished grade. Since heat is not used, there is no smoke pollution. However, excess dust may occur, and this is solved by spraying a small amount of water onto the pavement in front of the milling machine. Milling machines are used during all weather conditions and produce finished milled surfaces that conform to the project specifications (UFGS 32 01 16.71). The milled HMA becomes RAP material to be used on the existing project or on future projects to produce HR. Ensure project specifications clearly state who owns the RAP since most state DOTs provide the RAP collected from a project to the contractor at the end of the project.

5-3.1.2 Mixing and Placing.

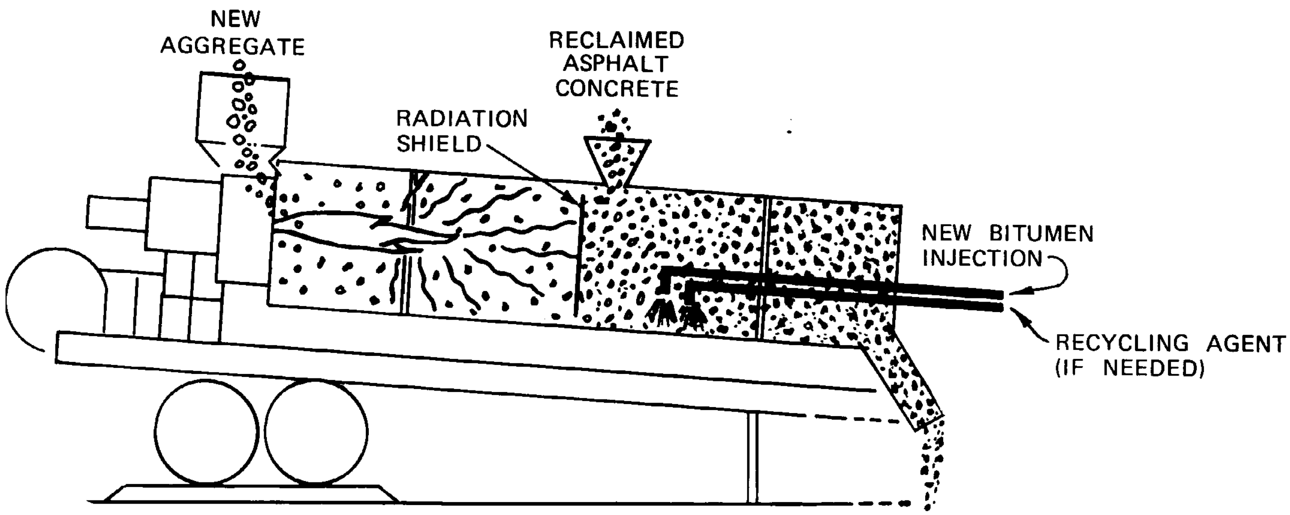
Use a batch or drum mix plant to blend recycled materials. Place recycled material with a conventional asphalt paver. When using a parallel flow drum mixer (aggregate flow and flame moving in same direction) for recycling, add the new aggregate at the high side of the drum near the flame, as indicated by Figure 5-5. The aggregate absorbs much of the heat from the burner and acts as a shield to protect the reclaimed asphalt concrete, new asphalt binder, and recycling agent from the adverse effects of the open flame. Add the RAP to the drum near the midpoint followed by the recycling agent and new asphalt. If air pollution is a problem, modify the mix design by lowering the percentage of RAP used in the mix to reduce emissions to an acceptable range.

When using a counter flow drum mix plant (aggregate flow and flame going in opposite directions), add the aggregate at the top of the drum and the flame is located at the bottom end of the drum. Add the RAP and asphalt binder in one of several processes, but in a way to keep the asphalt binder away from the open flame. This counter flow process has fewer emission issues when compared to the parallel flow drum plant.

Modify batch plants to produce recycled mixtures as shown in Figure 5-6. The modification consists of adding a feeder and conveyor to carry the reclaimed asphalt pavement directly to the weigh bucket. Superheat the new aggregate that passes through the dryer between 500 and 600 ºF (260 and 315 ºC) so that when blending, the resulting mix temperature is suitable for mixing and compaction. Increasing the amount of reclaimed asphalt in the mix requires an increase in the new aggregate temperature to achieve the desired mixture temperature. In addition, additional moisture in the new aggregate or reclaimed asphalt pavement stockpiles requires additional heat to dry and adequately mix the mixture components.

Place and compact the mix at a temperature suitable for obtaining density, surface smoothness, and other specified requirements (UFGS 32 12 15.13 and UFGS 32 12 16.16). Upon delivery, collect the mixture from the trucks and place across the full width of the pavement with an asphalt paver. Using a material transfer vehicle (MTV) allows the paver to move forward continuously and minimizes segregation. Airfield construction requires using an material transfer vehicle (MTV) (UFGS 32 12 15.13). Using an MTV, produces a smoother, more uniform pavement surface. Place the mixture uniformly at a depth that, when compacted, produces the required thickness and conforms to the specified grade and contour. Regulate paver speed to eliminate asphalt mat pulling and tearing. Unless otherwise permitted, begin placing the mixture along the centerline of a crowned section or on the high side of areas with a one-way slope.

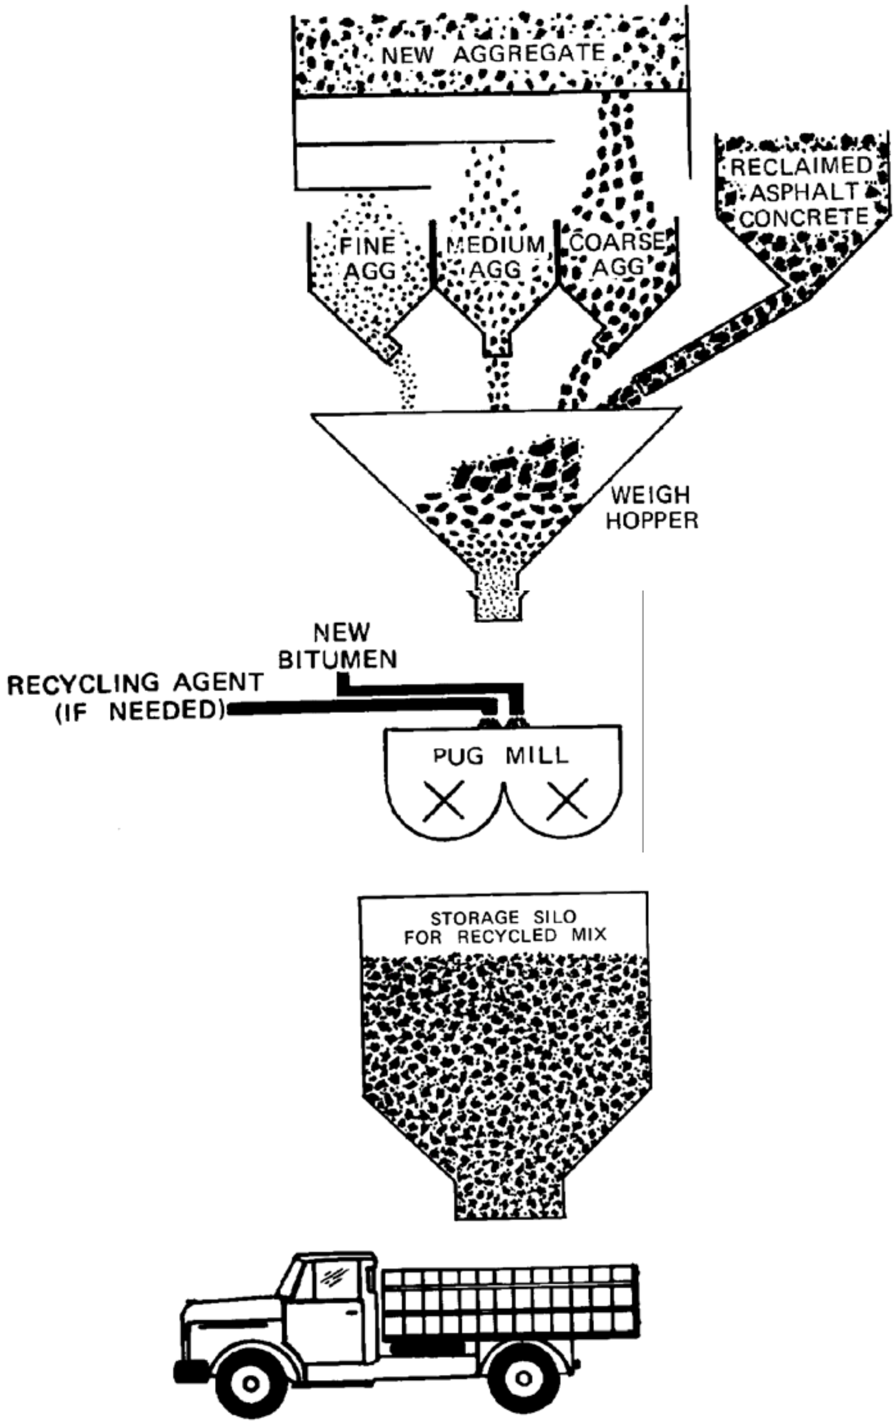
Figure 5-5 HR Production in a Parallel Flow Drum Mix Plant



5-3.1.3 Field Adjustments of the Mix.

The JMF obtained in the laboratory may require adjustments in the field to ensure that mixture and material properties meet the specifications. Make these adjustments based on the visual appearance of the recycled mix, test results obtained from samples of the HR, test results of the recovered aggregate, and test results from the recovered asphalt binder (ARRA, 2015).

Figure 5-6 Hot Recycled Asphalt Mix Production in a Batch Plant



5-3.1.4 Compaction.

Rollers used to compact asphalt mixtures include static steel-wheel, vibratory steel-wheel, and rubber-tired rollers. These rollers perform breakdown, intermediate, and finish rolling. Conduct breakdown rolling in vibratory mode, and occasionally, in static mode. Perform intermediate rolling in the vibratory mode while finish rolling in the static mode.

Rubber-tire rollers perform intermediate rolling of HMA mixtures. These rollers provide an increase in compaction after breakdown rolling and seal the surface. Ensure rubber-tired rollers are equipped with an operational watering system for the tires and that scrapers and pads affixed to prevent accumulation of materials on tires. Ensure rubber-tired rollers have skirts affixed to the roller that shield the tires from wind to prevent tire heat loss. Use a 10-ton or larger rubber-tired roller to compact all heavy-duty HMA pavements. Operate rollers at or below 3 to 5 mph (4.8 to 8 km/h) (fast walking speed). Make gradual starts and stops to avoid damaging the freshly laid mixture. Do not allow quick turns or any turns that cause cracking on freshly laid mixture. The contractor has discretion on sequence of rolling operations and the type of rollers used.

Compact the paving mixture while the mix is sufficiently hot, because rolling is relatively ineffective after the mixture cools below a minimum temperature and it is very difficult to obtain the required density. Following compaction and a cooling period, the pavement becomes very stable due to coarse and fine aggregate interlocking and adhesion of the asphalt binder as well as a high resistance to moisture penetration and frost damage.

Determine density results from 4 inch (100 mm) or 6 inch (150 mm) diameter cores randomly cut from the pavement. Use density gauges for QC testing, but not for final acceptance testing. Use cores for final acceptance of compaction.

5-3.2 HIR.

HIR treatment application is normally one lane wide (12 ft or 3.7 m). If pavement width is not a multiple of the treatment width, then overlap treatments. Limit overlaps to 2 to 6 inches (50 to 150 mm).

5-3.2.1 Construction Process.

5-3.2.1.1 Surface Recycling (HIR-I).

Major equipment includes brooms, trucks, front-end loaders, graders, asphalt distributors, self-contained heating units, heater-scarifiers, hot-milling machines, pavers, trucks, and/or cold-milling machines. Figures 5-7 through 5-9 show examples of a surface recycling heating unit, surface recycling scarification teeth, and surface recycling, respectively. There are single-pass (surface is recycled and left as final wearing course) and double-pass (surface is recycled and then an HMA overlay or a surface treatment is applied over it) procedures.

Figure 5-7 Surface Recycling Heating Unit

Figure 5-8 Surface Recycling Scarification Teeth*

*Source: ARRA, 2001.

Figure 5-9 Surface Recycle Mix Placement*

*Source: ARRA, 2001.

5-3.2.1.2 Remixing (HIR-II)

Hot in-place remixing operations encompass heating, scarifying, rejuvenating, mixing (and/or adding new HMA), leveling, re-profiling, and compacting. The remixing equipment heats, scarifies, or hot mills the existing pavement, mixes new materials, and lays the combined recycled and new mixtures. Figure 5-10 shows an example of a remixing train. Remove the existing pavement to depths of 0.4 to 2 inches (10 to 50 mm) (Kandhal and Mallick, 1997). Modern remixing equipment can work with up to 2 inches (50 mm) of the pavement and increase the pavement thickness by 1 inch (25 mm) (ARRA, 2001). There are two remixing methods:

a. Single Stage Remixing. Heat the existing asphalt pavement, soften with recycling agent or soft asphalt binder and scarify to the desired depth (1 to 2 inches [25 to 50 mm]), mix new HMA with the scarified material, and re-lay and compact the combined recycled mix. Figure 5-11 is an example of this method.

b. Multiple Stage Remixing. Heat the existing asphalt pavement, soften with recycling agent or soft asphalt cement, and scarify in a number of thin layers until achieving the pre-determined full treatment depth. Two to four layers are normally heated and scarified. Accumulate the scarified material is accumulated in a windrow to facilitate the continued heating and scarification of underlying layers. The range of treated depths is between 1-1/2 and 3 inches (40 to 75 mm). Figure 5-12 shows a windrow with scarified material.

Figure 5-10 Example of Remixing Train

Figure 5-11 Example of Single Stage Remixing Train

Figure 5-12 Multiple Stage Remixing with Windrow of Scarified Material

5-3.2.1.3 Repaving (HIR-III).

The equipment used in this process are the same as for HIR-I and HIR-II. In addition, ensure the repaving equipment can place an integral HMA overlay as thin as 1/2 inch (12.5 mm), using the appropriate HMA (use a fine graded mixture) (ARRA, 2001). As discussed earlier, repaving is a combination of surface recycling or remix with an overlay of HMA. The surface recycled or remixed layer and the HMA overlay are compacted simultaneously, which results in a thermal bond between the two layers. The surface recycled mix works as a leveling course and the HMA layer as a wearing course. The construction of HIR-III uses one of two approaches:

- Single Pass Repaving. Single Pass Repaving uses one unit equipped with two screeds. The unit scarifies the heated and softened pavement, adds the required amount of recycling agent, mixes the recycled mix prior to the first screed, receives the new HMA, and transports it over the recycled mix. The first screed places the recycled mix while the second screed places the new HMA overlay on top of the recycled mix. The two layers are then compacted.
- Multiple Pass Repaving. In this case, place the surface recycled mix and work with its own placing and screeding unit to meet the longitudinal profile and cross-slope requirements. Immediately place the new HMA overlay material on the hot uncompacted recycled mix with a conventional asphalt paver and then compact the two layers.

5-3.2.2 Placement of the HIR Material.

Place the recycled mixtures with a screed, often attached at the end of a recycling train or on a separate paver. After placement, compact the mix with rollers to achieve the desired density. Single-pass methods provide a relatively small opportunity for corrections from the existing grade.

Difficulty in placing the recycled material increases when the HMA overlay thickness and the underlying HIR treatment depth is greater than 3 to 4 inches (75 to 100 mm) (ARRA, 2001). Do not use layers greater than 3 inches (75 mm) compacted thickness.

5-3.2.3 Field Adjustments of the Mix.

See paragraph for HR.

5-3.2.4 Curing.

HIR mixes require no curing. Once these mixtures cool to 140 °F or lower, allow traffic.

5-3.2.5 Compaction.

See paragraph for HR.

5-3.2.6 Field Density.

See paragraph for HR.

5-3.2.7 Surface Course.

Add surface course over HIR mixtures to provide improved resistance to climatic conditions and traffic.

5-4 QUALITY CONTROL ISSUES.

5-4.1 Specifications.

Conduct all hot recycling projects (HR, HIR-I, HIR-II and HIR-III) in accordance with the respective UFGS specifications: UFGS 32 01 16.74, UFGS 32 01 16.75, UFGS 32 12 15.13 and UFGS 32 12 16.16.

5-4.2 Quality Control/Quality Assurance.

QC/QA practices for hot in-place recycling are the same as typically used for conventional HMA. QC/QA includes extracting, recovering, and testing of the blended asphalt binder. Consider variability of the RAP when preparing QC/QA limits and pay factors for individual projects, mainly for HIR (Kandhal and Mallick, 1997). Develop a Quality Control Testing Plan as part of the approved recycled mixture project. Ensure the plan addresses all elements that affect the quality of the pavement including, but not limited to, the following elements (UFGS 32 12 15.13 and UFGS 32 12 16.16):

- recovered asphalt binder properties
- mix design and unique JMF identification code
- aggregate grading, angularity, flat/elongated particles
- quality of materials
- stockpile management and procedures to prevent contamination
- proportioning
- mixing and transportation
- correlation of mechanical hammer to hand hammer
- moisture content of mixtures
- placing and finishing
- thickness
- joints
- field compaction, including joints
- surface smoothness
- truck bed release agent

When the contractor develops a Quality Control Plan, ensure performance of all required testing and inspection in accordance with the specification requirements. Ensure the plan clearly explains how the contractor will control the quality of work.

5-4.2.1 Field Sampling and QC Testing.

The field sampling and QC testing depend on the testing program requirements. The testing program, the main part of the QC/QA process, includes, but is not limited to,

- Tests for the control of asphalt content, aggregate gradation and specific gravity.
- Temperatures, aggregate moisture, and moisture in the asphalt mixture.
- Laboratory determined air voids (air voids in total mix (Va), voids in mineral aggregates (VMA), voids filled with asphalt (VFA)).
- Marshall stability and flow tests.
- In-place density (use a density gauge to monitor pavement density, when correlated to core samples but not for acceptance of density).
- Grade conformance and surface-smoothness.
- Perform additional testing at the discretion of the contractor as necessary to control the process. When field sampling follow UFGS requirements

(UFGS 32 01 16.74, UFGS 32 01 16.75, UFGS 32 12 15.13; UFGS 32 12 16.16).

Additional guidelines for preparing a field-sampling plan for roads are below (ARRA, 2001; FHWA, 1997):

- Divide the project into homogeneous sections (similar materials and/or performance.
- Design field sampling according to these homogeneous sections.
- Use random sampling methods for setting field sampling according to the homogeneous sections for adequate recycling mix.
- Use pavement coring to obtain field samples (typically, 6-inch (150-mm) diameter cores).
- If necessary, use sawing for block sampling.
- Determine number of samples according to the size of the project:
  - Large projects, with more than 4 miles (6.4 km), require at least two samples for every mile (1.6 km) with a minimum of 6 samples per project
  - Smaller projects, like in urban areas, would require at least 8 samples per mile (1.6 km) or one per block if the pavement is not homogeneous

To prepare a field sampling plan for airfields use the approach presented in Chapter 4.

CHAPTER 6 RECYCLING FOR CONCRETE SURFACED PAVEMENTS

6-1 INTRODUCTION.

Concrete pavement recycling is a rehabilitation technique that reuses PCC material in an existing concrete pavement structure. Accomplish the reuse through fractured slab technologies including break/crack-and-seat and rubblization. Alternatively, conduct slab demolition, removal, and reprocessing activities to produce RCA. Depending on the technique, the recycled material can serve as a base material or as aggregate in new PCC or lean concrete base. Recycle composite pavements, where HMA overlays PCC, by first milling off the existing HMA.

Concrete recycling offers significant savings in the cost of hauling and disposing of old concrete and it saves natural resources and reduces or eliminates the need for new virgin aggregates. In addition, compared to the conventional form of PCC rehabilitation, HMA overlay directly over existing PCC, recycling can provide substantial performance benefits in terms of alleviating or eliminating reflection cracking in the HMA surfacing.

As discussed in Chapter 2, concrete recycling techniques are mostly suitable for existing pavement with substantially reduced structural capacity. Other forms of rehabilitation better serve pavements with functional distresses or limited structural distress such as concrete pavement restoration (CPR) and HMA or bonded PCC overlays.

This chapter presents detailed information and guidance on the four basic forms of concrete recycling: (1) break-and-seat, (2) crack-and-seat, (3) rubblization, and (4) central plant recycling. Following an overview of the applications of each method, topic sections cover structural and mix design considerations, construction details, and QC/QA issues.

6-2 OVERVIEW OF RECYCLING METHODS.

6-2.1 Break/Crack and Seat.

The break-and-seat recycling process involves fracturing the slabs of JRCP into small segments (1.5 to 4 feet [0.5 to 1.2 m]) and adequately rupturing the bond between PCC and reinforcing steel to ensure discontinuity among the fractured pieces. Firmly seat the pieces in place in preparation for an overlay. Typically, the overlay is HMA, but PCC overlays are also successful. Similarly, the crack-and-seat recycling process involves fracturing the slabs of JPCP into small segments (2 to 6 feet [0.6 to 1.8 m]), which are then seated firmly into place in preparation for an overlay (again, typically HMA, but PCC can be an option). Typical HMA overlay thicknesses range between 4 to 8 inches (100 to 200 mm), depending on expected traffic loading and the strength characteristics of the fractured PCC and base layers.

Breaking/cracking and seating reduces joint and crack movement by shortening the effective slab length and seating the broken pieces into the supporting layer (Hoerner et al., 2001). Greater impact energy is required for the break-and-seat process in order to rupture the concrete bond to the steel in the slab. In both applications, consider incorporating edge drains to facilitate drainage, given that the fractured slab allows water to flow more freely into the underlying pavement layers (Hoerner et al., 2001).

Break/crack-and-seat techniques are most appropriate for concrete pavements experiencing significant load-related distresses (e.g., linear cracking, divided/shattered slabs, corner breaks), faulting, or environmental or materials related distresses (e.g., D-cracking, ASR, scaling). However, as noted below, existing PCC airfield pavements that exhibit ASR distress are subject to restrictions with this technique. Pavements with other distresses, such as patch deterioration and unstable or settled slabs, can also benefit from breaking/cracking and seating.

PCC pavements with many failed or shattered slabs are not suitable candidates for break/crack-and-seat techniques (Ahlrich, 1992). Moreover, in situations where the pavement foundation is weak or questionable, the fractured slabs will “float” on a soft layer, manifesting in vertical and/or rotational movement of the slabs. Since these movements seriously undermine the performance of the HMA overlay, use a great deal of caution in determining when the break/crack-and-seat procedure is effective under these circumstances.

DoD policy allows the use of break/crack-and-seat techniques on all auxiliary airfield pavements and on all roadway pavements. However, caution is warranted when considering break/crack-and-seat techniques for PCC airfield pavements suffering from ASR damage. Because of the uncertainty of the effects of this phenomenon on pavement performance, TSPWG M 3-250-04.06-2 recommends consulting with AFCEC on projects involving this situation. Additionally, TSPWG 3-250-07.07-6 provides a detailed procedure for assessing and controlling the risk of break/crack-and-seat applications involving PCC with ASR distress. Recycle ASR-infected PCC can be considered on roadway pavements that are not mission critical. Practitioners are encouraged to use the risk assessment procedure outlined in TSPWG 3-250-07.07-6.

6-2.1.1 Past and Current Use.

The practice of break/crack-and-seat on airfield and roadway pavements dates back to the 1980s and 1990s. Early successes in delaying the development of reflective cracking led to increased usage of this technique.

In recent years, the use of break/crack-and-seat has decreased due to variability in performance coupled with increased success with rubblization. While most studies have shown a considerable delay in the development of reflective cracking, some studies have shown that the severity of cracking in the long-term (5 to 7 years) is comparable to that of conventional HMA overlays over non-fractured concrete.

The use of a reinforcing fabric or SAMI following placement of the first lift of HMA (leveling layer) delays reflective cracking. Consider the use of an interlayer if representative data are available to show its cost-effectiveness.

6-2.2 Rubblization and Overlay.

Rubblization fractures existing PCC pavements (JRCP, JPCP, or CRCP) in-place into small, interlocked pieces that serve as a base course for a new HMA or PCC overlay (Buncher et al., 2008). The rubblized material, ranging from sand-sized particles to 6 inches (150 mm) at the surface and 6 to 15 inches (150 to 375 mm) at the slab bottom, resembles a dense aggregate base layer with a high degree of particle-to-particle interlock. Seat the rubblized layer using specific rolling protocols. Although the thickness of an HMA overlay depends largely on expected traffic loadings and the bearing capacity of the rubblized and foundational layers, thicknesses between 4 and 10 inches (100 to 250 mm) are most common. Installation of an edge drain system dramatically improves the constructability and performance of the rubblized layer.

Rubblization eliminates joint and crack movement. The resulting fractured particle sizes somewhat resemble crushed aggregate base material. Also, because of the type of equipment used—resonant and multi-head pavement breakers—the impact load is lighter, which minimizes disturbance to the support layers and any underground features (Hoerner et al., 2001).

Consider rubblization when the amount of deterioration of the existing pavement is so great that normal break/crack-and-seat methods would not be effective (Hoerner et al., 2001). Rubblization is generally a viable option for CRCP that is distressed beyond the point that restoration strategies, such as full-depth repairs and grinding, are no longer cost-effective. One advantage of rubblization over break-and-seat is that the steel reinforcement in the pavement does not require rupturing, as the concrete completely debonds from the steel. The main disadvantage of rubblization, compared to break/crack-and-seat, is that it requires a thicker HMA surface due to the lower structural capacity of the rubblized material.

Current DoD policy allows rubblization on all airfield pavements and on all roadway pavements. However, as with break/crack-and-seat, exercise caution in considering the use of rubblization on PCC airfield pavements suffering from ASR damage. Because of the uncertainty of the effects on pavement performance, TSPWG M 3-250-04.06-2 recommends consulting with AFCEC in projects involving this situation. Additionally, TSPWG 3-250-07.07-6 provides a detailed procedure for assessing and controlling the risk of rubblization applications involving pavements with ASR. Apply this risk assessment procedure to projects that rubblize ASR-infected PCC roadway pavements.

6-2.3 Past and Current Use.

Rubblization is currently the most widely used PCC slab fracturing technique.

6-2.4 RCA Applications.

a. RCA recycling involves demolishing existing concrete pavement on grade, loading and hauling the material to an off-site crushing plant, and processing (i.e., crushing, sizing, and steel removal) the material to produce recycled aggregate of specified sizes (Hoerner et al., 2001). Use RCA in unbound base/subbase layers, asphalt or cement-treated layers, lean concrete bases, or PCC surface courses (low-type facilities only).

b. RCA is best suited for existing PCC pavements that have reached the end of their useful life. Hence, pavements with extensive amounts of slab cracking, joint deterioration, slab settlement, faulting, or environmental or materials-related distresses are good candidates for this activity. Compared to conventional reconstruction using virgin materials, reconstruction using RCA conserves materials, reduces landfill requirements, and reduces project costs.

c. RCA recycling can be performed on any existing PCC pavement type—JPCP, JRCP, or CRCP (Hoerner et al., 2001). Reinforcing steel hampered the productivity and effectiveness of many early RCA recycling projects. Equipment innovations over the years have virtually eliminated problems in processing reinforced concrete material.

d. The coarse fraction of RCA retained on the 3/8-inch (9.5-mm) sieve is preferred for most applications. This is because of the high degree of angularity and high absorption capacity of the RCA fine fraction adversely affects the workability of a resulting mix (Hoerner et al., 2001). The addition of natural sand can restore workability.

e. Current DoD policy allows RCA as aggregate base and subbase material, and as aggregate for lean concrete base on all airfield and roadway pavements. The use of RCA in new PCC is limited to auxiliary airfields and minor roads. Do not use RCA from pavements with severe D-cracking in PCC surface courses. In addition, because of the uncertainty of the effects of ASR-infected RCA on pavement performance, TSPWG M 3-250-04.06-2 recommends that such material not be used in any application within an airfield pavement structure. Additionally, TSPWG 3-250-07.07-6 provides detailed procedures for assessing and controlling the risk of RCA applications involving ASR-infected pavements. Use this risk assessment procedure for roadway projects in which RCA from PCC pavement with ASR distress is used.

6-2.4.1 Past and Current Use.

RCA is used predominantly as a replacement for virgin aggregate in granular, cement-treated, or lean concrete base layers and, to a lesser extent, in PCC and HMA surface layers (Saeed et al., 2006). Roughly two-thirds of RCA usage in pavement applications is for unbound base or subbase layers.

RCA has been used at several DoD locations including Selfridge ANG, Shaw AFB and North Auxiliary Field in South Carolina, Grand Forks AFB in South Dakota, Mountain Home AFB in Idaho, Offutt AFB in Nebraska, and Holloman AFB in New Mexico (Saeed et al., 2006). Commercial airport applications include Atlanta Hartsfield-Jackson International Airport and the former Denver Stapleton International Airport.

Several State DOTs use RCA in pavement construction. A survey of state DOTs indicates the following usage (FHWA, 2005):

- RCA Used as Aggregate: 41 of 50 states.
- RCA Used as Base Aggregate: 38 of 50 states.
- RCA Used as PCC Aggregate: 11 of 50 states.
- RCA Used as HMA Aggregate: 8 of 50 states.

6-3 STRUCTURAL DESIGN CONSIDERATIONS.

6-3.1 Break/crack-and-seat and overlay.

a. The structural design of break/crack-and-seat and overlay projects centers on the structural characteristics of the fractured layer and underlying base and subgrade layers in response to anticipated traffic loading (Huang and White, 1995). The values selected for these parameters determine the thickness of the HMA overlay placed on the fractured PCC layer. Perform the HMA overlay thickness design using the flexible pavement design procedures provided in UFC 3-260-02.

b. Directly test fractured layer characteristics after completing the breaking/cracking process. Estimate initial values using the best available information. Key aspects include the condition/quality of the existing PCC, the presence of steel reinforcement, and the targeted size of PCC segments.

c. The size of the broken segments is critical to the performance of the HMA overlay (Hoerner et al., 2001). Small pieces generally reduce the likelihood of reflective cracking in the HMA overlay due to reduced horizontal thermal movements in the fractured layer. At the same time, a breaking or cracking concrete into smaller pieces produces an inherently weaker fractured layer (Ceylan et al., 2005). This places greater emphasis on the structural support from the underlying layers or may require a thicker, costlier overlay to meet the structural requirements of the rehabilitated pavement.

d. For crack-and-seat, broken pieces are limited to a maximum nominal diameter of 3 feet (0.9 m). For break-and-seat, 80 percent of fractured pieces must have a diameter smaller than 2 feet (0.6 m) with no pieces larger than 2.5 feet (0.8 m). These recommended values are variable based on the quality of the subgrade and base materials, and other factors. With regard to dimensions, several studies have recommended that broken/cracked pieces be nearly equal in length and width, or that the length be slightly greater than the width (Hoerner et al., 2001).

e. NDT testing of break/crack-and-seat airfield and highway pavements indicates that the range of back-calculated elastic moduli range from a few hundred thousand psi to a few million psi (National Asphalt Pavement

Association [NAPA], 1994). Similar testing of a crack-and-seat pavement at Hunter Army Airfield in Georgia yielded an average modulus of 590,750 psi (4,073 MPa) for the 6-inch (150-mm) fractured PCC layer (Buncher et al., 2008).

f. The Mechanistic Empirical Pavement Design Guide (MEPDG) produced under National Cooperative Highway Research Program (NCHRP) Project 1-37A recommends the design moduli (E_{fs}) shown below for break/crack-and-seat layers (ARA-ERES, 2004) based on a 75% reliability level. The MEPDG states that the values given for Level 3 are conservative and not for break-and-seat unless ensuring full debonding of PCC from reinforcing steel (ARA-ERES, 2004).

6-3.1.1 High-Level (Level 1) Design Analysis.

- Good to excellent slab fracture control expected (COV=25%): Efs = 600,000 psi (4,137 MPa)
- Fair to good slab fracture control expected (COV=40%): Efs = 450,000 psi (3,103 MPa)
- Poor to fair slab fracture control expected (COV=60%): Efs = 300,000 psi (2,069 MPa)

6-3.1.2 Low-Level (Level 3) Design Analysis.

- 12-in crack spacing: Efs = 200,000 psi (1,379 MPa)
- 24-in crack spacing: Efs = 250,000 psi (1,724 MPa)
- 36-in crack spacing: Efs = 300,000 psi (2,069 MPa)

For HMA overlay design using the layered elastic design (LED) procedure, use the MEPDG Level 3 moduli above as minimum values, with adjustments made upward based on the expected quality control of the cracking operation, as shown in Table 6-1.

Table 6-1 Recommended Elastic Moduli for Cracked and Seated PCC Layers

	Modulus for Various Levels of Expected Slab Fracture Control		
	Poor to Fair	Fair to Good	Good to Excellent
12 inches (300 mm)	200,000 psi (1,379 MPa)	300,000 psi (2,069 MPa)	400,000 psi (2,758 MPa)
24 inches (600 mm)	250,000 psi (1,724 MPa)	375,000 psi (2,586 MPa)	500,000 psi (3,448 MPa)
36 inches (900 mm)	300,000 psi (2,069 MPa)	450,000 psi (3,103 MPa)	600,000 psi (4,137 MPa)

For HMA overlay design using the CBR procedure, use CBR equivalency factors (i.e., thickness equivalent ratios of an unbound base or subbase material) for the fractured PCC layer. Equivalency factors between 1.2 and 1.6 are reasonable maximum values, with the lower end representative of shorter crack spacing and lower fracture control and the upper end representative of longer crack spacing and greater fracture control.

The minimum recommended HMA overlay thickness for a crack-and-seat project is 4 inches (100 mm). The use of a reinforcing fabric or SAMI following placement of the first lift of HMA (leveling layer) delays reflective cracking. Considered for use if representative data are available to show their cost-effectiveness. The HMA material recommended for use in a break/crack-and-seat project is a standard dense-graded asphalt mixture, conforming to UFGS 32 12 15.13 for airfield pavement applications or UFGS 32 12 16.16 for roadway pavement applications.

A final consideration in the design of break/crack-and-seat projects is subsurface drainage. The installation of edge drains is highly recommended where drainage problems exist. Thus, if pavement condition or evaluation data indicate serious moisture-related issues and the existing pavement is either not equipped with a drainage system or has an ineffective system, it is strongly recommended that a new system be installed. A properly installed and maintained retrofit drainage system can play an important role in achieving the intended design life of the HMA overlay (ARA-ERES, 2004).

6-3.2 Rubblization and Overlay.

As with overlay structural design for broken/cracked-and-seated PCC, the structural response characteristics of the rubblized layer is an important parameter in determining the thickness of the overlay. Rubblized layer characteristics are unknown at the time of design. Directly test the rubblized layer after rubblization is complete and the first lift of HMA placed. Make initial estimates using the best information available.

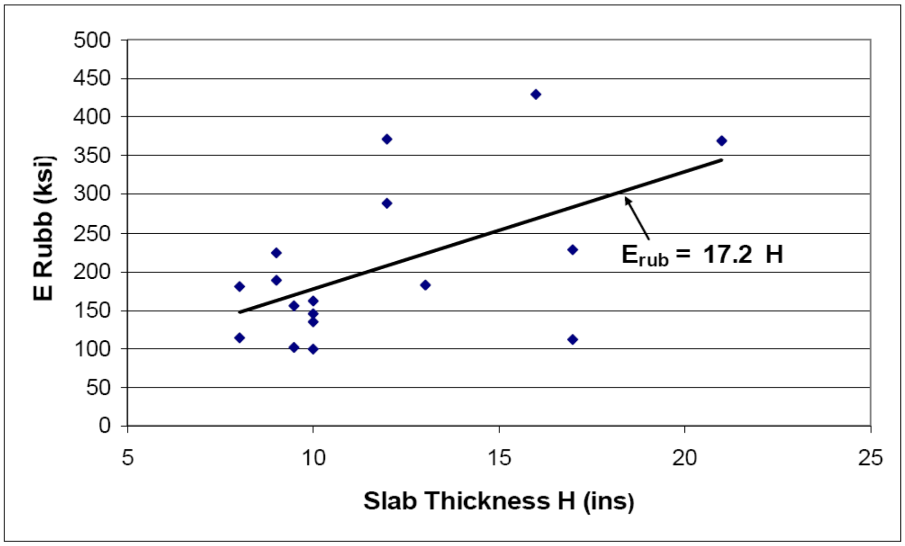
AAPTP Project 04-01, *Development of Guidelines for Rubblization*, is a comprehensive assessment on the rehabilitation of airfield pavements using rubblization. This report includes a very detailed assessment of back-calculated rubblized PCC moduli compiled from numerous studies and projects sponsored by agencies including USACE, FAA, Asphalt Institute, NAPA, FHWA, SHRP, airport authorities, state DOTs, and rubblization equipment manufacturers. Although it was acknowledged that various factors have an impact on the effective modulus of rubblized PCC (e.g., thicker slabs generally result in larger rubblized particles), results of the assessment indicated a general relationship between the modulus (E_{rub}) and slab thickness. Figure 6-1 shows this relationship. There is considerable scatter of the data points in the figure, and this sheds some concern as to its validity.

Combining this relationship with recommended moduli ranges given in the Asphalt Institute Manual Series No. 17, FAA *Engineering Brief No. 66* , American Association of State Highway and Transportation Officials (AASHTO) MEPDG, and other sources, the following ranges are recommended as design modulus values for rubblized PCC on airfield pavements (Buncher et al., 2008):

- For slabs 6 to 8 inches (150 to 200 mm) thick: moduli from 100,000 to 135,000 psi (690 to 931 MPa).

- For slabs 8 to 14 inches (200 to 350 mm) thick: moduli from 135,000 to 235,000 psi (931 to 1,620 MPa).
- For slabs >14 inches (>350 mm) thick: moduli from 235,000 to 400,000 psi (1,620 to 2,758 MPa).

Figure 6-1 Average Initial Modulus Versus Slab Thickness*



*Source: Buncher et al., 2008.

These moduli are substantially higher than that of crushed aggregate base (50,000 to 60,000 psi [345 to 414 MPa]) and are comparable to that of an asphalt-treated base (150,000 to 400,000 psi [1,034 to 2,758 MPa]). They are suitable for determining HMA overlay thickness when using LED procedures, including PCASE.

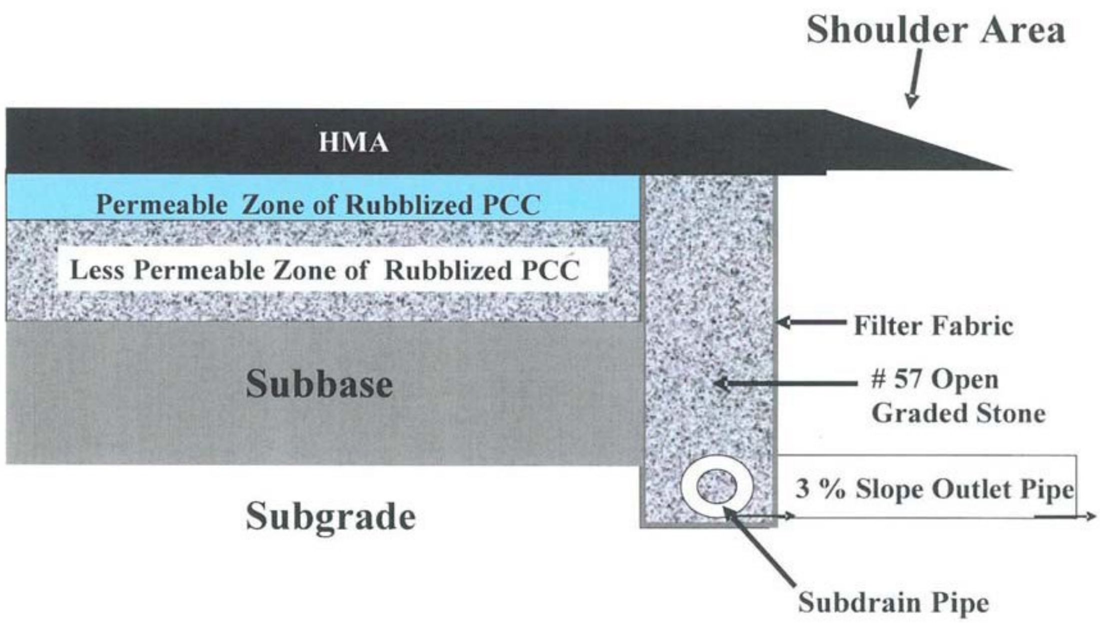
AAPTP Project 04-01 states that characterizing rubblized concrete as simply a crushed stone base layer with CBR = 100 is too conservative. The recommended method is to characterize the rubblized layer as a stronger material by using the following equivalency factors (EF) to convert the thickness of the rubblized layer to an "equivalent" thickness of crushed stone base:

- For rubblized layers 6 to 8 inches (150 to 200 mm) thick: EF = 1.2.
- For rubblized layers 8 to 14 inches (200 to 350 mm) thick: EF = 1.4.
- For rubblized layers >14 inches (>350 mm) thick: EF = 1.6.

The minimum recommended thickness of HMA overlay on a rubblized layer is 5 inches (125 mm) (Buncher et al., 2008). At least two lifts of HMA are necessary to meet grading and smoothness requirements. The minimum thickness of the first lift over the rubblized layer is 3 inches (75 mm) to prevent slippage at the interface between the HMA and the rubblized surface during compaction.

The issue of subsurface drainage is critical to the success of rubblization projects. Not only is it important in terms of the overall long-term performance of the pavement, but it can significantly affect the desired characteristics and long-term performance of the rubblized layer. A properly designed and installed edge drain system (Figure 6-2) facilitates the rubblization process by draining free water from the system, thereby yielding a stable platform for rubblizing the PCC.

Figure 6-2 Typical Longitudinal Edge Drain System for Rubblized PCC



6-3.3 Application.

When installing retrofit drains in conjunction with HMA overlays of fractured PCC slabs, consider the potential for fines generated during the slab fracturing process (particularly during rubblization) to clog the edge drain system. Carefully evaluate the potential for clogging. Choose the components of the drainage system to ensure the functionality of the drainage system. Further, since the slab fracturing process provides an open graded system, design the installed drains with adequate hydraulic capacity to handle the potential quantities of outflow. AASHTO MEPDG (ARA-ERES, 2004) provides additional guidance on edge drain systems for both break/crack-and-seat and rubblization projects.

6-3.4 RCA Applications.

Crush RCA and process to any desired grading (Saeed et al., 2006) to satisfy the intended application (unbound granular layer, lean concrete base, new PCC, etc.). Typical engineering and mechanical properties of RCA as compared to virgin aggregate materials are summarized in Table 6-2 (C). As can be seen, RCA possesses somewhat different properties than conventional virgin aggregates. Additionally, RCA typically has a lower dry density and higher optimum moisture content than virgin aggregate materials.

Table 6-2 Comparison of Typical Virgin Aggregate and RCA Properties[7]

Aggregate Property	Virgin Aggregate	RCA
Particle Shape and Texture	Well rounded, smooth (gravels) to angular and rough (crushed stone)	Angular with rough surface
Absorption Capacity, %	0.8 to 3.7	3.7 to 8.7
Specific Gravity	2.4 to 2.9	2.1 to 2.4
LA Abrasion Test Mass Loss, %	15 to 30	20 to 45
Sodium Sulfate Soundness Mass Loss, %	7 to 21	18 to 59
Magnesium Sulfate Soundness Mass Loss, %	4 to 7	1 to 9
Chloride Content, lb/yd^3 (kg/m^3)	0.00 to 2.03 (0.00 to 1.20)	1.01 to 12.00 (0.59 to 7.09)
California Bearing Ratio (CBR), %	25 to 100[a]	94 to 184[b]

[a]Typical CBR of crushed limestone is 100.

[b]Measured in lab to be up to 184, but set limit at 100 (UFC 3-250-01, UFC 3-260-02).

6-3.4.2 RCA as Unbound Base/Subbase Layer.

6-3.4.2.1 Mix Design.

UFGS 32 11 23 details the requirements for use of RCA (and other types of aggregate) as a base course in flexible pavements. Two different applications are covered, the first being an aggregate base course (ABC) having a CBR of 80 percent and the second being a graded-crushed aggregate (GCA) base course having a CBR of 100 percent.

In addition to meeting CBR, gradation, and density requirements, RCA under this specification requires the following:

- The subgrade soil contains less than 0.3 percent of sulfates to prevent expansive ettringite reaction with the RCA.
- The RCA material experience no greater than 0.08 percent expansion when tested for aggregate-alkali reactivity under ASTM C 1260 *Standard Test Method for Potential Alkali Reactivity of Aggregates (*mortar-bar method).

[7]Hoerner et al., 2001; Saeed et al., 2006.

RCA must meet all the same requirements as natural aggregates per UFGS 32 11 23.

Comparing these requirements with the typical values shown in Table 6-2, shows that abrasion resistance and soundness (sodium sulfate, in particular) are potential issues for RCA when it used as GCA base course in flexible pavements.

UFGS 32 11 20 details the requirements for use of RCA (and other types of aggregate) as a base course in rigid pavements (airfield and roadway) or as a subbase course in flexible pavements (airfield and roadway). In addition to meeting respective gradation requirements for subbase for flexible pavement, the combined aggregate must also meet the requirements for CBR equal to or larger than 50 and LA abrasion equal to or less than 50.

6-3.4.2.2 Structural Design.

The structural design of flexible pavements using RCA as an unbound granular base/subbase layer requires either a CBR or resilient modulus estimate for the subject layer. As shown previously in Table 6-2, RCA material generally exhibits CBR values between 94 and 184 that is considerable higher than crushed stone. Based on the design guides for flexible pavements (UFC 3-260-02 and UFC 3-250-01), the CBR used for base course is limited to 100 and the CBR for subbase is limited to 50.

For flexible or rigid pavement design using LED procedures in PCASE, the following relationship developed by the Transport Research Laboratory (TRL) can be used to convert CBR values to resilient modulus (psi) (ARA-ERES, 2004):

Equation 6-1. Conversion of CBR Values to Resilient Moduli

$$M_r = 2{,}555 \times (CBR)^{0.64}$$

This equation yields modulus values between 31,240 and 48,685 psi (215 and 336 MPa) for CBR values of 50 to 100 percent. Use higher modulus values (up to 70,000 psi [483 MPa]) if supported by actual test data.

For Westergaard design of rigid pavements using modulus of subgrade reaction, k, the design k-value is that effective on top of the aggregate base layer (UFC 3-260-02 for airfields; UFC 3-250-01 for roads). Derive this value using various relationships established between field plate-bearing tests performed on the subgrade (i.e., subgrade k-values) and the design thickness of the base layer (minimum of 4 to 6 inches [100 to 150 mm]). These relationships are valid for RCA base layer applications.

6-3.4.3 RCA in PCC (and Lean Concrete Base).

The following discussion focuses on new concrete mixes using RCA as aggregate for use in surface courses. Although some differences exist, the information and guidelines presented are generally applicable to RCA used in lean concrete base mixes.

6-3.4.3.1 Mix Design.

Ensure that the RCA meets the specification for aggregates. Additionally, if the original pavement being recycled is D-cracked, then crush the concrete to a maximum size of 0.75 inches (19 mm). Prohibit RCA exhibiting ASR in any airfield pavement structure.

Table 6-3 lists the effects that RCA has on PCC properties when used as the aggregate for the mix. In general, if only the coarse portion of RCA is used in the new mix, no significant changes are necessary in the mix design and workability should be unaffected (Hoerner et al., 2001). However, if recycled fines are used, the resulting mix can have reduced workability due to the highly angular nature of the recycled fines, and the mix can have a lower compressive strength due to higher water/cement ratio (greater demand for water caused by the higher absorption capacity of the recycled fines). Eliminate these problems by limiting the percentage of RCA fines to 20 percent and using natural sand for the remaining percentage.

Table 6-3 Effects of RCA on Properties of New Concrete[8]

Property	Range of Expected Changes from Similar Mixtures using Virgin Aggregates	
	Coarse RCA Only	**Coarse and Fine RCA**
Fresh Concrete Properties		
Water Demand	greater	much greater
Drying Shrinkage	20 to 50% more	70 to 100% more
Finishability	more difficult	more difficult
Mechanical Properties of Hardened Concrete		
Compressive Strength	5 to 24% less	15 to 40% less
Flexural Strength[a]	8% less	>8% less
Strength Variation	slightly greater	slightly greater
Modulus of Elasticity	10 to 33% less	25 to 40% less
Creep	30 to 60% greater	30 to 60% greater
Tensile Strength	10% less	10 to 20% less
Permeability	200 to 500% greater	200 to 500% greater
Specific Gravity	5 to 10% lower	5 to 10% lower

[a]From Hoerner et al., 2001. Assumes same water/cement ratio as conventional PCC.

[8]FHWA, 2007.

Other mix design considerations include:

- Crushing operations that are more effective at removing mortar from aggregate are desirable from the standpoint that the resulting RCA material performs more like a natural aggregate (Sturtevant et al., 2007).
- The higher mortar contents of RCA PCC mixes and the lower amounts of natural aggregate result in an increased coefficient of thermal expansion and a higher level of drying shrinkage. To reduce the potential for cracking due to drying shrinkage, shorter slab lengths (<18 feet [<5.5 m]) are used when using RCA PCC mixes (Sturtevant et al., 2007).
- Keep RCA material in a moistened state to help maintain uniformity of absorbed water during PCC production (FHWA, 2007).
- Where D-cracked pavement requires that the top size of RCA be reduced to 0.75 inches (19 mm), it is recommended that only short-jointed JPCP be constructed with this type of aggregate and that dowels be included at transverse joints (Hoerner et al., 2001). This reduces the potential for faulting and spalling at joints due to poorer aggregate interlock. As an alternative, supplement RCA with virgin aggregate with a larger maximum size.
- For applications involving ASR-infected RCA, employ proper ASR mitigation techniques, such as mandatory use of low alkali cement, use of Class F fly ash (25 to 30 percent) or ground granulated blast-furnace (GGBF) slag (40 to 50 percent), or blending of RCA with natural aggregates (HQUSACE, 2006; Sturtevant et al., 2007). Consider alkalis from deicing salts within the RCA.

6-3.4.3.2 Structural Design.

The structural design of PCC pavements using RCA is covered by UFC 3-260-02 and UFC 3-250-01. In addition to possible slab length reductions to prevent shrinkage cracking, the pavement designer must account for expected reductions in both the strength and modulus of elasticity of the RCA PCC. As seen in Table 6-3, these reductions depend significantly on whether only the coarse portion of RCA is included in the mix or both coarse and fine portions are included.

The lower effective modulus of the RCA reduces the modulus of elasticity for RCA PCC (Hoerner et al., 2001). The decreased compressive and flexural strengths of RCA PCC are primarily due to the following (Hoerner et al., 2001):

- Inherently weaker structure of the RCA (due to its cement paste–aggregate structure).
- Greater porosity of RCA PCC, due to the presence of the porous mortar component.

- Greater number of bonded interfaces in RCA PCC (i.e., between natural aggregate and the mortar [both old and new] and between the new and old mortars).
- Lower resistance of RCA concrete to mechanical action.

6-4 CONSTRUCTION.

This section describes the construction processes of each PCC recycling method. The following documents provide guide specifications covering the use of RCA in subbase and base layers or as aggregate in new PCC or lean concrete base mixtures:

- UFGS 32 11 20
- UFGS 32 11 23
- UFGS 32 11 36.13
- UFGS 32 13 14.13
- UFGS 32 13 13.06

TSPWG M 3-250-04.06-2 and 07-6 provide additional guidance concerning the use of PCC recycling methods when ASR is present in the existing PCC pavement.

6-4.1 Break/Crack-and-Seat and Overlay.

The major steps in performing rehabilitation via the break/crack-and-seat and overlay method are as follows (modified from Thompson, 1989):

1. Remove any existing HMA surfacing.
2. Isolate adjacent pavements.
3. Break/crack the existing PCC slabs.
4. Seat the fractured PCC pieces.
5. Apply special treatments.
6. Construct the HMA or PCC overlay (HMA leveling layer required for PCC overlays).

6-4.1.1 Step 1—Remove Existing HMA Surfacing.

In the case of breaking/cracking and seating of composite HMA/PCC pavements, remove the HMA surface layer for better efficiency and control of the slab fracturing process. The softer HMA layer may dissipate facture energy and slow the fracturing operation. Remove any HMA patches and any existing sealant and incompressible materials from joint reservoirs.

6-4.1.2 Step 2—Isolate Adjacent Pavement.

Prior to commencing with break/crack-and-seat operations, isolate adjacent pavement sections not subject to the fracturing work with full-depth saw cuts to prevent damage. All load-transfer devices (dowel bars, tie bars) between the pavement planned for fracturing and the adjacent pavement sections must be fully severed. At the same time, make transverse saw cuts at regular intervals along each fracture slab to ensure breakage of the reinforcing steel and disrupt continuity.

6-4.1.3 Step 3—PCC Slab Breaking/Cracking.

The purpose of slab breaking/cracking is to reduce existing PCC slabs into segments small enough to reduce movements caused by thermal stresses, yet segments are large enough to maintain structural stability (Hoerner et al., 2001). To achieve optimum success, the cracking must extend fully through the slab. In the case of JRCP, rupture/ shear the reinforcing steel at the pavement breaks and debond the concrete from the steel. To ensure that JRCP slabs are broken to size, the typical breaking pattern is somewhat smaller (nominal 1.5 to 2 feet [0.5 to 0.6 m]) than the pattern for crack-and-seat (nominal 2 to 4 feet [0.6 to 1.2 m]) (Morian et al, 2006). In addition, a significantly higher level of energy is required with breaking compared to cracking.

Various types of equipment are available for breaking/cracking PCC pavements, including impact hammers, gravity-drop hammers (Figure 6-3), guillotine hammers (Figure 6-4), and pile hammers (Figure 6-5). As Table 6-4 shows, some pieces of equipment are more suited for breaking operations than cracking operations. The effectiveness and production rates of breaking/cracking operations are highly dependent upon the equipment type and pavement thickness and other factors, such as, concrete strength and quality, foundation support conditions, presence and amount of reinforcing steel, and slab temperature.

Figure 6-4 Guillotine Hammer

Figure 6-5 Trailer-Mounted Pile Hammer*

*Source: Buncher, et al; TRB Circular No. E-C087.

Table 6-4 Summary of Equipment for Break/Crack-and-Seat Applications[9]

Type of Equipment	Operating Procedure	Manufacturer	Type of Concrete	Advantages/ Disadvantages
Gravity Drop Hammer (single-head)	Operates by lifting a mass mechanically or hydraulically, and then releasing the mass. The impact force is delivered to the pavement through an impact foot.	Arrow-Master 1350T	JPCP and wire mesh-reinforced JRCP	▪ Effective on JRCP ▪ Can develop unusual cracking patterns on JRCP ▪ Several passes required
Gravity Drop Hammer (multi-head)	Same as single-head gravity drop hammers, only multiple hammers equipped on machine	Antigo MHB Badger Breaker®	JPCP and wire mesh-reinforced JRCP	▪ Fairly high productivity ▪ More break-up at surface

Type of Equipment	Operating Procedure	Manufacturer	Type of Concrete	Advantages/ Disadvantages
Guillotine Hammer	JPCP and JRCP	Antigo 8600 Badger Breaker®, Antigo T8600 Badger Breaker®	JPCP and JRCP	▪ Versatile-effective with JPCP and JRCP ▪ Preferred by many agencies ▪ High productivity ▪ Covers full lane width ▪ Impacts adversely affected by uneven PCC surfaces
Impact Hammer	Hydraulic or pneumatic hammer commonly mounted on backhoes or skid steers	Brokk 250 Various skid steer models with hammer attachments	JPCP	▪ Low productivity ▪ Less effective on thicker PCC ▪ Typically used for localized removal of pavement
Pile Hammer (i.e., modified pile-driver)	Trailer-mounted diesel hammers		JRCP	▪ Covers full lane width ▪ Low productivity

[a]Breaking width = 8 feet (2.4 m)

Successful breaking/cracking largely depends on the equipment and the type and thickness of the pavement. The most common fracturing device, the guillotine hammer (Figure 6-4), typically requires one or two passes to break/crack the full width of a 12-ft or 12.5-ft (3.7- to 3.8-m) wide slab. Other breakers such as pile hammers and hydraulic drop hammers require multiple passes to deliver the grid pattern of strikes on the pavement. A test strip will define the desired breaking/cracking process (see the QC/QA section later in this chapter).

6-4.1.4 Step 4—Seat the Fractured PCC Pieces.

In the fourth step of the break/crack-and-seat technique, seat the PCC pieces with rolling equipment to ensure they are in contact with the supporting layer and achieve a relatively uniform grade for subsequent paving operations (Thompson, 1989; Freeman, 2002). During this process, identify unstable or soft areas (rocking or deflecting pieces) for appropriate action under Step 5.

[9]Hoerner et al, 2001; Antigo, 2009; Thompson, 2006.

Seating uses a heavy pneumatic-tire roller that “massages” each PCC piece into the foundation, while maintaining aggregate interlock (Hoerner et al., 2001). Steel-wheel static and vibratory rollers are generally not appropriate, as they tend to bridge over the high spots on the fractured PCC surface. Good results have been obtained with two passes of a 50-ton (45.4-metric ton) pneumatic roller for crack-and-seat operations and a minimum of five passes of the same equipment for break-and-seat operations. Employ additional passes for the latter since the slabs in the break-and-seat applications more thoroughly broken. For thin pavements on a weak foundation, use more passes (3 to 7) with a lighter roller (30 to 35 tons [27.2 to 31.8 metric tons]) (Buncher et al., 2008).

Avoid excessive rolling and rolling on wet subgrade. Excessive rolling breaks down the aggregate interlock between slab segments and overstress the foundational layers, leading to excessive deflection. Rolling in wet conditions causes non-uniform or excessive deformation of the fractured slabs. It can in turn result in some mixing of the subgrade and base, ultimately reducing the structural capacity of the final pavement.

6-4.1.5 Step 5—Apply Special Treatments.

The fifth step involves final preparations to the broken/cracked-and-seated pavement prior to placement of the HMA overlay. Repair or stabilize weak areas, punch-throughs, and shift-prone pieces detected during seating operations by surface patching or removal and replacement with HMA. Clear or sweep all sizeable loose debris atop the fractured pavement surface (Thompson, 1989). On projects designed to include a new edge drain system, install all system components (longitudinal edge drain, lateral outlets, etc.) as part of this step. Install underdrains at least two weeks prior to the cracking process.

6-4.1.6 Step 6—Construct HMA or PCC Overlay.

The sixth and final step is placement of the HMA or unbonded PCC overlay. Conventional construction procedures are used in this step, beginning with the application of a bituminous tack coat (0.07 to 0.10 gal/yd^2 [0.32 to 0.45 L/m^2] application rate) for use with an HMA overlay or an HMA leveling or bond breaker course (1 to 2 inches [25 to 50 mm] thick) for use with an unbonded PCC overlay.

To avoid incremental cracking of partial overlays carrying construction or other forms of traffic, it is recommended that the full HMA overlay thickness be placed promptly after application of the tack coat and the installation of edge drains (Thompson, 1989). For projects designed to include reinforcing fabric or a SAMI as part of the HMA overlay, apply the material at the specified location within the HMA paving layers.

6-4.2 Rubblization and Overlay.

The construction process for rubblization and overlay is similar to that of break/crack-and-seat and overlay. Installing a longitudinal edge drain system is the primary exceptions and fracturing the existing pavement into smaller sizes requires more time. In addition, the type of rolling equipment used to seat the rubblized layer may differ.

Rubblization and overlay consists of the following major steps (AI, 2000; Thompson, 2006; Buncher and Jones, 2006; Buncher et al. 2008):

1. Remove any existing asphalt surfacing.
2. Install drainage system (if specified).
3. Isolate adjacent pavement.
4. Rubblize PCC pavement.
5. Roll rubblized PCC.
6. Construct the HMA or PCC overlay.

6-4.2.1 Step 1—Remove Existing Asphalt Surfacing.

When rubblizing composite HMA/PCC pavements, first remove the HMA surfacing layers to allow application of the optimal amount of energy. Remove any HMA patches.

6-4.2.2 Step 2—Install Drainage System (If Specified).

On projects designed to include an edge drain system, install all system components including longitudinal edge drains and lateral outlets as part of this step. Ensure the installed drainage system is properly functioning for a minimum of 2 weeks prior to rubblization activities.

If no edge drains are specified, remove shoulders to the level of the PCC pavement base to allow water to drain from problem areas.

6-4.2.3 Step 3—Isolate Adjacent Pavement.

To prevent damage, isolate adjacent pavement sections that are not subject to the fracturing work with full depth saw cuts. Fully sever all load-transfer devices between the rubblized pavement and the adjacent pavement sections severed prior to rubblization.

6-4.2.4 Step 4—PCC Slab Rubblization.

Rubblization fractures existing PCC into small aggregate-sized pieces to eliminate the underlying slab integrity and movement that cause reflection cracking in HMA overlays. As with break/crack-and-seat operations, the cracking must extend fully through the slab and, in the case of JRCP and CRCP, debond the concrete from the reinforcing steel to achieve optimum success.

Rubblization is performed using two different types of equipment—the resonant pavement breaker (RPB) and the multi-head breaker (MHB). The RPB (Figure 6-6) typically applies a 2,000-lb (8,900-N) impact force at a frequency of 44 impacts/sec to the pavement surface through a breaking shoe attached to a massive steel beam (Hoerner et al., 2001). The vibrating beam acts like a “giant tuning fork,” shattering the pavement in narrow strips (6 to 12 inches [150 to 300 mm]) as the machine moves forward along the unfractured edge of the existing pavement (Buncher and Jones, 2006). The impact loads delivered through the shoe, induce diagonal cracks that extend the depth of the PCC slab, as illustrated in Figure 6-7.

The MHB (Figure 6-8) fractures concrete by lifting and dropping rows of steel hammers onto the pavement (Hoerner et al., 2001). The hammers are mounted laterally in pairs, with half the hammers in a forward row and the remainder diagonally offset in a rear row (Thompson, 2006). The MHB is a low-frequency, high-amplitude process (Buncher and Jones, 2006). It produces irregular-shaped PCC pieces, as compared to the highly angular, sheared pieces generated by the RPB.

Table 6-5 provides additional information about each type of equipment. The effectiveness and production rates are highly dependent upon the pavement type and thickness, and foundational support conditions and other factors, such as, concrete strength, presence and amount of reinforcing steel, and slab temperature.

The equipment defines the rubblizing process. RPB rubblization starts at a free or unfractured edge and continues with successive passes until the equipment has moved transversely across the width of the pavement (Buncher and Jones, 2006).

MHB rubblization entails a single pass covering the width of the slab.

Figure 6-8 Rubblization Using MHB*

*Source: Thompson, 2006.

Table 6-5 Summary of Pavement Rubblization Equipment[10]

Equipment	Manufacturer	Concrete Type	Advantages/ Disadvantages
Resonant Pavement Breaker (RPB)	RMI™	JPCP, JRCP, CRCP	▪ High degree of angular particle interlock due to diagonal (near 45° angle) fracturing. ▪ Potential for rutting by RPB tires on thin PCC/weak subgrade combinations
Multi-Head Breaker (MHB) (i.e., multi-head gravity drop hammer)	Antigo MHB Badger Breaker®	JPCP, JRCP, CRCP	▪ Equipment operates off of unfractured pavement, thereby minimizing operational problems associated with rubblizing pavements with thin PCC and/or weak foundation ▪ For slabs over 14 inches (350 mm) thick, pre-fracturing using guillotine hammer may be needed

On marginally stable and thin PCC pavements, the rubblization is not always effective. The deficient structural conditions cause problems with achieving full-depth fractures and result in overly large, disoriented PCC segments that make a very rough, uneven surface. In these instances, try a “modified rubblization” technique using the MHB with lowered drop heights and greater separations between impacts (achieved by increasing the equipment speed) (Buncher et al., 2008). Although this process produces larger pieces (nominal 8 to 18 inches [200 to 450 mm]) than specified with conventional rubblization, fracturing is more complete and the pieces remain better oriented for subsequent seating and overlay operations.

Pavements with thickened edges require adjustments to the RPB fracture energy or to the MHB hammer drop height to achieve the specified fracture size. Upon completion of the rubblization process, cut flush any exposed reinforcing steel at the surface or slightly below the surface, so that subsequent rolling operations are not adversely impacted.

6-4.2.5 Step 5—Roll Rubblized PCC.

In the fifth step, roll the rubblized layer to tighten the surface by seating loose particles and to smooth the surface in preparation for the HMA overlay (Buncher and Jones, 2006). During the rolling process, identify weak or unstable areas by observing significant deflection or settlement and repair by removing and replacing. Such

[10]Hoerner et al, 2001; Antigo, 2009, RMI, 2009; Buncher et al., 2008; Thompson, 2006.

detection is particularly important for MHB rubblization, since the rubblizing machine operates on the non-fractured portion of PCC pavement. With RPB rubblization, some level of detection is possible since the machine operates in a straddle position over the fractured and non-fractured portions of the pavement.

The rubblization equipment used dictates the rolling process. Start with the following standard rolling processes (roller weights as per Buncher and Jones [2006]):

6-4.2.5.1 RPB—Minimum of three passes with a vibratory steel-drum roller (minimum 10 tons [9.1 metric tons]) following completion of step 4.

6-4.2.5.2 MHB—Two passes with Z-grid roller (i.e., a vibratory steel-drum roller with Z-pattern grid on the drum face) (minimum 14 tons [12.7 metric tons]) and one pass with pneumatic-tired roller (25 tons [22.7 metric tons]), following completion of step 4. Immediately prior to HMA overlay, apply one pass with a vibratory steel-drum roller (10 tons [9.1 metric tons]).

Use of the Z-grid roller for MHB applications helps reduce the size of “flaky” particles (Thompson, 2006), leading to a tighter, smoother surface (Figure 6-9).

Figure 6-9 Z-Grid Roller Used on MHB Rubblized Pavement*

*Source: Thompson, 2006.

For the RPB process, apply a limited amount of water to the rubblized layer during the rolling process. The moisture lubricates particle surfaces and facilitates particle orientation (Buncher et al, 2008), leading to a tighter, more interlocked layer.

It is important to avoid excessive rolling and rolling in wet conditions. The former can destroy particle interlock and cause a weakening of the rubblized layer, while the latter can cause non-uniform or excessive deformation of the rubblized layer.

6-4.2.6 Step 6—Construct HMA or PCC Overlay.

The sixth and final step is placing the HMA or PCC overlay. In general, construction of the HMA overlay will proceed in the same manner as for a new or reconstructed HMA pavement structure. Two key exceptions are as follows:

6-4.2.6.1 Where marginally stable pavements are involved, such as a thin rubblized layer on a weak foundation, or there is difficulty in achieving a relatively smooth rubblized layer, consider applying a minimum 4-in (100-mm) thick aggregate leveling course (Buncher et al., 2008). Such a layer comprised of dense crushed aggregate, RAP, or RCA, provides a more stable and smoother platform for constructing the overlay.

6-4.2.6.2 A tack/prime coat on the rubblized layer is not needed (Buncher et al., 2008). The use or lack of use of a tack/prime coat has not been reported to impact pavement performance (Buncher et al, 2008), and its use increases project costs.

Depending on the overlay thickness and traffic control requirements, place the HMA overlay in two or three lifts (Buncher et al, 2008). Start with a minimum lift thickness of 3 inches (75 mm) for the first lift of HMA to increase the probability of achieving the in-place density requirements (Buncher et al., 2008). Windrow feeding the first lift of HMA is prohibited, due to the risk of disturbing/dislodging particles at the surface of the rubblized layer (Buncher et al., 2008).

If a PCC overlay is used, place a 1 to 2-in (25 to 50-mm) thick HMA leveling course or bond breaker on the rubblized layer.

6-4.3 RCA.

The construction process for RCA recycling involves the following seven steps:

1. Remove any existing asphalt surfacing.
2. Demolish existing PCC pavement.
3. Load and transport PCC material to crushing plant.
4. Crush PCC material.
5. Remove steel.
6. Size the aggregate.
7. Stockpile for use in aggregate subbase, base, lean concrete base, and/or PCC

The following sections review each step and discuss construction considerations for pavements using RCA materials.

6-4.3.1 Step 1—Remove Existing HMA Surface Layer.

Prior to breaking up the existing PCC pavement, remove any HMA patches or HMA surface layers (Hoerner et al., 2001). These materials slow the demolition process and contaminate the RCA material, which is especially important if using RCA in PCC or lean concrete. Although the amount of joint sealant material, if present, in the total volume of concrete rubble is very small, remove it as well.

6-4.3.2 Step 2—Demolish Existing PCC Pavement.

Pavement demolition breaks the PCC pavement into 18- to 24-in (450 to 600 mm) pieces small enough to lift and load into trucks (Hoerner et al., 2001). Typical equipment includes the excavator with ram hoe attachment shown in Figure 6-10. Table 6-6 lists the various types of equipment and their attributes.

Figure 6-10 Excavator W/Hydraulic Impact Hammer (Ram Hoe) Attachment*

*Source: Saeed et al., 2006.

Table 6-6 Summary of Equipment Used for Pavement Demolition[11]

Equipment	Description	Manufacturer	Pavement Type	Advantages/ Disadvantages
Drop Ball	A crane hoists and drops a heavy steel ball (2 to 7 tons [1.8 to 6.3 metric tons) onto pavement.		JPCP, JRCP, CRCP	▪ Not generally recommended because it breaks the pavement into excessively small pieces that are less salvageable

Equipment	Description	Manufacturer	Pavement Type	Advantages/ Disadvantages
Spring-Arm Whip Hammer	Uses a flexible arm made up of leaf springs that increase the velocity of the tool head and insulates the machine from reverse shock.		JPCP	▪ Covers full lane width through arc-like striking pattern ▪ Not particularly effective on thick PCC or on JRCP
Gravity Drop Hammer (single- head)	See Table 6-4	Arrow-Master 1350T	JPCP and wire mesh-reinforced JRCP	▪ Effective on JRCP ▪ Can develop unusual cracking patterns on JRCP ▪ Several passes required
RPB	See Construction-Rubblization section	RMI™ RB600	JPCP, JRCP, CRCP	▪ Rapid process but lower coverage rate (multiple pass) ▪ Good quality control
MHB (i.e., multi-head gravity drop hammer)	See Construction-Rubblization section	Antigo MHB Badger Breaker®	JPCP, JRCP, CRCP	▪ Relatively rapid process with higher coverage rate (single pass) ▪ Good quality control
Impact Hammer (i.e., ram hoe)	Hydraulic or pneumatic hammer commonly mounted on excavators	Brokk 250 Various models with hammer attachments	JPCP	▪ Limited power that can only be used with JPCP ▪ Typically used for localized removal of pavement
Impact Roller	Towed roller with heavy (19,000 to 29,000 lb. [8,597 to 13,122 kg]) cam-shaped drum that delivers impacts to pavement through its rotations	Impact Roller Technology (IRT) Impactor 2000/3000	JPCP and JRCP	▪ Rapid process with high coverage rate ▪ Quality control not as good
Pile Hammer (i.e., modified pile-driver)	See Table 6-4	???	JRCP	▪ Covers full lane width ▪ Low productivity

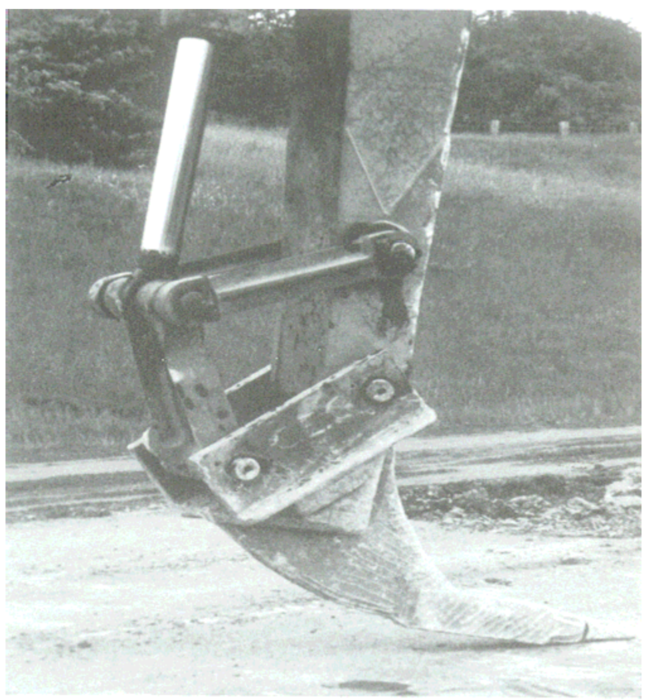
Besides the equipment itself, the most notable factors affecting production are slab thickness, concrete strength, quantity and type of steel reinforcement, and foundation support (Buncher, et al; TRB Circular No. E-C087.). Apply greater impact energy to thicker, stronger, and more heavily reinforced pavements as well as pavements resting on weaker foundations. Some control of the break energy is necessary to minimize damage to the subgrade and any underlying drainage features or utilities and to avoid pushing PCC pieces into the underlying granular layers (Buncher, et al; TRB Circular No. E-C087.). Keep disturbance of the foundation to a minimum.

[11] Hoerner et al., 2001; Antigo, 2009; IRT, 2009.

The breaking operation for CRCP pavement requires breaking rebar free of the concrete and removing prior to loading. Excavators with multi-processor attachments such as pulverizer jaws, shear jaws, and rakes effectively handle rebar as they can easily break concrete away from steel, rake steel from concrete rubble, and cut steel to size. A backhoe or front-end loader equipped with a rhino horn attachment (Figure 6-11) hooks and pulls the steel from the concrete rubble, but is less productive than equipment with multi-processor attachments.

Demolition operation generally severs mesh reinforcement (ACPA 1993). Break pieces too large for the primary crusher with multi-processor attachments or the rhino horn. Dowel bars and tie bars are typically removed during the crushing operation (Hoerner et al., 2001). However, during the demolition many of these pieces are loose and pop out.

Figure 6-11 Close-Up of Rhino Horn Attachment*



*Source: Buncher, et al; TRB Circular No. E-C087.

6-4.3.3 Step 3—Load and Transport PCC Material to Crushing Plant.

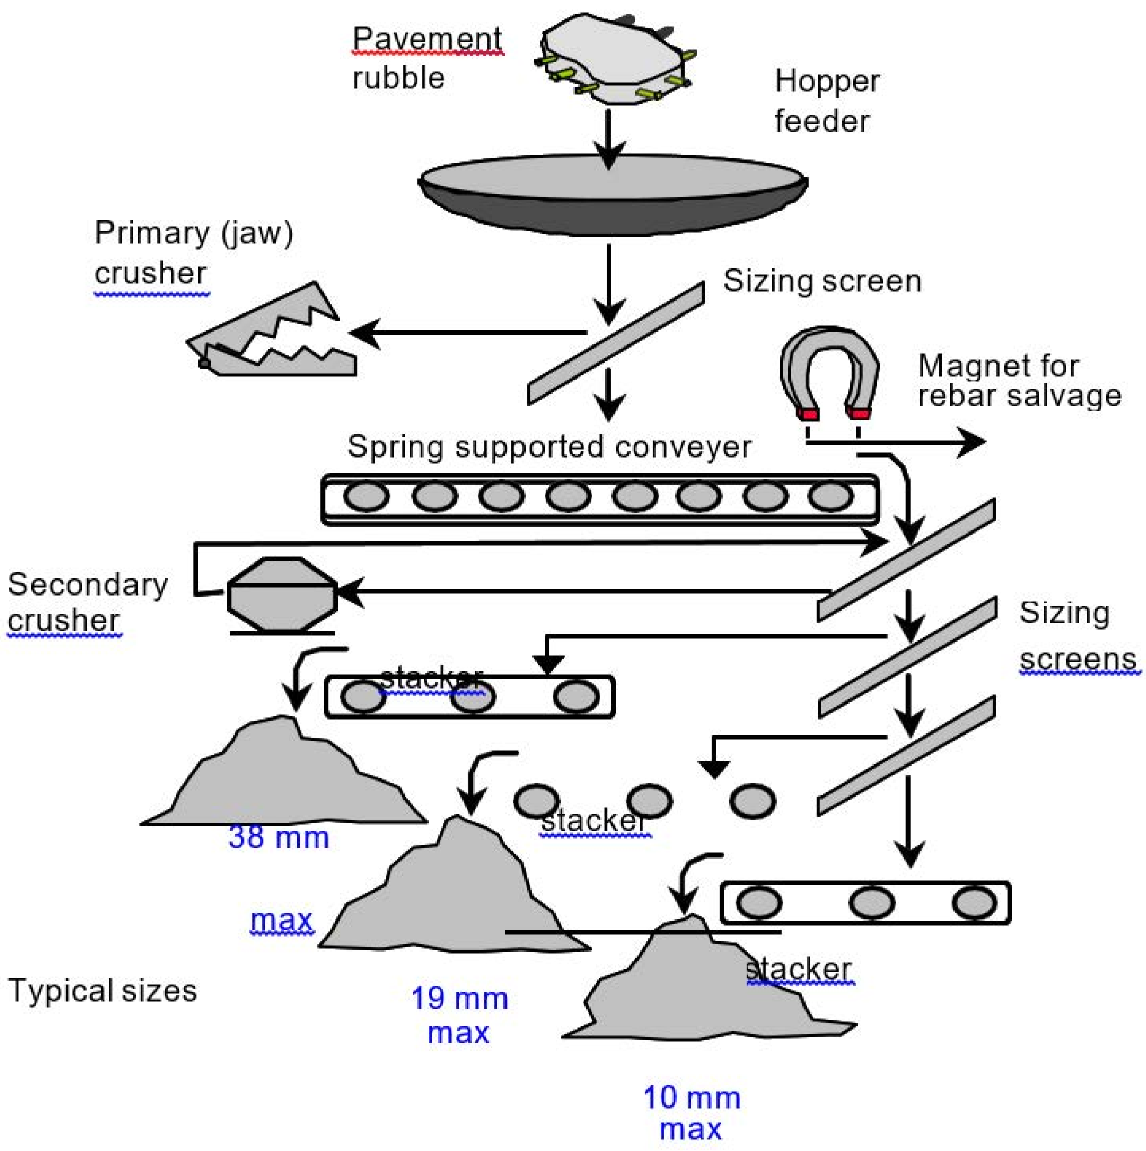
In off-site crushing and processing operations, load pavement rubble into dump trucks using an excavator with a shovel attachment or a front-end loader. Transport the material and stockpile at the crushing plant. During the loading operations, limit the amount of base material scooped up with the PCC rubble. Rubber-tired loaders are better at minimizing base disturbance than tracked loaders (Buncher, et al; TRB Circular No. E-C087.).

On-site crushing and processing operations negates the need for loading and hauling, as the excavators and/or front-end loaders perform the stockpiling work.

6-4.3.4 Steps 4 to7—Crush PCC Material, Remove Steel, Size Aggregate, and Stockpile for Use.

Process pavement rubble at the crushing plant to produce RCA. Figure 6-12 depicts the processes discussed in Steps 4 through 7 of RCA recycling (Hoerner et al., 2001).

Figure 6-12 Illustration of Operation Sequence at a PCC Recycling Plant*



*Source: Hoerner et al., 2001.

In the crushing step, load pavement rubble into a hopper that regulates the flow of the rubble onto the sizing screen (Hoerner et al., 2001). Divert pieces larger than 1 inch (25 mm) to a primary crusher that breaks the concrete away from the reinforcing steel and into pieces of a maximum size of 3 to 4 inches (75 to 100 mm). As the material transfers to a secondary crusher, an electromagnetic separator removes any remaining steel. The secondary crusher further breaks down the PCC material for screening to the desired gradation.

The two basic types of crushers are compression crushers and impact crushers (see Figure 6-13) (Buncher, et al; TRB Circular No. E-C087.). Compression crushers are either jaw or cone designs, and typically serve as the primary crusher. The jaw crusher (see Figure 6-14) provides a cyclic compression force to fracture the PCC while the cone crusher uses an eccentric rotating cone to do the same. The jaw crusher is often preferred as it can handle large PCC pieces. Impact crushers are either vertical or horizontal rotary designs and typically serve as the secondary crusher. These crushers use repeated blows from the rotary blow bars to reduce the size of concrete fragments (Buncher, et al; TRB Circular No. E-C087).

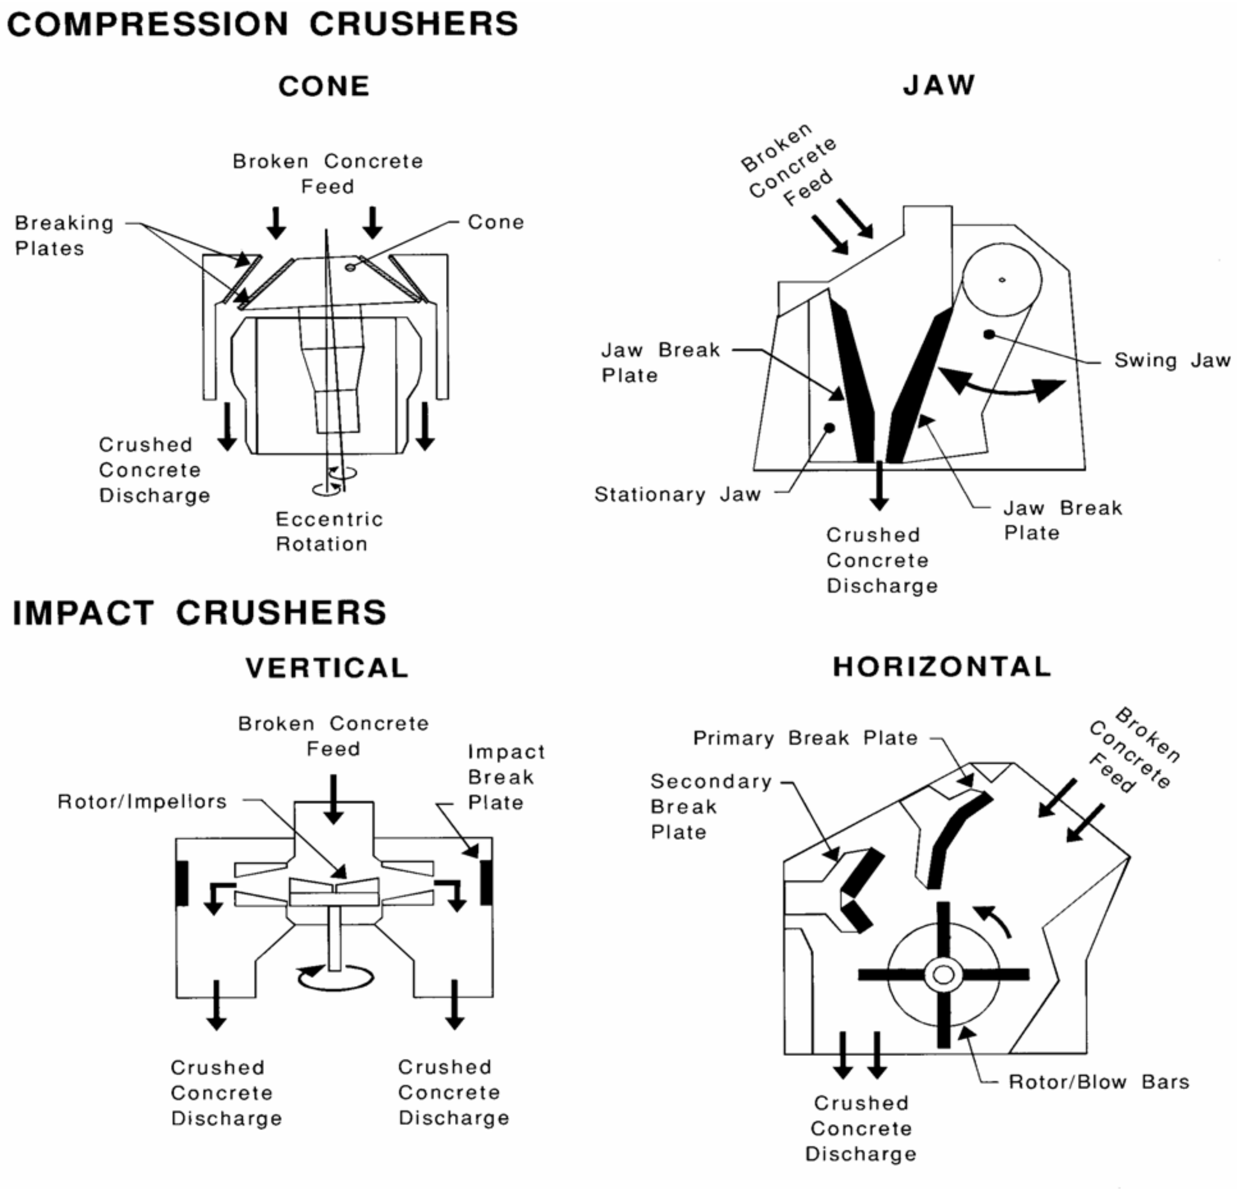
The primary crusher (e.g., jaw crusher) breaks the reinforcing steel from the concrete and reduces the concrete rubble to a maximum size of 3 to 4 inches (75 to 100 mm) (Buncher, et al; TRB Circular No. E-C087). The material processed by the primary crusher discharges onto a conveyor belt and moves to a screening dock. An electromagnetic separator removes virtually all steel present in the crushed material. Secondary crushing further breaks down the RCA for screening to the desired gradation. Pieces larger than the desired max size recirculate through a secondary cone crusher until all material passes through the screening sizes (Hoerner et al., 2001).

Typically, crushing operations yield about 75 percent coarse and 25 percent fine aggregate (Buncher, et al; TRB Circular No. E-C087). The ratio varies depending on the pavement type, broken concrete size, and the crushing plant design. When using RCA in new PCC, adjust the crushing operation to maximize the recovery of coarse aggregate, since the RCA fine aggregate is typically not used or is greatly limited in the new PCC. With a 0.75-inch (19-mm) top size, a coarse aggregate recovery of 55 to 60 percent is typical, while at a 1.5-inch (38-mm) top size, up to 80 percent or more can be recovered (Hoerner, et al., 2001).

6-4.3.5 Construction Considerations for Pavements Utilizing RCA.

Once processed, use the RCA material in an aggregate base or subbase layers or feed into a portable or central-plant mixer to produce lean concrete base material or new PCC. Listed below are several construction considerations for pavements that utilize RCA materials.

Figure 6-13 Types of Crushers used for PCC Recycling*



*Source: Buncher, et al; TRB Circular No. E-C087.

Figure 6-14 Jaw-Type Compression Crusher

6-4.3.5.1 RCA Unbound Base/Subbase.

To prevent segregation problems, use proper stockpiling and spreading techniques. Box spreaders or HMA pavers are preferred over motor graders (Saeed et al., 2006). Avoid excessive working of the RCA base or subbase material.

Ensure RCA base or subbase is in a saturated state to aid in compaction and migration of fines throughout the mix.

Suitable compaction equipment for RCA base and subbase layers includes static and vibratory steel-wheeled rollers and pneumatic-tire rollers.

6-4.3.5.2 RCA Used in New PCC or Lean Concrete Base.

Constructing PCC pavements containing RCA requires no special techniques or paving equipment (Hoerner et al., 2001). Use conventional mix plants, paving equipment, and normal paving and finishing practices.

The use of RCA in new PCC creates problems with mix workability, due to the high absorption capacity of the aggregate and the difficulty in maintaining a consistent and uniform saturated surface dry condition of the RCA. Overcome this problem by keeping stockpiles moist and by frequently testing aggregate for moisture content.

6-5 QUALITY CONTROL/QUALITY ASSURANCE.

6-5.1 Break/Crack-and-Seat.

6-5.1.1 Use a test strip to establish an acceptable breaking/cracking pattern for moderate to high-level projects. Examining the pavement and extracted cores resulting from varying degrees of energy and various strike patterns helps identify the procedure that best meets the design requirements.

6-5.1.2 Check crack patterns created by breaking/cracking operations at least twice a day by wetting the concrete surface with water and observing the appearance of cracks as the surface dries. If adjusting the crack pattern, consider coring to verify the full penetration of cracking.

6-5.1.3 Use NDT equipment to monitor the construction quality of cracking operations. Perform NDT testing on all broken-and-seated concrete to verify destruction of the bond between concrete and reinforcing steel in JRCP. Assure that the back-calculated modulus for broken JRCP (based on NDT performed directly on the fractured layer) is greater than 500,000 psi (3,448 MPa) and less than 1,000,000 psi (6,895 MPa) for 95 percent or more of the project area.

6-5.1.4 In the absence of NDT testing protocols conduct such testing every 500 to 1,000 feet (150 to 300 m) per paving lane with a typical width of 12 ft or 12.5 ft (3.7 or 3.8 m) wide directly on the fractured layer. Also, test that portion of the test strip in which the formal breaking/cracking pattern was established. Use test data to back calculate the elastic moduli for QC/QA purposes.

6-5.1.5 In the event that a break/crack-and-seat project includes an edge drain system, whether pre-existing or retrofit, visually inspect the system outlets for clogging issues. Properly clean and flush any segments with clogging problems.

6-5.2 Rubblization.

6-5.2.1 Use a test strip to optimize equipment operations and establish acceptable rubblizing and rolling practices on moderate to high-level projects. Use a test pit within the test strip to determine if a) the rubblizing procedure is producing pieces of the specified size, b) the fracturing is extending fully through the slab, and c) concrete is debonding from steel reinforcement. Use multiple test strips and test pits on projects with varying pavement structure conditions (Buncher et al., 2008).

6-5.2.2 Typical rubblization criteria are as follows:

- Resonate Pavement Breaker—Break slabs into pieces ranging from sand-sized to 6 inches. Ensure the majority of pieces are between 1 and 3 inches (25 and 75 mm) and ensure no individual piece exceeds 8 inches (200 mm). For JRCP, debond steel from concrete and leave in place and ensure no individual PCC piece exceeds 8 inches (200 mm).

- Multi-Head Breaker—Break slabs into pieces, with sizes in the top half of the slab generally ranging from sand-sized to 3 inches (75 mm) and sizes in the bottom half not exceeding 9 inches (225 mm). For reinforced PCC, debond steel from concrete and leave in place and ensure no individual PCC piece exceeds 9 inches (225 mm).
- Both RPB and MHB—Due to lack of edge support, the maximum size of PCC pieces below steel in reinforced PCC is 12 inches (300 mm).

6-5.2.3 The surface of the rubblized pavement is difficult to test and leads to wide levels of test variability. If the opportunity for NDT testing on a particular project exists, use the equipment on the pre-rubblized pavement to identify potential areas and localized weak spots that affect the rubblization process.

6-5.2.4 In the event that a rubblization project includes an edge drain system, visually inspect the system outlets for clogging. Properly clean and flush any segments with notable clogging problems to restore flow.

6-5.3 RCA Production.

QC/QA of the RCA production process focuses primarily on pavement demolition, the removal of steel and other contaminants, and the proper sizing and stockpiling of RCA material. Key considerations or measures to ensure the production of quality RCA for re-use in pavement structures are as follows:

- Evaluation and testing (ASTM C1260, ASTM C1293, ASTM C1567) of the old concrete is important in determining the severity of aggregate or mix problems, such as D-cracking and ASR.
- Careful monitoring of the pavement demolition operation to minimize the disturbance of the existing base and severely limit the amount of base material removed.
- Ensuring RCA consists of clean, sound, and durable crushed particles and is free of silt, clay, organic matter, AC, steel reinforcement, and other objectionable material (Saeed et al., 2006). While incidental amounts of AC, soil, base aggregates, or joint sealant are allowable for RCA used as unbound base or subbase, much tighter restrictions are necessary for RCA used in new PCC or lean concrete base.
- Monitoring crushing operations to ascertain that the yield of coarse aggregate is sufficient for the intended re-use application. Additionally, in the case of RCA PCC, monitor the amount of mortar retained on the coarse aggregate fraction to minimize the adverse effects of the mortar on PCC performance.
- To avoid segregation of the RCA material, use conveyor belts to create RCA stockpiles and carefully control stockpile heights.

6-5.4 RCA Re-Use.

QC/QA of re-used RCA material entails a variety of laboratory and field tests that are specific to the paving application. See the pertinent UFGS documents for further discussion of these tests. Key material and construction quality parameters are as follows:

6-5.4.1 RCA Base or Subbase.

- UFGS 32 11 20; RCA gradation, abrasion/wear, compaction/density (percent of laboratory maximum dry density), and thickness.
- UFGS 32 11 23: RCA gradation, wear, soundness, shape, angularity, density, and thickness.

6-5.4.2 RCA in Lean Concrete Base.

- UFGS 32 11 36.13: RCA gradation, slump, air content, temperature, compressive strength (7- and 28-day cylinders), and thickness (cores).

6-5.4.3 RCA in New PCC.

- UFGS 32 13 13.06: RCA gradation, workability and coarseness factors, unit weight, temperature, slump, air content, flexural strength (28- or 90-day values converted from compressive strength values on 7-day cylinders or from flexural strength values on 7-day beams), and thickness (cores).
- UFGS 32 13 14.13: RCA gradation, slump, air content, flexural strength (28- and 90-day beams), and thickness (cores).

C-2 TERMS

Additive Stabilization: Achieve stabilization by adding the proper percentages of additives to the soil. Select the type and determine the percentage of an additive depends on; the soil classification, amount of deleterious materials, such as, sulfates and organics, and the degree of soil quality improvement desired. Non-traditional additives, such as, polymer, fiber, lignin derivatives, enzymes, acids, etc. are addressed where appropriate. This UFC does not define specific criteria for all additives. Generally, smaller amounts of additives are required when only modifying soil properties, such as, gradation, workability, and plasticity. Obtaining significant strength and durability improvement requires greater quantities of additive. After mixing the additive with the soil at the optimum moisture content, spread and compact by conventional means.

Additives: Manufactured commercial products, when added to the soil in the proper quantities, improve some engineering characteristics of the soil such as strength, texture, workability, and plasticity are termed “traditional” additives and include materials such as lime, cement, fly ash, and asphalt emulsions. “Non-traditional” additives such as polymer emulsions, fiber, lignin derivatives, enzymes, acids, and other materials used to improve soil qualities are newer with little history of use. Additives addressed in this UFC are portland cement, lime, fly ash, bitumen, polymer emulsion, fiber, and select combinations of these.

Durability: Durability refers to the resistance of the soil to weathering, primarily by the action of water and abrasion after wet-dry and freezing and thawing cycles (ASTM D559 and D560).

Mechanical Stabilization: Mechanical stabilization mixes or blend soils of two or more gradations to obtain a material meeting the required specification. Soil blending may take place whenever convenient. Spread and compact the blended material to required densities at the optimum moisture content by conventional means. Compaction and fiber addition are also mechanical stabilization methods. Compaction consists of the mechanical rearrangement of soil particles into a denser configuration, typically resulting in increased strength and/or durability. The addition of fibers into a soil can mechanically stabilize the soil by creating interlock between particles.

Modification: Modification refers to the stabilization process that improves some material property of the soil, such as, the plasticity index (PI) but does not, by design, result in a significant increase in soil strength and durability.

Optimum Moisture Content: The optimum moisture content of soil is the water content, measured as a percentage by unit weight, that achieves the maximum dry unit weight for a given compactive effort. (See ASTM D1557 for further information.) A higher or lower moisture content produces a lower maximum dry unit weight after compaction.

Soils: Soils are naturally occurring materials used for the construction of all layers of concrete and asphalt pavements, except the surface, and is subject to classification tests (ASTM D2487) to provide a general concept of their engineering characteristics.

Stabilization: Stabilization is the process of blending and mixing materials with a soil to improve engineering properties of the soil. The process may include blending soils to achieve a desired gradation or mixing additives to alter the; chemistry, gradation, texture, plasticity, or water absorption or act as a binder for cementation of the soil. Stabilization significantly increases the strength and/or durability of the stabilized material.

Strength: In the context of this UFC, “strength” refers to the unconfined compressive tests measured using ASTM D1633.

This UFC supersedes UFC 3-250-11, *Soil Stabilization for Pavements*, dated January 16, 2004.

FOREWORD

The Unified Facilities Criteria (UFC) system is prescribed by MIL-STD 3007 and provides planning, design, construction, sustainment, restoration, and modernization criteria, and applies to the Military Departments, the Defense Agencies, and the DoD Field Activities in accordance with USD (AT&L) Memorandum dated 29 May 2002. UFC will be used for all DoD projects and work for other customers where appropriate. All construction outside of the United States is also governed by Status of Forces Agreements (SOFA), Host Nation Funded Construction Agreements (HNFA), and, in some instances, Bilateral Infrastructure Agreements (BIA). Therefore, the acquisition team must ensure compliance with the most stringent of the UFC, the SOFA, the HNFA, and the BIA, as applicable.

UFC are living documents and will be periodically reviewed, updated, and made available to users as part of the Services' responsibility for providing technical criteria for military construction. Headquarters, U.S. Army Corps of Engineers (HQUSACE), Naval Facilities Engineering Command (NAVFAC), and Air Force Civil Engineer Center (AFCEC) are responsible for administration of the UFC system. Defense agencies should contact the preparing Service for document interpretation and improvements. Technical content of UFC is the responsibility of the cognizant DoD working group. Recommended changes with supporting rationale may be sent to the respective DoD working group by submitting a Criteria Change Request (CCR) via the Internet site listed below.

UFC are effective upon issuance and are distributed only in electronic media from the following source:

- Whole Building Design Guide web site http://www.wbdg.org/ffc/dod.

Refer to UFC 1-200-01, *DoD Building Code*, for implementation of new issuances on projects.

UNIFIED FACILITIES CRITERIA (UFC)
REVISION SUMMARY SHEET

Document: UFC 3-250-11, *Soil Stabilization and Modification for Pavements*

Superseding: This UFC supersedes UFC 3-250-11, *Soil Stabilization for Pavements*, dated January 16, 2004.

Description: This UFC documents the standard practice of stabilizing and modifying soil for use in pavement and operating surfaces. It provides guidance for improving the engineering properties of soils used for pavement base courses, subbase courses, and subgrades by the use of additives mixed into the soil to effect the desired improvement. This UFC is also applicable to roads, airfields, and construction platforms having a stabilized surface layer.

Reasons for Document: This update brings the document in compliance with UFC 1-300-01, *Criteria Format Standard*. Editorial changes were made to improve readability, correct typographical errors, and update outdated references.

Impact: Cost impact is negligible; improved guidance typically results in improved performance and reduced lifecycle cost.

Unification Issues: None

CONTENTS

TABLES

CHAPTER 1 INTRODUCTION

1-1 PURPOSE.

This UFC documents the standard practice for improving the engineering properties of soils used for operating surfaces, pavement base courses, subbase courses, and subgrades by the use of additives mixed into the soil to effect the desired improvement. It also provides criteria and guidance for the stabilization and modification of soils for pavements, operating surfaces, and construction platforms. This UFC is also applicable to roads, airfields, and construction platforms having a stabilized surface layer. These soil improvements consist of applying a chemical such as lime, cement, or bitumen to a layer of soil or aggregate that will be included within a pavement area. Stabilization or modification measures discussed herein are useful to limit expansive soil's ability to expand and contract due to changes in moisture content, increase the soil's shear strength to prevent or minimize pumping, or to bind soils or aggregates.

1-2 SCOPE.

This UFC prescribes the appropriate type(s) of additive to be used with different soil types, procedures for determining a design treatment level for each type of additive, and standard construction practices for incorporating the additive into the soil. This UFC provides criteria and guidance on stabilization or modification using portland cement, lime, lime-fly ash, lime-cement-fly ash, bitumen, polymer, lime-cement, lime-bitumen, or geo-synthetic fibers.

1-3 APPLICABILITY.

Soil stabilization and modification are optional. The installation, in conjunction with the designers of record, determines whether to include soil stabilization or modification in the pavement design. Apply the requirements in this UFC when soil stabilization or modification is included in the design. These requirements are dependent upon each individual site's soil conditions.

1-4 USES OF STABILIZATION/MODIFICATION.

Pavement design is based on the premise that the specified structural quality will be achieved for each layer of material in the pavement system. Each layer resists shearing, avoids excessive deflections that cause cracking within the layer or in overlying layers, and prevents excessive permanent deformation. As the quality of a soil layer is increased, the ability of that layer to distribute the load over a greater area is increased so a reduction in the required thickness of the soil and surface layers is achieved.

1-4.1 Quality Improvement.

The most common improvements achieved through stabilization/modification include better soil gradation, reduced plasticity index (PI) or swelling potential, and increased durability and strength. Stabilization may be used to provide a working platform for construction.

1-4.2 Thickness Reduction.

The strength of a soil layer can be improved through the use of additives to permit a reduction in design thickness of the stabilized material compared with an unstabilized or unbound material. Procedures for designing and evaluating pavements that include stabilized soils are presented in UFC 3-250-01, *Paving Design for Roads and Parking Areas*, UFC 3-250-03, *Standard Practice Manual for Flexible Pavements*, and UFC 3-260-02, *Pavement Design for Airfields*. The design thickness of a base or subbase course can be reduced if the stabilized material meets the specified gradation, strength, stability, and durability requirements indicated in this UFC for the particular type of material. See Appendix A for examples of reducing design thickness when using stabilized materials.

1-4.3 Operating Surfaces.

Stabilized materials can be used to construct operating surfaces. These cases are typically for temporary construction platforms, roads, or airfields where poor soils exist and conventional pavements cannot be feasibly constructed. For roads and airfields, adhere to the strength, durability, and construction criteria in this UFC.

1-5 DEFINITIONS.

Appendix B contains a list of acronyms and definitions.

1-6 REFERENCES.

Appendix C contains a list of references used in this document. The publication date of the code or standard is not included in this document. Unless otherwise specified, the most recent edition of the referenced publication applies.

CHAPTER 2 SELECTION OF ADDITIVE

2-1 FACTORS TO CONSIDER.

In the selection of a stabilizer, the factors to consider are the type of soil to be stabilized, the purpose for which the stabilized layer will be used, the type of soil improvement desired, the required strength and durability of the stabilized layer, the type and availability of the additive, the cost, and environmental conditions.

2-1.1 Soil Types and Additives.

There may be more than one candidate stabilizer applicable for an individual soil type; however, there are general guidelines that make specific stabilizers more desirable based on soil granularity, plasticity, or texture. Portland cement, for example, is used with a variety of soil types; however, since it is imperative the cement be mixed intimately with the fines fraction (< 0.074 mm), avoid plastic soils unless steps are taken to reduce the plasticity. Generally, well-graded granular materials that possess fines to produce homogenous mixtures are best suited for portland cement stabilization. Lime will react with soils of medium to high plasticity to lower its plasticity, increase workability, reduce swell potential, and increase shear strength. In some cases, adding lime prior to adding soil cement will improve the workability of the soil cement. Lime is used to stabilize a variety of materials, including weak subgrade soils, transforming them into a "working table" or subbase; with marginal granular base materials (i.e., clay-gravels and "dirty" gravels) lime forms a strong, high-quality base course. Fly ash is a pozzolanic material—it reacts with lime and is therefore almost always used in combination with lime in soils that have little or no plastic fines. The use of portland cement with lime and fly ash for added strength is often required. This combination of lime-cement-fly ash (LCF) has been used successfully in base course stabilization. Asphalt, bituminous, or polymer materials are used for waterproofing and gaining strength. Generally, soils suitable for asphalt or polymer stabilization are silty sands and granular materials because thoroughly coating all the soil particles is desirable. Fibers may be used in combination with some additives to improve strength and crack resistance, but they severely limit workability after mixing with soil.

Do not create a solid, rigid, or brittle surface that will lead to reflective cracking of the surface pavement when designing stabilized base and subbase layers for pavements. Each type of stabilization method has limitations and appropriate uses; therefore, create and test a representative mix design for each individual scenario of the planned field operations. Evaluate each stabilized soil layer to establish the appropriate thickness of stabilized soil to prevent undesired effects to the finished pavement surfaces. Include a bond breaker when overlaying a stabilized layer using portland cement.

2-1.1.1 Portland Cement Stabilization.

Cement stabilization utilizes mixing dry portland cement powder into the subbase soils to increase the shear strength within the treated layer. Typically, this is accomplished by using a dosage rate of 3 to 6 percent by weight portland content and mixing it approximately 1 to 2 feet (0.3 to 0.6 m) in depth. These are general estimations; the procedure to determine the dosage rate is described in paragraph 3-1 and its subparagraphs. Use layered elastic pavement design procedures described in UFC 3-260-02 to determine the depths to which mixing must occur.

2-1.1.2 Lime Stabilization or Modification.

Lime modification utilizes mixing dry hydrated lime (powder) or quicklime (granulated) into the subgrade/subbase soils to lower the PI of the soil to control the shrink/swell potential of the soil. Lime stabilization utilizes mixing lime or quicklime into the subgrade, select fill, and or subbase material to increase the pH to generate a pozzolanic reaction that increases the soil's shear strength. This requires fine-grained soils with a minimum fraction of silt and clay to be reactive and is not effective on granular materials. Typically, lime modification is performed on the upper layer of subgrade, select fill, and/or subbase and mixing is approximately 0.75 to 2 feet (0.2 to 0.6 m) in depth**.** These are general estimations; the procedure to determine the dosage rate is described in paragraph 3-2 and its subparagraphs. Use layered elastic pavement design procedures described in UFC 3-260-02 to determine the depths to which mixing must occur.

2-1.1.3 Lime-Fly Ash or Lime-Cement-Fly Ash Stabilization.

Fly ash acts similarly to portland cement and is used to reduce the quantity of lime or portland cement necessary to achieve the desired stabilization/modification effect. Fly ash is a cheaply obtained industrial byproduct used for cost reduction and can stabilize more coarse gradations than lime alone. Fly ash physical and chemical properties can vary widely. Investigate each locally available product for its applicability to the specific project. Additional information is in paragraph 3-3.

2-1.1.4 Bitumen or Polymer Stabilization.

Bitumen and polymer stabilization increases adhesive properties, the shear strength of the soils, and decreases the effects of water on the treated soils. Bitumen and polymers are not effective against freeze-thaw action and testing the durability of the finished product is not possible. Additional information is in paragraph 3-4.

2-1.1.5 Lime-Cement or Lime-Bitumen Stabilization.

A lime-cement and lime-bitumen combination is used primarily when lime is needed to control the shrink/swell potential of soils and the treated soil has a low shear strength. Portland cement-bitumen is used to increase the shear strength to a desired minimum strength. Bitumen and polymers are not effective against freeze-thaw action and testing the durability of the finished product is not possible. Additional information is in paragraph 3-5.

2-1.1.6 Geosynthetic Fiber Stabilization.

Geosynthetic fiber stabilization increases the shear strength of the soils. It is not effective in controlling shrink/swell characteristics of soils. Installation of the fibers can be problematic in the field. It requires material-specific experience and attentive quality control and quality assurance to ensure proper construction. Additional information is in paragraph 3-6.

2-1.2 Screening Tests for Organic Matter and Sulfates.

The presence of organic matter and/or sulfates frequently has deleterious effects on stabilized soil or the additives used, preventing the stabilization process from occurring. Perform testing for detection of these materials if their presence is suspected.

2-1.2.1 Organic Matter.

A soil may be acidic, neutral, or alkaline and still respond well to cement treatment. Although certain types of organic matter, such as undecomposed vegetation, may not adversely influence stabilization, organic materials such as humic acid act as hydration retarders and reduce strength. When such organics are present, they inhibit the normal hardening process. A pH test to determine the presence of organic material is presented in Appendix A. If the pH of a 10:1 mixture (by weight) of soil and cement 15 minutes after mixing is at least 12.0, it is probable that any organics present will not interfere with normal hardening. Refer to ACI 230.1R, *Report on Soil Cement*, for additional guidance. Limit soil organic content to a maximum of 2 percent by weight and a minimum pH of 5.3 or more prior to the addition of soil cement, lime, or fly ash.

2-1.2.2 Sulfates.

Cements in contact with sulfates can generate a reaction that is expansive in nature and can damage aboveground, below ground, and nearby facilities if present with cement, lime, or fly ash-stabilized soils. The resistance to sulfate attack differs for cement-treated coarse-grained and fine-grained soils and is a function of sulfate concentrations. If sulfate concentration exceeds 0.1 percent by weight do not use cement or fly ash stabilization without prior authorization by the Pavements Discipline Working Group (DWG). Use the procedure in Appendix A or the current version of ASTM C1580, *Standard Test Method for Water-Soluble Sulfate in Soil*, to determine the concentrations of sulfate in the existing soil and groundwater. Do not design, specify, construct, or install soil cement, lime, or fly ash for soils containing more than 0.1 percent sulfate.

2-1.3 Traditional Additives.

2-1.3.1 Cement.

Portland cement can be used either to modify and improve the quality of the soil or transform the soil into a cemented mass with increased strength and durability. Cement can be used effectively as a stabilizer for a wide range of materials; however, the soil should have a PI less than 30 or the stabilization effects will be minimal. For coarse-grained soils, the amount passing the No. 4 (4.75 mm) sieve should be greater than 45 percent or the stabilization effects will be minimal. The amount of cement used depends on whether the soil is to be modified or stabilized.

When designing, specifying, or constructing using cement to stabilize base material for support of a rigid pavement, a bond breaker between the pavement concrete and the cement-stabilized base material to prevent adhesion at that interface is required. Adhesion of the concrete pavement to the cement-stabilized base results in unacceptable cracking. An asphalt emulsion bond breaker is not recommended because once the emulsion begins to dry and harden it does not perform as a bond breaker and instead causes further adherence problems. To create a bond break, install a layer of #89 stone meeting ASTM C33, *Standard Specification for Concrete Aggregates*, specifications between 0.25 and 0.5 inches (6.3 and 12.7 mm) in thickness. Then install a fabric meeting the requirements of AASHTO M288, *Standard Specification for Geosynthetic Specification for Highway Applications*, class I fabric with elongation less than 50 percent at the specified strengths, or install a double layer of liquid membrane-forming compound on the stabilized base prior to the placement of concrete. Do not design, specify, or install a layer of plastic or rubberized sheet material as a bond breaker without prior approval of the Pavements DWG. Do not design, specify, or construct PCC pavement slabs with joint spacing greater than 13 feet (4 m) over cement-stabilized base.

2-1.3.2 Lime.

Experience shows that lime will react with many medium-, moderately fine-, and fine-grained soils to produce decreased plasticity, increased workability, reduced swell, and increased strength. Consider using lime to stabilize soils classified according to the Unified Soil Classification System (USCS) as CH, CL, MH, ML, OH, OL, SC, SM, GC, GM, SW-SC, SP-SC, SM-SC, GW-GC, GP-GC, ML-CL, and GM-GC. Consider lime with all soils having a PI greater than 12 and more than 25 percent of the soil passing the No. 200 (0.075 mm) sieve. Do not design, specify, or construct lime-stabilized subgrade, subbase, or base soils with a sulfate content greater than 0.1 percent.

2-1.3.3 Fly Ash.

Fly ash, when mixed with lime, can effectively stabilize most coarse- and medium-grained soils; however, the PI cannot be greater than 25 and remain effective. Soils classified by the USCS as SW, SP, SP-SC, SW-SC, SW-SM, GW, GP, GP-GC, GW-GC, GP-GM, GW-GM, GC-GM, and SC-SM can be stabilized with fly ash. Some sources of fly ash may contain high amounts of sulfates. In some soils, this may lead to the formation of ettringite, which may swell excessively. Do not design, specify, or construct fly ash-stabilized subgrade, subbase, or base soils with a sulfate content greater than 0.1 percent.

2-1.3.4 Bituminous.

Most bituminous soil stabilization has been performed with asphalt cement, cutback asphalt, and asphalt emulsions. Soils that can be stabilized effectively with bituminous materials usually contain less than 30 percent passing the No. 200 (0.075 mm) sieve and have a PI less than 10. Soils classified by the USCS as SW, SP, SW-SM, SP-SM, SW-SC, SP-SC, SM, SC, SM-SC, GW, GP, SW-GM, SP-GM, SW-GC, GP-GC, GM, GC, and GM-GC can be effectively stabilized with bituminous materials, provided the above-mentioned gradation and plasticity requirements are met.

2-1.3.5 Combination.

Combinations of lime and cement are often acceptable expedient stabilizers. Lime can be added to the soil to increase the soil’s workability and mixing characteristics as well as reduce its plasticity. Cement or fly ash can then be mixed into the soil to provide rapid strength gain. Combinations of lime and asphalt are often acceptable stabilizers. The lime addition may prevent stripping at the asphalt-aggregate interface and increase the mixture’s stability. Do not design, specify, or construct lime cement combination-stabilized subgrade, subbase, or base soils with a sulfate content greater than 0.1 percent.

2-1.4 Non-Traditional Additives.

2-1.4.1 Polymers.

Polymer emulsions (sometimes referred to as latex) can be used for soil stabilization. The most common types of polymer emulsions used for soil stabilization are polyvinyl acetate-based copolymers. These materials have excellent adhesive characteristics and provide stiffness, toughness, and water resistance. Polymer emulsions typically consist of 45 to 60 percent polymer content by weight and cure mainly by water loss. These materials may be limited by shelf life. Do not mix polymer emulsions with gray water or salt water for dilution. Soils that can be stabilized with polymer emulsions are similar to those that can be stabilized by bitumen.

2-1.4.2 Fibers.

Numerous fiber types (e.g., polypropylene, polyvinyl alcohol, nylon, and natural) and morphologies (monofilament, fibrillated, and tape) are available. Most soils can be stabilized with fibers; however, mixing may be difficult in highly plastic soils. This difficulty limits the use of fibers for stabilizing fine-grained soils.

2-1.4.3 Non-traditional Additives.

A variety of other non-traditional soil stabilization and modification additives, such as acids, lignin derivatives, enzymes, tree resin emulsions, and silicates, are available from the commercial sector. These additives vary widely in their chemical composition and action mechanism, may be liquid or solid, and are often touted to be applicable for most soils. Research studies in this area have demonstrated that many non-traditional soil additives have little to no benefit for granular soil types. Sandy and gravelly soils are often problematic for stabilization, requiring a binder such as cement, polymer, or asphalt emulsion to provide cohesion between soil grains. Medium- and fine-grained soils are likely to benefit most from the other non-traditional stabilizers; however, these are treated on a case-by-case basis. Do not design, specify, or construct otherwise stabilized subgrade, subbase, or base soils without prior approval by the Pavements DWG.

2-1.4.4 Non-traditional Combinations.

Soil blended with combinations of traditional and non-traditional additives has been shown to be more effective than soil blended with a single additive. Polymer emulsions and hydraulic cements with and without synthetic fibers combine well, as do synthetic fibers and hydraulic cements. These combinations have shown promise in laboratory testing and field demonstrations. A synergism exists between emulsions and hydraulic cement: the water in the emulsion hydrates the cement and the polymer adds flexibility, water resistance, and crack resistance. The use of fibers improves the resistance of the soil to deformation and resists the tensile stresses that lead to cracking. However, fibers are difficult to use during construction as they reduce workability and are difficult to place in wind as they blow around and even be blown completely out of the construction area.

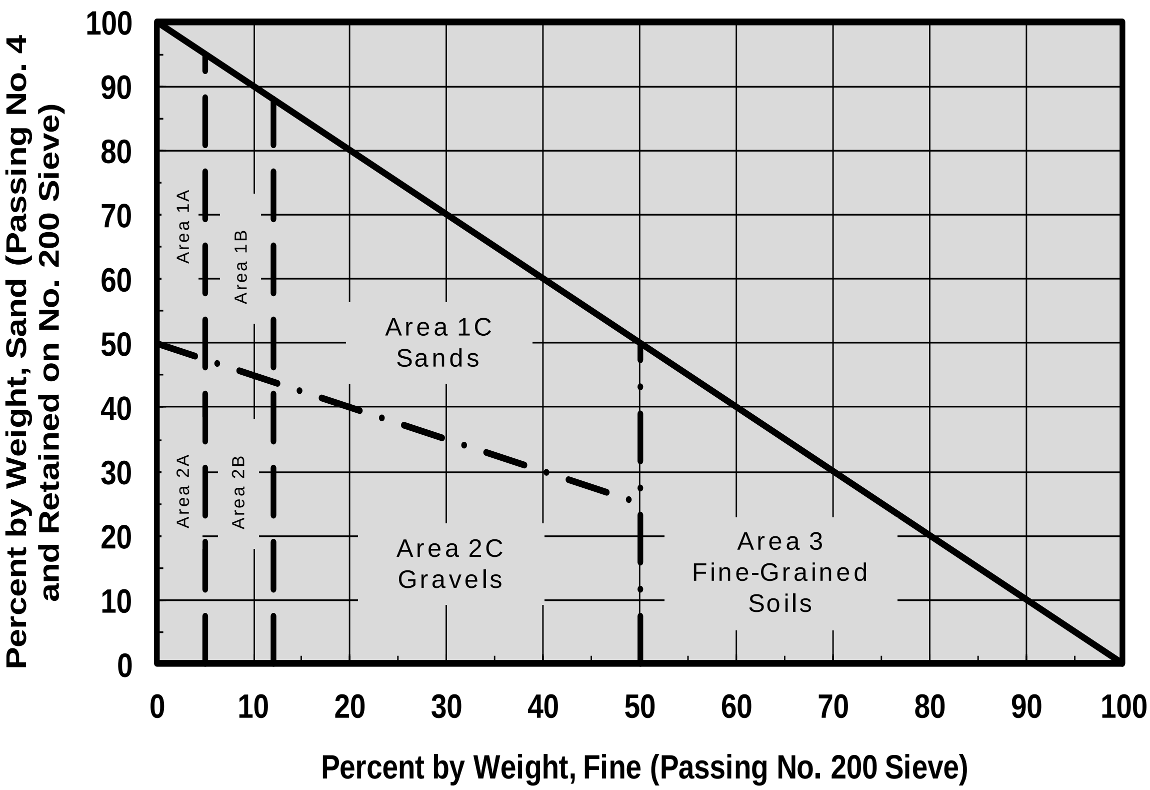
2-1.5 Selection of Candidate Additives.

2-1.5.1 Candidate Stabilizers.

The selection of candidate stabilizers is made using Figure 2-1 and Table 2-3. The soil gradation triangle in Figure 2-1 is based upon the soil grain-size characteristics. The triangle is divided into areas of soils with similar grain size and therefore pulverization characteristics. The selection process is continued with Table 2-3, which indicates candidate stabilizers for each area shown in Figure 2-1, with restrictions-based percent passing the No. 200 (0.075

mm) sieve, on grain size and/or PI. Also provided in the second column of Table 2-3 is a listing of soil classification symbols applicable to the area determined from Figure 2-1. This is an added check to ensure the proper area has been selected. Thus, the soil is characterized in terms of grain-size distribution and Atterberg limits to initiate the additive selection process. Data required to enter Figure 2-1 are (1) percent material passing the No. 200 (0.075 mm) sieve and (2) percent material passing the No. 4 (4.75 mm) sieve but retained on the No. 200 (0.075 mm) sieve (i.e., total percent material between the No. 4 (4.75 mm) and the No. 200 (0.075 mm) sieves). The triangle is entered with these two values and the applicable area (1A, 2A, 3, etc.) is found at their intersection. The area determined from Figure 2-1 is then found in the first column of Table 2-3 and the soil classification is checked in the second column. Candidate stabilizers for each area are indicated in the third column and restrictions for the use of each material are presented in the subsequent columns.

Figure 2-1 Gradation Triangle for Aid in Selecting Commercial Stabilizing Agent



2-1.5.2 Restrictions.

These restrictions prevent the use of stabilizing agents that are not applicable for the particular soil type under consideration. For example, assume a soil classified as an SC, with 93 percent passing the No. 4 (4.75 mm) sieve and 25 percent passing the No. 200 (0.075 mm) sieve with a liquid limit (LL) of 20 and a plastic limit of 11. Thus, 68 percent of the material is between the No. 4 and No. 200 (0.075 mm) sieves and the PI is 9. Entering Figure 2-1 with the values of 25 percent passing the No. 200 (0.075 mm) sieve and 68 percent between the No. 4 (4.75 mm) and No. 200 (0.075 mm) sieves, the intersection of these values is found in area 1-C. Then, going to the first column of Table 2-3, we find area 1-C and verify the soil classification, SC, is included in the second column. From the third column, all four stabilizing materials are found to be potential candidates. The restrictions in the following columns are now examined. Bituminous/polymer stabilization is acceptable since the PI does not exceed 10 and the amount of material passing the No. 200 (0.075 mm) sieve does not exceed 30 percent. However, note that the soil barely qualifies under these criteria and bituminous/polymer stabilization is probably not the first choice. The restrictions under portland cement indicate the PI is less than the equation indicated in footnote b. Since the PI, 9, is less than that value, portland cement is a candidate material. The restrictions under lime indicate that the PI not be less than 12; therefore, lime is not a candidate material for stabilization. The restrictions under LCF stabilization indicate that the PI does not exceed 25; thus, LCF is also a candidate stabilizing material. At this point, the designer makes the final selection based on other factors, such as availability of material, economics, etc. Once the type of stabilizing agent to be used is determined, samples are prepared and tested in the laboratory to develop a design mix meeting minimum engineering criteria for field stabilization.

2-1.5.3 Fibers.

Fibers can be used in many soil types because they provide mechanical stabilization. Monofilament, tape, and fibrillated fibers are most common for improving soils. They provide immediate improvements in load bearing and crack resistance by enhancing strain resistance. Fibers mixed into soil without adhesives (i.e., cement) rely on mechanical interlock, friction, and fiber entanglement between themselves and soil particles to anchor the fiber in place. Thus, a high surface area fiber (such as a tape fiber) may be more efficient in a fine-grained clay soil than in a coarse-grained soil such as gravel, where fewer soil grains are in contact with the fiber. Longer fibers generally result in improved performance but hamper construction. They are more difficult to mix and considerable “balling” may occur, diminishing efficiency. After mixing, workability is sharply reduced, making blade work and grading difficult.

2-2 USE OF STABILIZED SOILS IN FROST AREAS.

2-2.1 Frost Considerations.

Pavement systems may experience two general types of freeze-thaw action. Cyclic freeze-thaw occurs in the material when freezing occurs as the advancing frost line moves by and thawing subsequently occurs. Heaving conditions develop when a quasi-equilibrium frost line condition is established in the stabilized material layer. If the material is frost-susceptible, the static frost line situation provides favorable conditions for moisture migration and subsequent ice lens formation and heaving. While bituminous, polymer, portland cement, lime, and LCF stabilization are the most common additives, other stabilizers may be used for pavement construction in areas of frost design but only with approval from the Pavements DWG. Additives and cold weather placement techniques are also available for portland cement stabilization and are addressed in Chapter 4.

2-2.2 Limitations.

In frost areas, stabilized soil is used in one of the upper elements of a pavement system only if the cost is justified by the reduced pavement thickness. Use a soil treatment with a lower degree of additive than that indicated for stabilization (i.e., soil modification) in frost areas only with caution and after intensive tests because weakly cemented material usually has less capacity to endure repeated freezing and thawing than firmly cemented material. A possible exception is modifying a soil that will be encapsulated within an impervious envelope as part of a membrane-encapsulated-soil-layer pavement system. A soil unsuitable for encapsulation due to excessive moisture migration and thaw weakening may be made suitable by moderate amounts of a stabilizing additive. Test modified materials to ascertain the desired improvement is durable through repeated freeze-thaw cycles. Do not stabilize soils to improve the strength at the expense of making the soil more susceptible to ice segregation.

2-2.3 Construction Cutoff Dates.

Construct materials stabilized with cement, lime, or LCF early enough during the construction season to allow the development of adequate strength before the first freezing cycle begins. The rate of strength gain is substantially lower at 50 °F (10 °C) than at 70 °F or 80 °F (21 °C or 27 °C). Chemical reactions will not occur rapidly for (1) lime-stabilized soils when the soil temperature is less than 60 °F (16 °C) and is not expected to increase for one month or (2) cement-stabilized soils when the soil temperature is less than 40 °F (4 °C) and is not expected to increase for one month. In frost areas, set a construction cutoff date well in advance of the onset of freezing conditions (e.g., 30 days) because it is not adequate to protect the mixture from freezing during a seven-day curing period as required by the applicable guide specifications if the lime or cement reactions continue past the seven-day period.

2-3 THICKNESS REDUCTION FOR BASE AND SUBBASE COURSES.

Ensure the stabilized base and subbase course materials meet the requirements of gradation, strength, and durability to qualify for reduced layer thickness design. Gradation requirements are presented in paragraphs 3-1 through 3-6 covering design with each type of stabilizer. Unconfined compressive strength and durability requirements for bases and subbases treated with cement, lime, lime-cement, lime-fly ash (LF), and LCF are indicated in Tables 2-1 and 2-2, respectively. For bituminous-stabilized materials to qualify for reduced thickness, ensure they meet strength requirements in UFC 3-260-02. Polymer emulsion materials qualify for reduced thickness when they meet a minimum unconfined compressive strength of 400 psi (2.76 MPa). Ensure all stabilized materials except those treated with bitumen and polymer emulsion meet minimum durability criteria to be used in pavement structures. There are no durability criteria for bituminous- or polymer emulsion-stabilized materials since it is assumed they will be waterproof if properly designed and constructed.

Table 2-1 Minimum Unconfined Compressive Strength for Cement-, Lime-, Lime-Cement, and Lime-Cement-Fly Ash-Stabilized Soils

Stabilized Soil Layer	Minimum Unconfined Compressive Strength psi (MPa)[a]	
	Flexible pavement	Rigid pavement
Base course	750 (5.17)	500 (3.45)
Subbase course, select material or subgrade	250 (1.72)	200 (1.38)

[a] Unconfined compressive strength determined at 7 days for cement stabilization and 28 days for lime, LF ash, or LCF ash stabilization.

Table 2-2 Durability Requirements

Type of Soil Stabilized	Maximum Allowable Weight Loss After 12 Wet-Dry or Freeze-Thaw Cycles (Percent of Initial Specimen Weight)
Granular, PI < 10	11
Granular, PI > 10	8
Silt	8
Clays	6

2-4 DRYING WET SOILS.

2-4.1 Chemicals.

The chemicals of choice for drying are oxides of calcium and magnesium, generally referred to as quicklime. Depending on the source, they may be further defined as high-calcium quicklime, magnesium quicklime, or dolomitic quicklime. These substances contain metal oxides (e.g., calcium oxide, CaO) that react with water to form the metal hydrate (e.g., $CaO{\cdot}(OH)_2$). As quicklime hydrates with water in the soil, it releases considerable heat (i.e., is exothermic), which in turn evaporates more water and further reduces the moisture content of the soil. Because this reaction is fast and exothermic, it is effective for drying soils down to freezing temperatures.

2-4.2 Lime.

Lime is a generic term used to cover a variety of materials. Only quicklime is effective for drying soils. Hydrated lime has already combined with water and will not draw moisture into new chemical forms. It will have certain chemical reactions (cation exchange) with some clay minerals that will make them less plastic and easier to dry by conventional methods, but this is much different from the avid drying of quicklime that is not related to soil type. Be aware that “agricultural lime” has no value for engineering stabilization or drying uses. Do not construct stabilized soil materials using agricultural lime.

Any product that contains free quicklime (CaO) can be used as a drying agent. The more CaO it contains, the more effective it will be as a drying agent. Portland cement, fly ash (particularly high calcium Class C ashes), and kiln dust are examples of common industrial materials with significant CaO content that can be used for soil drying. Their effectiveness for drying is directly dependent on their free CaO content. Quicklime is a caustic material; hence, normal safety precautions for such materials need to be followed (long sleeves and pants, rubber gloves, goggles, and mask). Quicklime is a relatively granular material and does not dust like the much finer hydrated lime. While safety precautions are required to handle this material, they are within the range of precautions used on construction sites. Quicklime is a commonly used industrial and construction material and the safety precautions required are reasonable to comply with in the field to ensure worker health and safety. Delivery is typically by dump truck and mixing is typically with a conventional field rotary mixer. Thorough mixing enhances uniform drying.

2-4.3 Amounts.

Amounts for use are generally by trial and error. Take a known weight of a wet soil sample and mix with a known amount of quicklime and see visually and texturally if it dries the wet soil sample. The reaction with CaO is quick and results will be evident very rapidly. Repeat but vary the amount of additive. This is a practical way to ascertain if non-quicklime materials such as portland cement, fly ash, or kiln dust have free CaO to be effective to dry the soil. A qualitative assessment of a simple test of this sort is generally all that is justified for military engineering applications. This will also provide a rough initial estimate of the amount of additive to use for drying.

2-4.4 Factors.

Three factors are involved with drying of the soil: chemical hydration of CaO, exothermic-reaction-caused evaporation, and normal evaporation because of ambient conditions. Therefore, trying to assign exact formulas for how much quicklime to add to gain a specific reduction in moisture content is not justified. It is better to make multiple additions to close in on the desired moisture content. One to two percent quicklime for each percent reduction in desired moisture content is a good starting point.

Table 2-3 Guide for Selecting a Stabilizing Additive

Area	Class (b)	Type of Stabilizer	Restriction (LL and PI)	RESTRICTION (% PASS NO. 200) (c)	REMARK
1A	SW or SP	1. Polymer/bituminous emulsion and cement 2. Portland cement 3. Lime-cement-fly ash 4. 2 and 3 with fiber (a)	PI not to exceed 25	3 & 4. Lime requires at least 25% passing the No. 200 (0.075 mm) sieve	Soils near or above their optimum moisture content may require drying prior to emulsion stabilization.
1B	SW-SM or SP-SW or SW-SC or SP-SC	1. Polymer/bituminous emulsion and cement 2. Portland cement and fiber (a) 3. Lime and fiber (a) 4. Lime-cement-fly ash and fiber (a) 5. 2, 3, and 4 with fiber (a)	1. PI not to exceed 10 2. PI not to exceed 30 3. PI not less than 12 4. PI not to exceed 25	3, 4, 5. Lime requires at least 25% passing the No. 200 (0.075 mm) sieve	Soils near or above their optimum moisture content may require drying prior to emulsion stabilization.
1C	SM or SC or SM-SC	1. Polymer/bituminous emulsion and cement 2. Portland cement and fiber (a) 3. Lime and fiber (a) 4. Lime-cement-fly ash and fiber (a) 5. 2, 3, and 4 with fiber (a)	1. PI not to exceed 10 2. (b) 3. PI not less than 12 4. PI not to exceed 25	1. Not to exceed 30% by weight 3, 4, 5. Lime requires at least 25% passing the No. 200 (0.075 mm) sieve	Soils near or above their optimum moisture content may require drying prior to emulsion stabilization.
2A	GW or GP	1. Polymer/bituminous emulsion and cement 2. Portland cement and fiber (a) 3. Lime-cement-fly ash and fiber (a) 4. 2 and 3 with fiber (a)	PI not to exceed 25	3 & 4. Lime requires at least 25% passing the No. 200 (0.075 mm) sieve	Well-graded material only. Material to contain at least 45% by weight of material passing No. 4 (4.75 mm) sieve. Soils near or above their optimum moisture content may require drying prior to emulsion stabilization.
2B	GW-GM or GP-GM or GW-GC or GP-GC	1. Polymer/bituminous emulsion and cement 2. Portland cement and fiber (a) 3. Lime and fiber (a) 4. Lime-cement-fly ash and fiber (a) 5. 2, 3, and 4 with fiber (a)	1. PI not to exceed 10 2. PI not to exceed 30 3. PI not less than 12 4. PI not to exceed 25	3, 4, 5. Lime requires at least 25% passing the No. 200 (0.075 mm) sieve	Well-graded material only. Material to contain at least 45% by weight of material passing No. 4 (4.75 mm) sieve. Soils near or above their optimum moisture content may require drying prior to emulsion stabilization.
2C	GM or GC or GM-GC	1. Polymer/bituminous emulsion and cement 2. Portland cement and fiber (a) 3. Lime and fiber (a) 4. Lime-cement-fly ash and fiber (a) 5. 2, 3, and 4 with fiber (a)	1. PI not to exceed 10 2. (c) 3. PI not less than 12 4. PI not to exceed 25	1. Not to exceed 30% by weight 3, 4, 5. Lime requires at least 25% passing the No. 200 (0.075 mm) sieve	Well-graded material only. Select Material to contain at least 45% by weight of material passing No. 4 (4.75 mm) sieve.
3	CH or CL or MH or ML or OH or OL or ML-CL	1. Portland cement and fiber (a) 2. Lime (a) 3. 2 with fiber (a)	1. LL less than 40 and PI less than 20 2. PI not less than 12	2 & 3. Lime requires at least 25% passing the No. 200 (0.075 mm) sieve	Organic and strongly acidic soils falling within this area are not susceptible to stabilization by conventional means.

(a) Monofilament polypropylene fiber – Length and denier will vary depending on soil type
(b) Soil classification corresponds to ASTM D2487-17. Restriction on liquid limit (LL) and plasticity index (PI) is in accordance with ASTM D4318-17e1.
(c) PI ≤ 20 + 50 – percent passing No. 200 (0.075 mm) sieve

This Page Intentionally Left Blank

CHAPTER 3 DETERMINING STABILIZER CONTENT

3-1 STABILIZATION WITH PORTLAND CEMENT.

Portland cement can be used either to modify and improve the quality of the soil or to transform the soil into a cemented mass with increased strength and durability. The amount of cement used will depend upon whether the soil is to be modified or stabilized.

3-1.1 Types of Portland Cement.

Several different types of cement have been successfully used for stabilizing soils. Type I normal portland cement and Type IA air-entraining cements were used extensively in the past with similar results. At the present time, Type II cement has greater sulfate resistance obtained while the cost is often the same. High early strength cement (Type III) has been found to give higher strength in certain soils and cures much faster than Type I or Type II. Type III cement has a finer particle size than the other cement types. Chemical and physical property specifications for portland cement can be found in ASTM C150, *Standard Specification for Portland Cement*.

3-1.2 Water for Hydration.

Potable water is normally used for cement stabilization, although seawater has been found to be satisfactory.

3-1.3 Gradation Requirements.

Gradation requirements for cement-stabilized base and subbase courses are in Table 3-1.

Table 3-1 Gradation Requirements for Cement-Stabilized Base and Subbase Courses

Type Course	Sieve Size	Percent Passing
Base	1.5 inch (37.5 mm)	100
	0.75 inch (19 mm)	70–100
	No. 4 (4.75 mm)	45–70
	No. 40 (0.425 mm)	10–40
	No. 200 (0.075 mm)	0–20
Subbase	1.5 inch (37.5 mm)	100
	No. 4 (4.75 mm)	45–100
	No. 40 (0.425 mm)	10–50
	No. 200 (0.075 mm)	0–20

3-1.4 Cement Content for Modifying Soils.

3-1.4.1 Improved Plasticity.

In a majority of cases, lime is preferred over soil cement to reduce the PI or control expansive behavior. If lime is not locally or economically available for a project, it is possible to use cement to reduce the plasticity. Do not design, specify, or install soil cement to reduce the PI of a soil without prior authorization by the Pavements DWG. The amount of cement required to improve the quality of the soil through modification is determined by the trial-and-error approach, as described below.

To reduce the PI of the soil, prepare successive samples of soil-cement mixtures prepared at different treatment levels and the PI of each mixture determined in accordance with ASTM D4318, *Standard Test Methods for Liquid Limit, Plastic Limit, and Plasticity Index of Soils*. The minimum cement content that yields the desired PI is selected but, since it was determined based upon the minus No. 40 (0.425 mm) sieve material, this value is adjusted to find the design cement content based upon total sample weight expressed as:

$$A = 100BC$$

where

A = design cement content, percent total weight of soil
B = percent passing No. 40 (0.425 mm) sieve size, expressed as a decimal
C = percent cement required to obtain the desired PI of minus No. 40 (0.425 mm) sieve material, expressed as a decimal

3-1.4.2 Improved Gradation.

If the objective of modification is to improve the gradation of a granular soil through the addition of fines then conduct a particle size analysis (ASTM D7928, *Standard Test Method for Particle-Size Distribution (Gradation) of Fine-Grained Soils Using the Sedimentation (Hydrometer) Analysis*) on samples at various treatment levels to determine the minimum acceptable cement content.

3-1.4.3 Reduced Swell Potential.

Portland cement may reduce swell potential of certain expansive soils. However, portland cement is not as effective as lime in reducing swell potential and may be considered too expensive for this application. Determining cement content to reduce the swell potential of fine-grained plastic soils can be accomplished by molding several samples at various cement contents and soaking the specimens along with untreated specimens for four days. The lowest cement content that eliminates the swell potential or reduces the swell characteristics to the minimum is the design cement content. Procedures for measuring swell characteristics of soils are found in ASTM D4546-14e1, *Standard Test Methods for One-Dimensional Swell or Collapse of Soils*. Check the cement content found to accomplish soil modification to determine whether it provides an unconfined compressive strength great enough to qualify for a reduced thickness design in accordance with criteria established for soil stabilization.

3-1.4.4 Frost Areas.

Cement-modified soil may also be used in frost areas but, in addition to the procedures for mixture design described in paragraphs 3-1.5.1 through 3-1.5.5, cured specimens are subjected to the 12 freeze-thaw cycles prescribed by ASTM D560, *Standard Test Methods for Freezing and Thawing Compacted Soil-Cement Mixtures* (but omitting wire-brushing). Follow the determination of frost design soil classification by means of standard laboratory freezing tests. If cement-modified soil is used as subgrade, its frost susceptibility, determined after freeze-thaw cycling, is used as the basis of the pavement thickness design if the reduced subgrade design method is applied.

3-1.5 Cement Content for Stabilized Soil.

Determine the design cement content for cement-stabilized soils using the following procedure.

3-1.5.1 Step 1.

Determine the gradation, Atterberg limits, and classification of the untreated soil following procedures in ASTM D7928, ASTM D4318, and ASTM D2487, *Standard Practice for Classification of Soils for Engineering Purposes (Unified Soil Classification System)*, respectively.

3-1.5.2 Step 2.

Using the soil classification, select estimated cement content for moisture-density tests from Table 3-2.

Table 3-2 Cement Requirements for Various Soils

Soil Classification	Initial Estimated Cement Content (percent dry weight)
GW, SW	5
GP, GW-GC, GW-GM, SW-SC, SW-SM	6
GC, GM, GP-GC, GP-GM, GM-GC, SC, SM, SP-SC, SP-SM, SM-SC, SP	7
CL. ML, MH	9
CH	11

3-1.5.3 Step 3.

Conduct moisture-density tests at the estimated cement content and at cement contents 2 percent above and 2 percent below the initial estimated cement content from Table 3-2 to determine the maximum dry density and optimum water content of the soil-cement mixtures at each cement content. Use the procedure in ASTM D558, *Standard Test Methods for Moisture-Density (Unit Weight) Relations of Soil-Cement Mixtures*, to prepare the soil-cement mixture and make the necessary calculations. Use the procedures in ASTM D1557, *Standard Test Methods for Laboratory Compaction*

Characteristics of Soil Using Modified Effort (56,000 ft-lbf/ft^3 (2,700 kN-m/m^3)), to conduct the moisture density test. The maximum dry density determined in the laboratory will be used to set an allowable range for field density (see ASTM D1557, Section 12). In most cases, the density of the cement-treated soil will be higher than for the untreated soil due to the high specific gravity of portland cement; so, as the amount of cement dosage increases, the density may increase slightly.

3-1.5.4 Step 4.

Prepare triplicate samples of the soil-cement mixture for unconfined compression and durability tests at the cement content selected in step 2 and at cement contents 2 percent above and 2 percent below that determined in step 2. Prepare the samples at compaction time and minimum density to be expected in field construction. For example, if the design field density is 97 ± 2 percent of the laboratory maximum density at 9 ± 2 percent moisture content, prepare the samples at 97 percent density and 9 percent moisture content. If field compaction will be not be immediate then compact the samples at a time after mixing representative of when field compaction will occur. Prepare the samples in accordance with ASTM D1632, *Standard Practice for Making and Curing Soil-Cement Compression and Flexure Test Specimens in the Laboratory*, except that when more than 35 percent of the material is retained on the No. 4 (4.75 mm) sieve, use a 4-inch (100-mm) -diameter by 8-inch (200-mm) -high mold to prepare the specimens. Cure the specimens for seven days in a humid room before testing. Test three specimens using the unconfined compression test in accordance with ASTM D1633, *Standard Test Methods for Compressive Strength of Molded Soil-Cement Cylinders*, and subject three specimens to durability tests, either wet-dry (ASTM D559, *Standard Test Methods for Wetting and Drying Compacted Soil-Cement Mixtures*) or freeze-thaw (ASTM D560) tests, as appropriate. Determine the frost susceptibility of the treated material as indicated in UFC 3-260-02.

3-1.5.5 Step 5.

Compare the results of the average of the three unconfined compressive strength and durability tests with the requirements shown in Tables 2-1 and 2-2. The lowest cement content that meets the required unconfined compressive strength requirement <u>and</u> demonstrates the required durability is the design cement content. If the mixture meets the durability requirements but not the strength requirements, the mixture is considered to be a modified soil. If the results of the specimens tested do not meet both the strength and durability requirements then higher cement content may be selected and steps 3 and 4 above repeated.

3-2 STABILIZATION WITH LIME.

Generally, lime-treated, fine-grained soils exhibit decreased plasticity, improved workability, and reduced volume change characteristics. However, not all soils exhibit improved strength characteristics. Note that the properties of soil-lime mixtures are dependent on many variables. Soil type, lime type, lime percentage, and curing conditions (time, temperature, and moisture) are the most important. Perform preliminary lime reactivity testing on each soil type intended for use on a project as not all soil-lime combinations are reactive.

Prior to designing a stabilization program to treat a shrink/swell soil, thoroughly examine the geological/geotechnical conditions with respect to the groundwater and runoff water. Eliminate or mitigate the water source that causes expansive soil to swell rather than treating the soil or reduce the treatment regimen to save costs as much as possible. This requires the initial design study to be robust and thorough, with specific attention paid to the water conditions above and below the surface. Modifying the soils at the surface without mitigating water intrusion to the expansive soils at or below the surface will result in premature failure and poor performance of the soil layer.

Designing a lime treatment based on the potential vertical rise (PVR) has the potential to overestimate the actual vertical rise and therefore over-prescribe the amount of lime treatment depth and quantity required once the water source is mitigated. Conversely, if the water source is not removed, diverted, or mitigated in some way, the stabilization treatment will likely not be adequate to handle the swell induced during a surge of water flow into the expansive zone.

3-2.1 Types of Lime.

Various forms of lime have been successfully used as soil-stabilizing agents for many years. However, the most commonly used products are hydrated high-calcium lime, monohydrated dolomitic lime, calcitic quicklime, and dolomitic quicklime. Hydrated lime is used most often because it is much less caustic than quicklime. Under certain circumstances, the quantity of lime may be reduced if quicklime is used in lieu of hydrated lime; however, only reduce the amount of lime prescribed by the mix design at the direction of the Pavements DWG. Specifications for quicklime and hydrated lime may be found in ASTM C977, *Standard Specification for Quicklime and Hydrated Lime for Soil Stabilization*.

3-2.2 Gradation Requirements.

Consider lime stabilization of soils containing a minimum of 25 percent passing the No. 200 (0.075 mm) sieve.

3-2.3 Lime Content for Lime-Modified Soils.

The amount of lime required to improve the quality of a soil is determined through the same trial-and-error process used for cement-modified soils. Highly weathered soils may require higher lime content than usually specified by previous guideline documents. The following procedures are recommended for determining the lime content of lime-stabilized soils.

3-2.3.1 Step 1.

The preferred method for determining initial design lime content is the pH test (ASTM D6276, *Standard Test Method for Using pH to Estimate the Soil-Lime Proportion Requirement for Soil Stabilization*). In this method, several lime-soil slurries are prepared at different lime treatment levels, such as 2, 4, 6, and 8 percent lime, and the pH of each slurry is determined. The lowest lime content at which a pH of at least 12.4 (the pH of free lime) is obtained is the initial design lime content. This is the initial starting point and is the minimum required lime content for the pozzolanic reactions to occur.

3-2.3.2 Step 2.

Using the initial design lime content, conduct moisture-density tests to determine the maximum dry density and optimum water content of the soil-lime mixture. Use the procedures in ASTM D3551, *Standard Practice for Laboratory Preparation of Soil-Lime Mixtures Using Mechanical Mixer*, to prepare the soil-lime mixture. Conduct the moisture density test following procedures in ASTM D1557.

3-2.3.3 Step 3.

Prepare samples of the soil-lime mixture—three each for unconfined compression and durability tests at the initial design lime content and at lime contents 2 and 4 percent above design if based on the preferred method, or 2 percent above and 2 percent below design if based on the alternate method. Prepare the mixture as indicated in ASTM D3551. If less than 35 percent of the soil is retained on the No. 4 (4.75 mm) sieve, mold approximately 2-inch (50 mm) -diameter and 4-inch (100 mm) -high samples. If more than 35 percent is retained on the No. 4 (4.75 mm) sieve, mold 4-inch (100 mm) -diameter and 8-inch (200 mm) -high samples. Prepare the samples at the density and water content expected in field construction. For example, if the design density is 95 percent of the laboratory maximum density, prepare the sample at 95 percent density. Cure specimens in a sealed container to prevent moisture loss and lime carbonation. Sealed metal cans, plastic bags, and so forth are satisfactory. The preferred method of curing is 73 °F (23 °C) for 28 days. Accelerated curing at 120 °F (49 °C) for 48 hours has also been found to give satisfactory results; however, conduct additional check tests at 73 °F (23 °C) for 28 days. Research has shown that if accelerated curing temperatures are too high, the pozzolanic compounds formed during laboratory curing differ substantially from those that develop in the field.

3-2.3.4 Step 4.

Test three specimens using the unconfined compression test in accordance with ASTM D2166/D2166M, *Standard Test Method for Unconfined Compressive Strength of Cohesive Soil*. If frost design is a consideration, subject an additional three specimens to 12 cycles of freeze-thaw durability tests (ASTM D560), except omit wire brushing. Determine the frost susceptibility of the treated material as indicated in UFC 3-260-02.

3-2.3.5 Step 5.

Compare the results of the unconfined compressive strength and durability tests with the requirements shown in Tables 2-1 and 2-2. The lowest lime content that meets the unconfined compressive strength requirement and demonstrates the required durability is the design lime content. Ensure the treated material also meets frost susceptibility requirements as indicated in UFC 3-260-02. If the mixture meets the durability requirements but not the strength requirements, it is considered to be a modified soil. If results of the specimens tested do not meet both the strength and durability requirements, higher lime content may be selected and steps 1 through 5 repeated.

3-3 STABILIZATION WITH LIME-FLY ASH (LF) AND LIME-CEMENT-FLY ASH (LCF).

Stabilization of coarse-grained soils having little or no fines can often be accomplished by the use of LF or LCF combinations. Fly ash, also termed coal ash, is a mineral residual from the combustion of pulverized coal. It contains silicon and aluminum compounds that, when mixed with lime and water, form a hardened cementitious mass capable of obtaining high compressive strengths. Lime and fly ash in combination can often be successfully used to stabilize granular materials since the fly ash provides an agent with which the lime can react; thus, LF or LCF stabilization is often appropriate for base and subbase course materials.

3-3.1 Types of Fly Ash.

Fly ash is classified according to the type of coal from which the ash was derived. Class C fly ash is derived from the burning of lignite or subbituminous coal and is often referred to as "high lime" ash because it contains a high percentage of lime. Class C fly ash is self-reactive or cementitious in the presence of water, in addition to being pozzolanic; however, using Class C fly ash has proven to be sensitive and difficult at times. Class F fly ash is derived from the burning of anthracite or bituminous coal and is sometimes referred to as "low lime" ash, depending on locale. It requires the addition of lime to form a pozzolanic reaction. Volcanic ash, rice hull ash (Type N natural pozzolans), and slag (ground-granulated blast-furnace slag [GGBFS]) may be used as stabilizers, where available. In certain geographic locations, they are widely available and have been used successfully as stabilizers for many years.

3-3.2 Evaluation of Fly Ash.

Fly ash used for stabilization is acceptable quality when it meets the requirements indicated in ASTM C593, *Standard Specification for Fly Ash and Other Pozzolans for Use with Lime for Soil Stabilization*.

3-3.3 Gradation Requirements.

LF and LCF stabilization are useful only in soils with a PI less than 25 and less than 50 percent passing the No. 200 (0.075 mm) sieve.

3-3.4 Selection of Lime-Fly Ash Content for LF and LCF Mixtures.

Design with LF is different from stabilization with lime or cement. For a given combination of materials (aggregate, fly ash, and lime), a number of factors—such as percentage of lime-fly ash, the moisture content, and the ratio of lime to fly ash—can be varied in the mix design process. In general, engineering characteristics such as strength and durability are directly related to the quality of the matrix material. The matrix material is that part consisting of fly ash, lime, and minus No. 4 aggregate fines. Higher strength and improved durability are achievable when the matrix material is able to "float" the coarse aggregate particles. In effect, the fine-sized particles overfill the void spaces between the coarse aggregate particles. For each coarse aggregate material, a quantity of matrix is required to effectively fill the available void spaces and "float" the coarse aggregate particles. The quantity of matrix required for maximum dry density of the total mixture is referred to as the optimum fines content. In LF mixtures, it is recommended that the quantity of matrix be approximately 2 percent above the optimum fines content. At the recommended fines content, the strength development is also influenced by the ratio of lime to fly ash. Adjustment of the lime-fly ash ratio will yield different values of strength and durability properties.

3-3.4.1 Step 1.

The first step is to determine the optimum fines content that will give the maximum density. This is done by conducting a series of moisture-density tests using different percentages of fly ash and determining the mix level that yields maximum density. Start with the initial fly ash content of approximately 10 percent based on dry weight of the mix. It is recommended that material larger than 0.75 inch (19 mm) be removed and the test conducted on the minus 0.75 inch (19 mm) fraction. Tests are run at increasing increments of fly ash (e.g., 2 percent) up to a total of about 20 percent. Conduct moisture-density tests following procedures in ASTM D1557. The design fly ash content is then selected at 2 percent above that yielding maximum density. An alternate method is to conduct single-point compaction tests at fly ash contents of 10 to 20 percent of the estimated optimum water content, make a plot of dry density versus fly ash content, and determine the fly ash content that yields maximum density. The design fly ash content is 2 percent above this value. A moisture-density test is then conducted to determine the optimum water content and maximum dry density for the LF-stabilized soil.

3-3.4.2 Step 2.

Determine the ratio of lime to fly ash that will yield highest strength and durability. Using the design fly ash content and the optimum water content determined in step 1, prepare triplicate specimens, each set at three different lime-fly ash ratios, following procedures in ASTM D1557. Use LF ratios of 1:3, 1:4, and 1:5. If desired, about 1 percent of portland cement may be added at this time.

3-3.4.3 Step 3.

Test three specimens using the unconfined compression test in ASTM D2166/D2166M. If frost design is a consideration, subject three additional specimens to 12 cycles of freeze-thaw durability tests (ASTM D560) but omit wire brushing. Determine the frost susceptibility of the treated material as indicated in UFC 3-260-02.

3-3.4.4 Step 4.

Compare the results of the unconfined compressive strength and durability tests with the requirements shown in Tables 2-1 and 2-2. The lowest LF ratio content (i.e., the ratio with the lowest lime content, which meets the required unconfined compressive strength requirement and demonstrates the required durability) is the design LF content. Also, meet frost-susceptibility requirements as indicated in UFC 3-260-02 for the treated material. If the mixture meets the durability requirements but not the strength requirements, it is considered to be a modified soil. If the results of the specimens tested meet neither the strength nor the durability requirement, select a different LF content or use additional portland cement and repeat steps 2 through 4.

3-3.5 Selection of Cement Content for LCF Mixtures.

Portland cement may also be used in combination with LF for improved strength and durability. If it is desired to incorporate cement into the mixture, follow the same procedures indicated for LF design but include cement beginning at step 2. Generally, about 1 to 2 percent cement is used. Cement may be used in place of or in addition to lime; however, maintain the total fines content. Conduct strength and durability tests on samples at various LCF ratios to determine the combination that gives best results.

3-4 STABILIZATION WITH BITUMEN AND POLYMER EMULSION.

Stabilizing soils and aggregates with asphalt and polymer emulsion differs greatly from stabilizing soils with cement and lime. The basic mechanism involved in stabilizing fine-grained soils is a waterproofing phenomenon. Soil particles or soil agglomerates are coated with an asphalt or polymer film that prevents or slows the penetration of water, which typically results in a decrease in soil strength. In addition, asphalt or polymer stabilization can improve durability characteristics by making the soil resistant to the detrimental effects of water, such as volume changes. In non-cohesive materials—such as sands and gravel, crushed gravel, and crushed stone—two basic mechanisms are active: waterproofing and adhesion. The asphalt or polymer coating on the cohesionless materials provides a membrane that prevents or hinders the penetration of water, thereby reducing the tendency of the material to lose strength in the presence of water. The second mechanism is adhesion. The aggregate particles adhere to the binder and the binder acts as a cement between soil particles. The cementing effect thus increases shear strength by increasing cohesion. Criteria for design of bitumen-stabilized soils are based almost entirely on stability and soil gradation requirements. For polymer emulsions, the criteria are based solely on unconfined compressive strength. Freeze-thaw and wet-dry durability tests are not applicable for asphalt-stabilized or polymer-stabilized mixtures.

3-4.1 Types of Bituminous-Stabilized Soils.

3-4.1.1 Sand Bitumen.

A mixture of sand and bitumen in which the sand particles are cemented together to provide a material of increased stability.

3-4.1.2 Gravel or Crushed Aggregate Bitumen.

A mixture of bitumen and a well-graded gravel or crushed aggregate that, after compaction, provides a stable, waterproof mass of subbase or base course quality.

3-4.1.3 Bitumen Lime.

A mixture of soil, lime, and bitumen that, after compaction, may exhibit the characteristics of any of the bitumen-treated materials indicated above. Lime is used with material that has a high PI (i.e., above 10).

3-4.2 Types of Bitumen.

3-4.2.1 Bituminous stabilization is generally accomplished using asphalt cement, cutback asphalt, or asphalt emulsions. The type of bitumen to be used depends upon the type of soil to be stabilized, location, method of construction, and weather conditions. Generally, the most satisfactory results are obtained when the most viscous liquid asphalt that can be readily mixed into the soil is used. For higher quality mixes in which a central plant is used, use viscosity-grade asphalt cements. Much bituminous stabilization is performed in place, with the bitumen being applied directly on the soil or soil-aggregate system and the mixing and compaction operations being conducted immediately thereafter. For this type of construction, liquid asphalts (i.e., cutbacks and emulsions) are used. Emulsions are preferred over cutbacks because of safety, reduced energy consumption, and environmental regulations. The specific type and grade of bitumen will depend on the characteristics of the aggregate, the type of construction equipment, and the climatic conditions. Generally, the following types of bituminous materials will be used for the soil gradation indicated:

3-4.2.1.1 Open-graded Aggregate.

- Rapid- and medium-curing liquid asphalts RC-250, RC-800, and MC-3000
- Medium-setting asphalt emulsion MS-2 and CMS-2

3-4.2.1.2 Well-graded Aggregate with Little or No Material Passing the No. 200 (0.075 mm) Sieve.

- Rapid- and medium-curing liquid asphalts RC-250, RC-800, MC-250, and MC-800
- Slow-curing liquid asphalts SC-250 and SC-800
- Medium-setting and slow-setting asphalt emulsions MS-2, CMS-2, SS-1, and CSS-1

3-4.2.1.3 Aggregate with a Considerable Percentage of Fine Aggregate and Material Passing the No. 200 (0.075 mm) Sieve.

- Medium-curing liquid asphalts MC-250 and MC-800
- Slow-curing liquid asphalts SC-250 and SC-800
- Slow-setting asphalt emulsions SS-1, SS-01h, CSS-1, and CSS-1h

3-4.2.2 The simplest type of bituminous stabilization is applying liquid asphalt to the surface of an unbound aggregate road. For this type of operation, slow- and medium-curing liquid asphalts—SC-70, SC-250, MC-70, and MC-250—and slow-setting emulsions as defined in paragraph 3-4.2.1 are used.

3-4.3 Soil Gradation.

The recommended soil gradations for subgrade materials and base or subbase course materials are shown in Tables 3-3 and 3-4, respectively.

Table 3-3 Recommended Gradations for Bituminous-Stabilized Subgrade Materials

Sieve Size	Percent Passing
3 inch (75 mm)	100
No. 4 (4.75 mm)	50–100
No. 30 (0.600 mm)	38–100
No. 200 (0.075 mm)	2–30

Table 3-4 Recommended Gradations for Bituminous-Stabilized Base and Subbase Materials

Sieve Size	1.5 inch (37.5 mm) Maximum	1 inch (25 mm) Maximum	0.75 inch (19 mm) Maximum	0.5 inch (12.5 mm) Maximum
1.5 inch (37.5 mm)	100	--	--	--
1 inch (25 mm)	84 ± 9	100	--	--
0.75 inch (19 mm)	76 ± 9	83 ± 9	100	--
0.5 inch (12.5 mm)	66 ± 9	73 ± 9	82 ± 9	100
3/8 inch (9.5 mm)	59 ± 9	64 ± 9	72 ± 9	83 ± 9
No. 4 (4.75 mm)	45 ± 9	48 ± 9	54 ± 9	62 ± 9
No. 8 (2.36 mm)	35 ± 9	36 ± 9	41 ± 9	47 ± 9
No. 16 (1.18 mm)	27 ± 9	28 ± 9	32 ± 9	36 ± 9
No. 30 (0.600 mm)	20 ± 9	21 ± 9	24 ± 9	28 ± 9
No. 50 (0.300 mm)	14 ± 7	16 ± 7	17 ± 7	20 ± 7
No. 100 (0.150 mm)	9 ± 5	11 ± 5	12 ± 5	14 ± 5
No. 200 (0.075 mm)	5 ± 2	5 ± 2	5 ± 2	5 ± 2

3-4.4 Mix Design.

Guidance for the design of bituminous-stabilized base and subbase courses is in UFC 3-250-01. For subgrade stabilization, the following equation may be used for estimating the preliminary quantity of cutback asphalt to be selected:

$$p = \frac{0.02(a) + 0.07(b) + 0.15(c) + 0.20(d)}{(100 - S)} \times 100$$

where

p = percent cutback asphalt by weight of dry aggregate
a = percent of mineral aggregate retained on No. 50 (0.300 mm) sieve
b = percent of mineral aggregate passing No. 50 (0.300 mm) sieve and retained on No. 100 (0.150 mm) sieve
c = percent of mineral aggregate passing No. 100 (0.150 mm) sieve and retained on No. 200 (0.075 mm) sieve
d = percent of mineral aggregate passing No. 200 (0.075 mm) sieve
S = percent solvent

The preliminary quantity of emulsified asphalt to be used in stabilizing subgrades can be determined from Table 3-5. Select the final design content of cutback or emulsified asphalt based upon the results of the Marshall Stability Test (ASTM D6927, *Standard Test Method for Marshall Stability and Flow of Asphalt Mixtures*). The minimum Marshall Stability recommended for subgrades is 500 lb (227 kg). If a soil does not show increased stability when reasonable amounts of bituminous materials are added, modify the gradation of the soil or use another type of bituminous material. Poorly graded materials may be improved by the addition of suitable fines containing considerable material passing the No. 200 (0.075 mm) sieve. The amount of bitumen required for a given soil increases with an increase in percentage of the finer sizes.

Table 3-5 Emulsified Asphalt Requirements

Percent Passing No. 200 (0.075 mm) Sieve	Pounds (kg) of Emulsified Asphalt per 100 Pounds (45 kg) of Dry Aggregate at Percent Passing No. 10 (2 mm) Sieve					
	< 50	60	70	80	90	100
0	6.0 (2.7)	6.3 (2.8)	6.5 (2.9)	6.7 (3.0)	7.0 (3.2)	7.2 (3.3)
2	6.3 (2.8)	6.5 (2.9)	6.7 (3.0)	7.0 (3.2)	7.2 (3.3)	7.5 (3.4)
4	6.5 (2.9)	6.7 (3.0)	7.0 (3.2)	7.2 (3.3)	7.5 (3.4)	7.7 (3.5)
6	6.7 (3.0)	7.0 (3.2)	7.2 (3.3)	7.5 (3.4)	7.7 (3.5)	7.9 (3.6)
8	7.0 (3.2)	7.2 (3.3)	7.5 (3.4)	7.7 (3.5)	7.9 (3.6)	8.2 (3.7)
10	7.2 (3.3)	7.5 (3.4)	7.7 (3.5)	7.9 (3.6)	8.2 (3.7)	8.4 (3.8)
12	7.5 (3.4)	7.7 (3.5)	7.9 (3.6)	8.2 (3.7)	8.4 (3.8)	8.6 (3.9)
14	7.2 (3.3)	7.5 (3.4)	7.7 (3.5)	7.9 (3.6)	8.2 (3.7)	8.4 (3.8)
16	7.0 (3.2)	7.2 (3.3)	7.5 (3.4)	7.7 (3.5)	7.9 (3.6)	8.2 (3.7)
18	6.7 (3.0)	7.0 (3.2)	7.2 (3.3)	7.5 (3.4)	7.7 (3.5)	7.9 (3.6)
20	6.5 (2.9)	6.7 (3.0)	7.0 (3.2)	7.2 (3.3)	7.5 (3.4)	7.6 (3.4)
22	6.3 (2.8)	6.5 (2.9)	6.7 (3.0)	7.0 (3.2)	7.2 (3.3)	7.5 (3.4)
24	6.0 (2.7)	6.3 (2.8)	6.5 (2.9)	6.7 (3.0)	7.0 (3.2)	7.2 (3.3)
25	6.2 (2.8)	6.4 (2.9)	6.6 (3.0)	6.9 (3.1)	7.1 (3.2)	7.3 (3.3)

3-4.5 Polymer Emulsion.

Due to the wide variety of polymer emulsion properties, it is best to follow the manufacturer’s recommendations for starting dosage amounts for the classification and gradation of the soil.

3-4.5.1 Polymer Content for Stabilized Soil.

The following procedure is recommended for determining the design polymer content. It is similar to that for cement and lime stabilization where the optimum moisture content is first determined for the initial trial polymer content followed by a trial-and-error approach to determine the design polymer content.

3-4.5.1.1 Step 1.

Determine the gradation, Atterberg limits, and classification of the untreated soil following procedures in ASTM D6913/D6913M-17, *Standard Test Methods for Particle-Size Distribution (Gradation) of Soils Using Sieve Analysis*, D4318-17e1, and D2487-17, respectively.

3-4.5.1.2 Step 2.

Using the manufacturer's recommendation as a starting point, select an initial polymer content for moisture-density tests (ASTM D1557).

3-4.5.1.3 Step 3.

Using the initial polymer emulsion content, determine the amount of water that will be added to the soil from the polymer emulsion based upon its percent solids. Then conduct moisture-density tests to determine the maximum dry density (MDD_{OMC}) and optimum water content (OMC) of the soil-polymer mixture at each polymer emulsion content. Use the procedure in ASTM D558 to prepare the soil-polymer mixture and make the necessary calculations; however, use the procedures in ASTM D1557 to conduct the moisture-density tests.

3-4.5.1.4 Step 4.

Prepare triplicate samples of the soil-polymer mixture for unconfined compression tests at the initial polymer content selected in step 2 and at polymer contents 1 percent above and 1 percent below that determined in step 2. For example, if the design field density is 97 ± 2 percent of the laboratory maximum density at 9 ± 2 percent moisture content, prepare the samples at 97 percent density and 9 percent moisture content. If field compaction will not be immediate then compact the samples at a time after mixing representative of when field compaction will occur. Prepare the samples in accordance with ASTM D1632 except that when more than 35 percent of the material is retained on the No. 4 (4.75 mm) sieve, use a 4-inch (100 mm) -diameter by 8-inch (200 mm) -high mold to prepare the specimens. Cure the specimens for seven days at 77 °F (25 °C) in a 50 percent humidity environment before testing. Test three specimens using the unconfined compression test in accordance with ASTM D1633.

3-4.5.1.5 Step 5.

Ensure the average of the three tests are above 400 psi (2.76 MPa). The lowest polymer content that meets the required unconfined compressive strength is the design polymer content. If the results of the specimens tested do not meet the strength requirements then lower or higher polymer content may be selected and steps 1 through 4 above repeated.

3-4.5.2 Portland Cement Content for Polymer-Stabilized Soil.

Portland cement may be used in combination with polymer emulsion. The polymer provides strength, flexibility, and water resistance while the cement provides strength and helps the emulsion cure by reacting with the emulsion water. The mix design procedure is the same as described in paragraph 3-4.5.1. Begin the initial trial with a polymer emulsion content suggested by the manufacturer. If used in combination, the initial trial cement is 1 percent and does not exceed the design polymer emulsion content.

3-5 STABILIZATION WITH LIME-CEMENT AND LIME-BITUMEN.

The advantage in using combination stabilizers is that one of the stabilizers in the combination compensates for the lack of effectiveness of the other in treating a particular aspect or characteristics of a given soil. For instance, in clay areas devoid of base material, lime has been used jointly with other stabilizers, notably portland cement or asphalt, to provide acceptable base courses. Since portland cement or asphalt cannot be successfully mixed with plastic clays, the lime is incorporated into the soil to make it friable, thereby permitting the cement or asphalt to be adequately mixed. While this stabilization practice may be more costly than the conventional single stabilizer methods, it may still prove to be economical in areas where base aggregate costs are high. Two combination stabilizers are considered in this section: lime-cement and lime-asphalt.

3-5.1 Lime-Cement.

Lime can be used as an initial additive with portland cement or alone as the primary stabilizer. The main purpose of lime is to improve workability characteristics, mainly by reducing the plasticity of the soil. The design approach is to add enough lime to improve workability and reduce the PI to acceptable levels. The design lime content is the minimum that achieves desired results. The design cement content is arrived at following procedures for cement-stabilized soils in paragraph 3-1.

3-5.2 Lime-Asphalt.

Lime can be used as an initial additive with asphalt as the primary stabilizer. The main purpose of lime is to improve workability characteristics and act as an anti-stripping agent. In the latter capacity, the lime acts to neutralize acidic chemicals in the soil or aggregate that tend to interfere with bonding of the asphalt. Generally, about 1 to 2 percent lime is all that is needed for this objective. When asphalt is the primary stabilizer, follow the procedures for asphalt-stabilized materials in paragraph 3-4.

3-5.3 Lime Treatment of Expansive Soils.

Expansive soils as defined for pavement purposes are those that exhibit swell in excess of 3 percent. Expansion is characterized by heaving of a pavement or road when water is imbibed in the clay minerals. The plasticity characteristics of a soil are often a good indicator of the swell potential, as indicated in Table 3-6. If it has been determined that a soil has potential for excessive swell, lime treatment may be appropriate. Lime will reduce swell in an expansive soil to greater or lesser degree, depending on the activity of the clay minerals present. The amount of lime to be added is the minimum amount that will reduce swell to acceptable limits, less than 1 percent swell. Use the procedure for conducting swell tests described in ASTM D4546-14e1. The maximum depth that the lime is incorporated into the soil is typically limited by the construction equipment used. However, 2 to 3 feet (0.6 m to 0.9 m) generally is the maximum depth that can be treated directly without removal of the soil. Once the design lime content has been determined, perform testing to verify the intended lime stabilization will also prevent soil expansion. The lime content necessary to reduce the PI is not always suitable to control shrink/swell.

Table 3-6 Swell Potential of Soils

Liquid Limit	Plasticity Index	Potential Swell
> 60	> 35	High
50–60	25–35	Marginal
< 50	< 25	Low

3-6 STABILIZATION WITH FIBERS.

Fiber stabilization in soils is an emerging field. Polypropylene fibers are the most common for soil applications. It is best to follow manufacturer's recommendations for starting dosage amounts for the classification and gradation of the soil. Fibers are very efficient at adding toughness to the soil; they usually do not add stiffness but improve ductility. Fibers may be used alone but are recommended to be used with an adhesive (cement, bitumen, or polymer). Fibers blended with cement reduce the amount of shrinkage cracking. Criteria on the amount of fibers to use are not available at this time; however, there are general guidelines to follow. Refer to UFC 3-220-08FA, *Engineering Use of Geotextiles*, for additional guidance in using geosynthetic materials.

Testing has shown that monofilament and tape fibers are more efficient for rapid stabilization. Fibrillated fibers require extensive mixing (multiple passes of a soil mixer) to effectively defibrillate the fiber for maximum efficiency. Fibers mixed into soil without adhesives (i.e., cement) rely exclusive on mechanical interlock, friction, and fiber entanglement with other fibers and between soil particles to anchor the fiber in place. Thus, a high surface area fiber (such as a tape fiber) may be more efficient in a fine-grained clay soil than in a coarse-grained soil such as gravel, where fewer soil grains are in contact with the fiber.

Fiber amounts will vary depending on the length, denier, and morphology. Fiber lengths for soils typically range from 0.5 to 3 inches (13 to 76 mm). Longer fibers are recommended if no adhesives are used. Successful soil stabilization projects have been performed on virgin granular soils with 2 inch (51 mm) long discrete fibers. Longer fibers generally result in improved performance but hamper construction, as they are more difficult to mix due to entanglement. Shorter fibers (less than 1 inch [25 mm]) are recommended when using adhesives, as the adhesive helps to create a composite network of fiber through the soil. A recommended fiber starting dosage is 0.1 percent with a maximum of 0.8 percent. Increased amounts of fiber may reduce the stiffness of the soil and become difficult to mix with soil.

CHAPTER 4 CONSTRUCTION PROCEDURES

4-1 CONSTRUCTION WITH PORTLAND CEMENT.

4-1.1 General Construction Steps.

In soil-cement construction, the objective is to thoroughly mix a pulverized soil material and cement in correct proportions with moisture to permit maximum compaction. Construction methods are simple and follow a specific procedure:

4-1.1.1 Initial Preparation.

4-1.1.1.1 Shape the area to crown and grade.

4-1.1.1.2 If necessary, scarify, pulverize, and pre-wet the soil.

4-1.1.1.3 Reshape to crown and grade.

4-1.1.1.4 Precompact.

4-1.1.2 Processing.

4-1.1.2.1 Spread portland cement and mix.

4-1.1.2.2 Apply water, if necessary, to achieve the optimum moisture content.

4-1.1.2.3 Mix the additive and soil thoroughly.

4-1.1.2.4 Compact.

4-1.1.2.5 Finish.

4-1.1.2.6 Cure.

4-1.2 Mixing Equipment.

Soil, cement, and water can be mixed in place using traveling mixing machines or mixed in a central mixing plant.

4-1.2.1 Traveling Mixing Machines.

4-1.2.1.1 Transverse single-shaft mixer

4-1.2.1.2 Windrow-type pugmill

4-1.2.2 Central Mixing Plants.

4-1.2.2.1 Continuous flow-type pugmill

4-1.2.2.2 Batch-type pugmill

4-1.2.3 Principles and Objectives.

Regardless of the type of mixing equipment used, the general principles and objectives are the same. Certain soil materials cannot be pulverized and mixed in central mixing plants because of their high silt and/or clay content and plasticity. If necessary, determine if the soil materials can be pulverized and mixed by running a trial batch. Almost all types of soil materials, from granular to fine-grained, can be adequately pulverized and mixed with transverse-shaft mixers, given proper moisture control. The exception is material containing predominantly highly plastic clays. These clays may require more mixing effort to obtain pulverization. Revolving-blade central mixing plants and traveling pugmills can be used for non-plastic to slightly plastic granular soils. For coarse, non-plastic granular materials, a rotary-drum mixer can provide a suitable mix; however, if the material includes a small amount of slightly plastic fines, mixing may not be adequate. For plastic soils, it is very important to pulverize the soil thoroughly prior to mixing with the additive to reduce the “clod” size. Reducing the average particle size through pulverization increases the specific surface area of the soil, thereby improving the coating and ability of the additive to penetrate further into the particles.

4-1.3 Equipment for Handling and Spreading Cement.

There are a number of methods for handling cement. For mixed-in-place construction using traveling mixing machines, bulk cement is spread on the area to be processed in required amounts by mechanical bulk cement spreaders. It is permissible to use bag cement on jobs that are too limited in size to require mass quantities of cement. Cement spreaders for mix-in-place construction are of two general types: those that spread cement over the soil material in a blanket and those that deposit cement on top of a partially flattened or slightly trenched windrow of soil material. For centrally mixed soil-cement projects, cement meters on continuous-flow central mixing plants are of three types: the belt with strikeoff, screw, or vane. The cement for batch-type pugmill mixers and rotary drum-mixers is batch weighed.

4-1.4 Construction*.*

Construction with soil cement involves two steps: preparation and processing. Variations in these steps, dictated by the type of mixing equipment used, are discussed in this chapter. Regardless of the equipment and methods used, it is essential to have an adequately compacted, thorough mixture of pulverized soil material and proper amounts of cement and moisture. Adequately cure the completed soil-cement.

4-1.4.1 Preparation.

Before construction starts, check the crown and grade and complete fine grading. Since there is little displacement of material during processing, grade at the start of construction will determine final grade to a major extent. If borrow material is to be used, compact and shape the subgrade to the proper crown and grade before the borrow material is placed. Correct any soft subgrade areas. To avoid costly delays, carefully check all equipment to ensure it is in proper operating condition and meets construction requirements of the job. Utilize guide stakes and string lines to control the width and guide the operators during construction. Make arrangements to receive, handle, and spread the cement and water efficiently. The number of cement and water trucks required depends on length of haul, condition of haul roads, and anticipated rate of production. For maximum production, an adequate cement and water supply is essential. The project engineer establishes the limits of the different materials and their corresponding cement requirements. Pre-wetting the soil by adding moisture before cement is applied often saves time during actual processing. Friable granular materials, which are most commonly used, require little or no scarification or pulverization. Silty and clayey soils may require extra effort to pulverize them, particularly if they are too dry or too wet. Soils that are difficult to pulverize when dry and brittle can be broken down readily if water is added and allowed to soak in, whereas sticky soils can be pulverized more easily when they have been dried out slightly. Most specifications require that the soil material be pulverized so that at the time of compaction 100 percent of the soil-cement mixture will pass a 1 inch (25 mm) sieve and a minimum of 80 percent will pass a No. 4 (4.75 mm) sieve, exclusive of any gravel or stone. Ensure gravel or stone are no more than 2 inch (50 mm) maximum size or the stabilization effects will be minimal. Test the final pulverization at the conclusion of mixing operations. When borrow material is specified, distribute it on an accurately graded, well-compacted roadway in an even layer or uniform windrow, depending on the type of mixing equipment to be used. Place the fill by weight or volume as required by the specifications. Pre-compaction of the soil can help ensure the target design cement content and proper layer thickness are reached as well as provide a stable construction platform for equipment operation.

4-1.4.2 Processing.

For maximum efficiency and to meet specification time limits, break down a day's work into several adjacent sections rather than one or two long sections. This procedure will result in maximum daily production and will prevent a long stretch of construction from being rained out in case of a sudden severe rainstorm. This will help reduce issues from compaction of adjacent sections due to rapid cement curing.

4-1.4.2.1 Handling and Spreading Cement.

Bulk cement is typically trucked to the jobsite in bulk transport trucks or shipped to the nearest railroad siding in enclosed hopper cars. Compressed air or vibrators are used to loosen the cement in the hopper cars during unloading. Transfer to cement trucks is done pneumatically or by a screen or belt conveyor. The trucks are usually enclosed or fitted with canvas covers. The cement is weighed in truckloads on portable platform scales or at a nearby scale. Soil materials that contain excessive amounts of moisture will not mix readily with cement. Sandy soils can be mixed with moisture content at optimum or slightly above. Ensure that clayey soils have a moisture content below optimum when cement is spread. Do not apply cement onto puddles of water. If the soil material is excessively wet, aerate it to dry it before cement is applied. Handling and spreading procedures for different types of equipment are presented below.

(1) **Mechanical Cement Spread, Mixed-In-Place Construction*.*** Mechanical cement spreaders may be built into a truck, attached to a dump truck, or pulled behind a vehicle. As the vehicle moves forward, cement flows through the spreader, which regulates the quantity of cement placed on the prepared soil. To obtain a uniform cement spread, operate the spreader at a constant, slow speed and with a constant level of cement in

the hopper. Maintain a true line at the pavement edge with a string line. To produce a uniform cement spread, ensure the mechanical spreader has adequate traction. Traction can be aided by wetting and rolling the soil material before spreading the cement. When operating in loose sands or gravel, slippage can be overcome by the use of cleats on the spreader wheels or by other modifications; sometimes, the spreader is mounted on a tractor or high lift. The mechanical cement spreader can also be attached directly behind a bulk cement truck. Cement is then moved pneumatically from the truck through an air separator cyclone that dissipates the air pressure and falls into the hopper of the spreader. Operate the spreader with a slow, even forward speed to avoid variation in the spread rate. Sometimes a motor grader or loader pulls the truck to maintain this slow, even forward speed. Pipe cement spreaders attached to cement transport trucks have been used in some areas with variable results. Many modern cement spreaders utilize automated controls to ensure the correct amount of cement is metered during placement.

(2) **Bagged-Cement Spread, Mixed-In-Place Construction.** When bags of cement are used on small jobs, a simple but exact method for properly placing the bags is necessary. A grid or lane placement may be used. For grids, space the bags at approximately equal transverse and longitudinal intervals that will ensure the proper percentage of cement. For lanes, the bags are spaced equally within the lane. Positions can be spotted by flags or markers fastened to lines at proper intervals to mark the transverse and longitudinal rows. When the bags are opened, dump the cement so it forms fairly uniform transverse windrows across the area being processed. A spiketooth harrow, nail drag, or length of chain-link fence can be used to spread the cement evenly. Make at least two round trips using the drag over the area to uniformly spread the cement.

(3) **Cement Application, Central-Mixing-Plant Construction.** When a continuous-flow central mixing plant is used, the cement is usually metered onto the soil aggregate and the two materials are carried to the pugmill mixer on the main feeder belt. Variations in moisture and gradation of the soil aggregate will result in variations in the amount of material being fed onto the feeder belt. A high bulkhead placed in front of the soil hopper will help obtain a more uniform flow through the soil material feeder. The chance of loss of cement due to wind can be minimized by the use of a small plow attachment that forms a furrow for the cement in the soil aggregate. After the cement is added, a second plow attachment a little farther up on the main feeder belt closes the furrow and covers the cement. A cover on the main feeder belt will also minimize cement loss due to wind. One of three types of cement meters—belt, screw, or vane—can be used to proportion the cement on a volumetric basis. Each requires a 450- to 750-lb (204- to 340-kg) -capacity surge tank or hopper between the cement silo and the cement feeder. This tank maintains a constant head of cement for the feeder, thus providing a more uniform cement discharge. Use compressed air of 2- to 4-lb/in.^{2} pressure to prevent arching of cement in the silo and the surge tank. Portable vibrators

attached to the surge tank can be used instead of air jets. Include a positive system to automatically stop the plant if the cement flow suddenly stops. The correct proportion of cement, soil material, and water entering the mixing chamber is determined by calibrating the plant before mixing and placing operations begin.

4-1.4.2.2 Mixing and Applying Water.

Procedures for applying water and mixing depend on the type of mixing machine used. Thoroughly mix the pulverized soil material, cement, and water. Uniformity of the mix is easily checked by digging trenches or a series of holes at regular intervals for the full depth of treatment and inspecting the color of the exposed soil-cement mixture. Uniform color and texture from top to bottom indicate a satisfactory mix; a streaked appearance indicates improper mixing. Proper width and depth of mixing are also important. Following are methods of applying water and mixing for the different types of mixing machines.

(1) **Windrow-Type Traveling Mixing Machine.** Windrow-type traveling mixing machines will pulverize friable soil materials. Other soils, however, may need preliminary pulverizing to meet particle-size specification requirements. This is usually done before the soil is placed in windrows for processing. The prepared soil material is bladed into windrows and a proportion pulled along to make them uniform in cross-section. When borrow materials are used, a windrow spreader can be used to proportion the material. Non-uniform windrows cause variations in cement content, moisture content, and pavement thickness. The number and size of windrows needed depend on the width and depth of treatment and on the capacity of the mixing machine. Cement is spread on top of the partially flattened or slightly trenched, prepared windrow. The mixing machine then picks up the soil material and cement and dry-mixes them with the first few paddles in the mixing drum. At that point, water is added through spray nozzles and the remaining paddles complete the mixing. A strike-off attached to the mixing machine spreads the mixed soil-cement. If a motor grader is used to spread the mixture and a tamping roller is used for compaction, first loosen the mixture to ready it for compaction. If two windrows have been made, the mixing machine progresses 350 to 500 feet (107 to 152 m) along one windrow and then is backed up to process the other windrow for 700 to 1,000 feet (213 to 305 m). The cement-spreading operation is kept just ahead of the mixing operation. Water is supplied by tank trucks. A water tank installed on the mixer will permit continuous operation while the tank trucks are being switched. As soon as the first windrow is mixed and spread on one section of the roadway, it is compacted. At the same time a second windrow is being mixed and spread. It in turn is then compacted. Finishing the entire roadway is completed in one operation. Water requirements are based on the quantity of soil material and cement per unit length of windrow.

(2) **Single-Shaft Traveling Mixing Machine.** The only preparation required is shaping the soil material to the approximate required crown and grade. If

an old roadbed is extremely hard and dense, prewetting and scarification will facilitate processing. Applying water at this stage of construction saves time during actual processing operations because most of the required water will already have been added to the soil material. In very granular materials, pre-wetting prevents cement from sifting to the bottom of the mix by causing it to adhere more readily to the sand and gravel particles. Mixing the soil material and cement is easier if the moisture content of the raw material is two or three percentage points below optimum; however, very sandy materials can be mixed, even if the moisture content is one or two percentage points above optimum. Apply moisture uniformly during pre-wetting. By mixing it into the soil material, evaporation losses are reduced. Because of the hazard of night rains, some contractors prefer to do the pre-wetting in the early morning. After scarifying and pre-wetting, the loose, moist soil material is shaped to crown and grade. Pre-compaction of the soil can help ensure the target design cement content and proper layer thickness are achieved and provide a solid working platform for the spreading and mixing equipment. Cement is spread by a mechanical cement spreader or from bags. The mixer picks up the soil material and cement and mixes them in place. Water, supplied by a tank truck, is usually applied to the mixture by a spray bar mounted in the mixing chamber or it can be applied ahead of the mixer by water distribution equipment. Blend the soil material and cement when free water contacts the mixture to prevent the formation of cement balls. Accomplish processing in lanes 250 to 500 feet (76 to 152 m) long and as wide as the mixing machine. Cement is spread on the soil material in front of the mixing machine. Complete cement spreading in the first working lane and begin cement spreading in the second lane before mixing operations are begun. This ensures a full-width cement spread without a gap between lanes and keeps spreading equipment out of the way of mixing equipment. If water is being applied by injection, not the mixing chamber, then minimize the overlap of additional lanes to prevent overwatering. This can be readily accomplished using string lines.

4-1.4.2.3 Central Mixing Plant.

Central mixing plants are often used for projects involving borrow materials. The basic principles of thorough mixing, adequate cement content, proper moisture content, and adequate compaction apply. Friable granular borrow materials are generally used because of their low cement requirements and ease in handling and mixing. Pugmill-type mixers, either continuous flow or batch, and rotary-drum mixers are used for this work. Generally, the twin-shaft continuous-flow pugmill is used on highway projects. Provide facilities for efficiently storing, handling, and proportioning materials at the plant. Quantities of soil material, cement, and water can be proportioned by volume for achieving the desired mixture based upon dry unit weight. Mixing is continued until a uniform mixture of soil material, cement, and water is obtained. Equip haul vehicles with protective covers to reduce evaporation losses due to excessive temperature, high winds, and to protect the mixture against sudden rain. To prevent excessive haul time, do not allow more than 60 minutes to elapse between the start of moist-mixing and the start of compaction. Haul time is usually limited to 30 minutes. Place the mixed soil-cement on the subgrade without segregation in a quantity that will produce a compacted base of uniform density conforming to the specified grade and cross-section. Spread the mixture to full roadway width, either by one full-width spreader or by two or more spreaders operating in staggered positions across the roadway. Less preferable is the use of one piece of spreading equipment operating one lane at a time in two or more lanes. Do not spread cement so far ahead of the adjoining lane that a time lapse of more than 30 minutes occurs between the times of placing material in adjoining lanes at any location. Dampen the subgrade immediately prior to placing the soil-cement. Bituminous pavers have been used for spreading soil-cement, although modification may be necessary to increase volume capacity before they can be used. Perform compaction immediately behind the spreader. Leave a narrow, compacted ridge adjacent to the second lane during compaction of the first lane to serve as a depth guide when placing the mix in the second lane. Make equipment and water available and within reach to keep the joint areas damp. The amount of water needed to bring the soil-cement mixture to required moisture content in continuous-flow-type mixing plants is based on the amount of soil material and cement coming into the mixing chamber per unit of time. The amount of water required in batch-type central mixing plants is similarly calculated, using the weights of soil material and cement for each batch.

4-1.4.3 Compaction.

The principles governing compaction of soil-cement are the same as those for soil materials without cement treatment. Compact the soil-cement mixture at optimum moisture to maximum density and finish immediately. Treat moisture loss by evaporation during compaction, indicated by a graying of the surface, with light applications of water. Tamping rollers are generally used for initial compaction except for the more granular soils. Self-propelled, vibratory, and pneumatic rubber-tired models are also used. To obtain adequate compaction, it is sometimes necessary to operate the rollers with ballast to give greater unit pressure, depending on the soil characteristics as determined in the field at the time of construction. The general rule is to use the greatest contact pressure that will not exceed the bearing capacity of the soil-cement mixture and that will still "walk out" in a reasonable number of passes. Friable silty and clayey sandy soils will compact satisfactorily using rollers with unit pressures of 75 to 125 lb/in^2. Clayey sands, lean clays, and silts that have low plasticity can be compacted with 100- to 200-lb/in^2 rollers. Medium to heavy clays and gravelly soils require greater unit pressure: 150 to 300 lb/in^2. Compacted thickness up to 8 or 9 inch (200 to 230 mm) can be compacted in one lift. Greater thicknesses can be compacted with equipment designed for deeper lifts. When tamping rollers are used for initial compaction, ensure the mixed material is in a loose condition at the start of compaction so the feet will pack the bottom material and gradually walk out on each succeeding pass. If penetration is not being obtained, the scarifier on a motor grader or a traveling mixer can be used to loosen the mix during start of compaction, thus allowing the feet to penetrate. Vibratory-steel-wheeled rollers and grid and segmented rollers can be used to satisfactorily compact soil-cement that contains granular soil materials. Vibratory-plate compactors are used on non-plastic granular materials. Pneumatic rubber-tired rollers can be used to compact coarse sand and gravel soil-cement mixtures with very little plasticity and very sandy mixtures with little or no binder material, such as dune, beach, or blow sand. Some rollers are fabricated to permit rapid inflation and deflation of the tires while compacting to increase their versatility. Heavy three-wheeled steel rollers can be used to compact coarse granular materials containing little or no binder material. Gravelly soils that contain up to about 20 percent passing the No. 200 (0.075 mm) sieve and have low plasticity are best suited for compaction with these rollers. Tandem-steel-wheeled rollers are often used during final rolling to press down or set rock particles and smooth out ridges.

There are two general types of road cross-sections: trench and featheredge. Both can be built satisfactorily with soil-cement. In trench-type construction, the shoulder material gives lateral support to the soil-cement mixture during compaction. In the featheredge type of construction, the edges are compacted first to provide edge stability while the remaining portion is being compacted. Do not construct the edge slope steeper than 2:1 to facilitate shaping and compacting. Shoulder material is placed after the soil-cement has been finished. Occasionally, during compaction and finishing, a localized area may yield under the compaction equipment. This may be due to one or more causes: the soil-cement mix is much wetter than optimum moisture; the subsoil may be wet and unstable; or the roller may be too heavy for the soil. If the soil-cement mix is too damp, aerate it with a cultivator, traveling mixer, or motor grader. After it has dried to near-optimum moisture, it can be compacted. For best results, start compaction immediately after the soil material, cement, and water have been mixed. It is critical that compaction occur as soon after mixing the materials as possible because hydration of the cement will begin as soon as the dry cement comes into contact with moist soil or free mixing water added to achieve optimum moisture content for compaction. Required densities are then obtained more readily, there is less water evaporation, and daily production is increased. Perform compaction by moving side-to-side over an area and not back and forth in a lane until the required number of passes is reached. This will help incrementally compact the soil and knead the soil back and forth across adjacent lanes to prevent a seam.

4-1.4.4 Finishing.

There are several acceptable methods for finishing soil-cement. The exact procedure depends on the available equipment, job conditions, and soil characteristics. Regardless of method, meet all fundamental requirements of adequate compaction, close to optimum moisture, and remove all surface compaction planes to produce a high-quality surface. It is critical that the design crown and grade be established prior to mixing to minimize the corrections required after mixing and compaction when the stabilized material is hardening due to hydration. If proper preparation and mixing are achieved, finishing is typically not necessary except at construction joints. If finishing is needed, finish the surface smooth, dense, and free of ruts, ridges, or cracks. When shaping is done during finishing, scarify (scratch) all smooth surfaces, such as tire imprints and blade marks, with a weeder, nail drag, coil spring, or spiketooth harrow to remove cleavage or compaction planes from the surface. Scratching may be done on all soil-cement mixtures except those containing appreciable quantities of gravel. Keep the surface damp during finishing operations. Steel-wheeled rollers can be used to smooth out ridges left by the initial pneumatic-tire rolling. Steel-wheeled rollers are particularly advantageous when rock is present in the surface. A broom drag can be used advantageously to pull binder material in and around pieces of gravel that have been set by the steel-wheeled roller. Instead of using a steel roller, surfaces can be shaved with the motor grader and then rerolled with a pneumatic rubber-tired roller to seal the surface. Shaving consists of lightly cutting off any small ridges left by the finishing equipment. Only a very thin depth is cut and all material removed is bladed to the edge of the road and wasted. The final operation usually consists of a light application of water and rolling with a pneumatic rubber-tired roller to seal the surface. Any surface corrections are achieved immediately after compaction since the stabilized soil will be rapidly gaining strength. The finished soil-cement is then cured.

4-1.4.5 Curing.

Compacted and finished soil-cement contains moisture for cement hydration. A moisture-retaining cover is placed over the soil-cement soon after completion to retain this moisture and allow the cement to hydrate. Most soil-cement is cured with a bituminous material surface application but other materials such as polymer emulsion, waterproof paper or plastic sheets, wet straw or sand, fog-type water spray, and wet burlap or cotton mats are satisfactory. The type of bituminous material most commonly used is emulsified asphalt SS-1. Polymer emulsions may also be used. The rate of application varies from 0.15 to 0.30 US gal/sq yd (0.68 to 1.36 liter/sq m). At the time of application, ensure the soil-cement surface is free of all dry, loose, and extraneous material. Moisten the surface with a fog spray before emulsion materials are applied. In most cases, a light application of water is placed immediately ahead of the emulsion application. This helps improve penetration into the surface and increases adhesion.

4-1.4.6 Construction Joints.

After each day's construction, form a transverse vertical construction joint by cutting back into the completed soil-cement to the proper crown and grade. This is usually the last task performed at night or the first task performed the following morning. This may be accomplished using the mixer or a dry-cut walk-behind saw can be used to provide a clean cutting edge. Ensure the joint is vertical and perpendicular to the centerline. After the next day's mixing has been completed at the joint, clean the area of all dry and unmixed material and re-trim if necessary. Mixed moist material is then bladed into the area and thoroughly compacted. The joint is left slightly high until final rolling when it is trimmed to grade with the motor grader and rerolled. Joint construction requires special attention to make sure the joints are vertical and the material in the joint area is adequately mixed and thoroughly compacted. When bituminous material is used as a curing agent, apply it right up to the joint and sanded to prevent pickup.

4-1.4.7 Multiple-Layer Construction.

When the specified thickness of soil-cement base course exceeds the depth (usually 8 or 9 inches [200 to 230 mm] compacted) that can be compacted in one layer, construct in multiple layers. Construct all layers to be less than 4 inches (100 mm) thick. The lower layer does not have to be finished to exact crown and grade nor do surface compaction planes have to be removed since they are too far from the final surface to be harmful. The lower layer can be cured with the moist soil that will subsequently be used to build the top layer, which can be built immediately, the following day, or at a later time. With mixed-in-place construction, take care to eliminate any raw-soil seams between the layers.

4-1.5 Special Construction Problems.

4-1.5.1 Rainfall.

Attention to a few simple precautions before processing will greatly reduce the possibility of serious damage from wet weather. For example, crown any loose or pulverized soil so it will shed water and trench low places in the grade where water can accumulate so the water will freely drain off. As shown by the construction of millions of square yards of soil-cement in all climates, it is unlikely that rainfall during actual construction will be a serious problem to the experienced engineer or contractor. Usually, construction requires the addition of water equivalent to 1 to 1.5 inches (25 to 37.5 mm) of rain. If rain falls during cement-spreading operations, stop spreading cement and quickly mix the cement already spread into the soil mass. A heavy rainfall that occurs after most of the water has already been added, however, can be serious. The best defense against rainfall is not to allow the cement placement to exceed the mixing and compaction. It is easy for the placement and mixing to outpace compaction because compaction is usually the slowest step. Then, if rainfall becomes imminent, try to obtain rapid compaction by using every available piece of equipment so the section will be compacted and shaped before too much damage results. In such instances, it may be necessary to complete final blade work later; any material bladed from the surface is wasted. After the mixture has been compacted and finished, rain will not harm it.

4-1.5.2 Wet Soils.

Excessively wet material is difficult to mix and pulverize. Experience has shown that cement can be mixed with sandy materials when the moisture content is as high as 2 percent above optimum with adequate results. For clayey soils, the moisture content needs to be below optimum for efficient mixing. It may be necessary to dry out the soil material by aeration prior to mixing. This can be done by using single-shaft traveling mixers with the hood in a raised position or by cutting out the material with the tip of a motor grader blade and working and aerating with a disc. The maintenance of crown and surface grade to permit rapid runoff of surface water before soil-cement processing is the best insurance against excessive amounts of wet material.

4-1.5.3 Cold Weather.

Soil-cement, like other cement-using products, hardens as the cement hydrates. Since cement hydration practically ceases when temperatures are near or below freezing, do not place soil-cement when the temperature is 40 °F (4.4 °C) or below. Moreover, protect it to prevent its freezing for a period of seven days after placement and until it has hardened by a suitable covering of hay, straw, or other protective material.

4-2 CONSTRUCTION WITH LIME.

4-2.1 Lime Stabilization Methods.

There are three recognized lime-stabilization methods: in-place mixing, plant mixing, and pressure injection.

4-2.1.1 In-Place Mixing.

In-place mixing may be subdivided into three methods: mixing lime with the existing materials in place at the construction site or pavement; off-site mixing in which lime is mixed with borrow and the mixture is then transported to the construction site for final manipulation and compaction; and mixing in which the borrow source soil is hauled to the construction site and processed in place as in the first method.

The following procedures are for in-place mixing:

4-2.1.1.1 One increment of lime is added to clays or granular base materials that are easy to pulverize. The material is mixed and compacted in one operation and no mellowing period is required. (The term "mellow" refers to the reaction of the lime on clay to make it more friable and easier to pulverize.)

4-2.1.1.2 One increment of lime is added and the mixture is allowed to mellow for a period of 1 to 7 days to assist in breaking down heavy clay soils.

4-2.1.1.3 One increment of lime is added for soil modification and pulverization before treatment with cement or asphalt.

4-2.1.1.4 One increment of lime is added to produce a working table. Proof rolling is required instead of pulverization and density requirements.

4-2.1.1.5 Two increments of lime are added for soils that are extremely difficult to pulverize. Between the applications of the first and second increments of lime, the mixture is allowed to mellow.

4-2.1.1.6 Deep stabilization may be accomplished by one of two approaches.

- One increment of lime is applied to modify soil to a depth of 24 inches (600 mm). Greater depths are possible but to date have not been attempted. A second increment of lime is added to the top 6 to 12 inches (130 to 300 mm) for complete stabilization. Plows and rippers are used to break down the clay chunks in the deep treatment. Heavy disc harrows and blades are also used in pulverization of these clay soils. In frost zones, the use of lime for soil modification under certain circumstances results in a frost-susceptible material that can produce a weak sublayer. Perform trial batches to determine these characteristics prior to construction.
- One increment of lime is applied for complete stabilization to a depth of 18 in (460 mm). Mechanical mixers are now available to pulverize the lime-clay soil to the full depth by progressive cuts as follows: first-pass cut to a depth of 6 inches (150 mm), second to 9 inches (230 mm), third to 12 inches (300 mm), fourth to 15 inches (380 mm), and then a few passes to a depth of 18 inches (460 mm) to accomplish full pulverization. The full 18 inch (460 mm) is compacted from the top by vibratory and conventional heavy rollers. Make all attempts to compact in normal 8- to 9-inch (200 to 230 mm) lifts if the stabilized soil will be used near the surface of a pavement.

4-2.1.2 Plant Mixing.

The plant-mix operation usually involves hauling the soil to a central plant where lime, soil, and water are uniformly mixed and then transported to the construction site for further manipulation. The amount of lime for either method is usually predetermined by test procedures. Specifications may be written to specify the actual strength gain required to upgrade the stabilized soil and notations can be made on the plans concerning the estimated percent of lime required. This note stipulates that changes in lime content may be necessary to meet changing soil conditions encountered during construction.

4-2.1.3 Pressure Injection.

Pressure injections of lime slurry to depths of 7 to 10 feet (2.1 to 3 m) for control of swelling and unstable soils on highways and under building sites are usually placed on 5-foot (1.5-m) spacing and attempts are made to place horizontal seams of lime slurry at 8 to 12 inches (200 to 300 mm) intervals. Stabilize the top 6- to 12-inch (150 to 300 mm) layer by conventional methods.

4-2.2 Construction Steps.

4-2.2.1 Soil Preparation.

Bring the in-place subgrade soil to final grade and alignment. The finished grade elevation may require adjustment because of the potential fluff action of the lime-stabilized layer because soils tend to increase in volume when mixed with lime and water. This volume change may be exaggerated when the soil-lime is remixed over a long period of time, especially at moisture contents less than optimum moisture. The fluff action is usually minimized if adequate water is provided and mixing is accomplished shortly after lime is added. For soils that tend to fluff with lime, lower the subgrade elevation slightly or the excess material trimmed. Trimming can usually be accomplished by blading the material onto the shoulder of embankment slopes. The blading operation is desirable to remove the top 0.25 inch (6 mm) because this material is not often well-reacted due to lime loss during construction. Excess rain and construction water may wash lime from the surface and carbonation of lime may occur in the exposed surface. If dry lime is used, ripping or scarifying to the desired depth of stabilization can be accomplished either before or after lime is added. If the lime is applied in a slurry form, scarify prior to adding lime.

4-2.2.2 Lime Application.

4-2.2.2.1 Dry Hydrated Lime.

Dry lime can be applied either in bulk or by bag. The use of bagged lime is generally the simplest but also the costliest method of lime application. Fifty-pound bags of lime are delivered in dump or flatbed trucks and placed by hand to give the required distribution. After the bags are placed, they are slit and the lime is dumped into piles or transverse windrows across the roadway. The lime is then leveled either by hand-raking or by a spike-tooth harrow or drag pulled by a tractor or truck. Immediately after, the lime is sprinkled with water to reduce dusting. The major disadvantages of the bag method are the higher costs of lime because of bagging costs, greater labor costs, and slower operations. Nevertheless, bagged lime is often the most practical method for small projects or for projects in which it is difficult to utilize heavy equipment. For stabilization projects, particularly where dusting is no problem, the use of bulk lime has become common practice. Lime is delivered to the job in self-unloading transport trucks. These trucks are efficient, being capable of hauling 15 to 24 tons (13,600 to 21,800 kg). One type is equipped with one or more integral screw conveyors that discharge at the rear. Pneumatic trucks have increased in popularity and are preferred over the older auger-type transports. With the pneumatic units, the lime is blown from the tanker compartments through a pipe or hose to a cyclone spreader or pipe spreader bar-mounted at the rear. Bottom-dump hopper trucks have also been tried but they are undesirable because of difficulty in unloading and obtaining a uniform rate of discharge. With auger trucks, spreading is handled by means of a portable, mechanical-type spreader attached to the rear or through metal downspout chutes or flexible rubber boots extending from the screw conveyors. The mechanical spreaders incorporate belt, screw, rotary vane, or drag-chain conveyors to uniformly distribute the lime across the spreader width. When boots or spouts are used, the lime is deposited in windrows but, because of lime's lightness and flowability, the lime becomes distributed rather uniformly across the spreading lane. Whether mechanical spreaders, downspouts, or boots are used, the rate of lime application can be regulated by varying the spreader opening, spreader drive speed, or truck speed so the required amount of lime can be applied in one or more passes. With pneumatic trucks, spreading is generally handled with a cyclone spreader mounted at the rear, which distributes the lime through a split chute or with a spreader bar equipped with several downspout pipes. Fingertip controls in the truck cab permit the driver to vary the spreading width by adjusting the air pressure. Experienced drivers can adjust the pressure and truck speed so accurate distribution can be obtained in one or two passes. When bulk lime is delivered by rail, a variety of conveyors can be used for transferring the lime to transport trucks, including screw, belt, or drag-chain conveyors, bucket elevators, and screw elevators. The screw-type conveyors are most commonly used, with units of 10 to 12 inches (254 to 305 mm) in diameter being recommended for high-speed unloading. To minimize dusting, enclose all conveyors. Rail-car unloading is generally facilitated by means of poles and mechanical or air-type vibrators. Lime has also been handled through permanent or portable batching plants; the lime is weigh-batched before loading. Generally, a batch plant setup is practical only on exceptionally large projects such as a runway, airport, or main apron at an installation. Obviously, the self-unloading tank truck is the least costly method of spreading lime because there is no rehandling of material and payloads can be carried and spread quickly.

4-2.2.2.2 Dry Quicklime.

Quicklime may be applied in bags or bulk. Because of higher cost, bagged lime is used only for drying of isolated wet spots or on small jobs. The distribution of bagged quicklime is similar to that of bagged hydrated lime except that an emphasis on safety is needed. First, the bags are accurately spaced on the area to be stabilized and, after spreading, water is applied and mixing operations started immediately. The fast watering and mixing operation helps minimize the danger of burns. Quicklime may be applied in the form of pebbles of approximately 3/8 inch (9.5 mm), granular, or pulverized. The first two are more desirable because less dust is generated during spreading. Bulk quicklime may be spread by self-unloading auger or pneumatic transport trucks, similar to those used for dry hydrated lime. However, because of its coarser size and higher density, quicklime may also be tailgated either from a regular dump truck with tailgate-opening controls to ensure accurate distribution or from a bulk transport truck. Because quicklime is anhydrous and generates heat on contact with water, take special care during stabilization to avoid lime burns. Where quicklime is specified, provide the engineer with a detailed safety program covering precautions and emergency treatment available on the jobsite. Include in the program protective equipment for eyes, mouth, nose, and skin, as well as a first-aid kit containing an eyewash station. Ensure this protective equipment is available on the jobsite during spreading and mixing operations. Actively enforce this program for protecting workers and others in the construction area.

4-2.2.2.3 Slurry Method.

In this method either hydrated lime or quicklime and water are mixed into a slurry. With quicklime, the lime is first slaked and excess water added to produce the slurry.

4-2.2.2.4 Slurry Made with Hydrated Lime.

This method was first used in the 1950s and remains popular, especially where dust from using dry lime is a problem. The hydrated lime-water slurry is mixed either in a central mixing tank, jet mixer, or in a tank truck. The slurry is spread over the scarified roadbed by a tank truck equipped with spray bars. One or more passes may be required over a measured area to achieve the specified percentage based on lime solids content. To prevent runoff and consequent nonuniformity of lime distribution that may occur under certain conditions, it may be necessary to mix the slurry and soil immediately after each spreading pass. A typical slurry mix proportion is 1 ton (907 kg) of lime and 500 gal (1893 L) of water, which yields about 600 gal (2271 L) of slurry containing 31 percent lime solids. At higher concentrations there is difficulty in pumping and spraying the slurry; 40 percent solids is the maximum pumpable slurry. The actual proportion used depends on the percentage of lime specified, the type of soil, and its moisture condition. When small lime percentages are required, the slurry proportions may be reduced to 1 ton (907 kg) of lime per 700 to 800 gal (2650 to 3028 L) of water. Where the soil moisture content is near optimum, a stronger lime concentration is typically required. In plants employing central mixing, agitation is usually accomplished by using compressed air and recirculating pumps, although pugmills have also been used. The typical slurry plant incorporates slurry tanks that handle whole tanker truckloads of hydrated lime of approximately 20 tons (18,144 kg). The mixer and auxiliary equipment can be mounted on a small trailer and readily transported to the job, giving great flexibility to the operation. In another type of slurry setup, measured amounts of water and lime are charged separately to the tank truck, with the slurry being mixed in the tank either by compressed air or by a recirculating pump mounted at the rear. The water is metered and the lime proportioned volumetrically or by means of weight batchers. Spreading from the slurry distributors is effected by gravity or pressure spray bars, the latter being preferred because of better distribution. The use of spray deflectors is also recommended for proper distribution. The general practice in spreading is to make either one or two passes per load; however, several loads may be needed to distribute the required amount of lime. The total number of passes will depend on the lime requirement, the optimum moisture of the soil, and the type of mixing employed. Windrow mixing with the grader generally requires several passes.

4-2.2.2.5 Double Application of Lime.

In areas where extremely plastic clay (PI 50+) abounds, it may prove advantageous to add the requisite amount of lime in two increments to facilitate adequate pulverization and obtain complete stabilization. For example, 2 or 3 percent lime is added first, partially mixed, then the layer is sealed and allowed to mellow for up to a week. The remaining lime is then added before final mixing. The first application mellows the clay and helps achieve final pulverization and the second application completes the lime-treatment process.

4-2.2.2.6 Slurry Made with Quicklime.

A slurry lime rig consists of a 10-foot (3 m) -diameter by 40-foot (12.2 m) tank that incorporates a 5-foot (1.5 m) -diameter single-shaft agitator turned by a diesel engine. The batch slaker can handle 20 to 25 tons (18,144 to 22,680 kg) of quicklime and about 25,000 gal (94,635 L) of water, producing the slurry in about 1 to 1.5 hours. Because of the exothermic action of quicklime in water, the slurry is produced at a temperature of about 185 °F (85 °C).

4-2.2.2.7 Advantages and Disadvantages of Dry Hydrated Lime.

(1) Advantages:

- Dry lime can be applied two or three times faster than a slurry.
- Dry lime is very effective in drying out soil.

(2) Disadvantages:

- Dry lime produces a dusting problem that makes its use undesirable in urban areas.
- The fast-drying action of the dry lime requires an excess amount of water during dry, hot seasons.

4-2.2.2.8 Advantages and Disadvantages of Dry Quicklime.

(1) Advantages:

- Dry quicklime is more economical since it contains approximately 25 percent more available free lime.
- It has greater bulk density for smaller-sized silos.
- It has faster drying action in wet soils and faster reaction with all soils. Construction season can be extended in both spring and fall because of faster drying.

(2) Disadvantages:

- The field hydration of dry quicklime, which produces a coarser material with poorer distribution in soil mass, is less effective than commercial hydration.
- Quicklime requires more water than hydrated lime for stabilization, which may present a problem in dry areas.
- Workers with dry quicklime have greater susceptibility to skin and eye burns.

4-2.2.2.9 Advantages and Disadvantages of Lime Slurry.

(1) Advantages:

- Dust-free application is more desirable from an environmental standpoint.
- Better distribution is achieved with the slurry.
- In the lime slurry method, the lime spreading and watering operations are combined, reducing job costs.
- During summer months, a slurry application wets the soil and minimizes drying action.
- The added heat when slurry is made from quicklime speeds the drying action, which is especially desirable in cooler weather.

(2) Disadvantages:

- Application rates are slower. High-capacity pumps are required to achieve acceptable application rates.
- Extra equipment is required; therefore, costs are higher.
- Extra manipulation may be required for drying purposes during cool, wet, or humid weather, which occurs during the fall, winter, and spring construction season.
- Lime slurries are not practical for use with very wet soils.

4-2.2.3 Pulverization and Mixing.

To obtain satisfactory soil-lime mixtures, achieve adequate pulverization and mixing. For heavy clay soils, two-stage pulverization and mixing may be required but, for other soils, one-stage mixing and pulverization may be satisfactory. The difference is primarily due to heavy clays being more difficult to break down. Perform a test strip at the beginning of new projects to establish the most efficient pulverization, additive distribution, and mixing process for the available equipment and existing site conditions.

4-2.2.3.1 Two-stage Mixing.

Construction steps in two-stage mixing consist of preliminary mixing, moist curing for 24 to 48 hours (or more), and final mixing or remixing. The first mixing step distributes the lime throughout the soil, thereby facilitating the mellowing action. For maximum chemical action during the mellowing period, ensure the clay clods are less than

2 inches (50 mm) in diameter or the reaction will not completely reach all soils. Before mellowing, liberally sprinkle the soil to bring it up to at least two percentage points above optimum moisture to aid the disintegration of clay clods. The exception to excess watering is in cool, damp weather when evaporation is at a minimum. In hot weather and coarser gradations, it may be difficult to add too much water. After preliminary mixing, lightly seal the roadway with a pneumatic rubber-tired roller as a precaution against heavy rain because the compacted subgrade will shed water, thereby preventing moisture increases that might delay construction. Generally, in 24 to 48 hours the clay becomes friable enough so desired pulverization can be easily attained during final mixing. Additional sprinkling may be necessary during final mixing to bring the soils to optimum moisture or slightly above. In hot weather, more than optimum moisture is needed to compensate for loss through evaporation. Although disc harrows and grader scarifiers are suitable for preliminary mixing, high-speed rotary mixers or one-pass travel plant mixers are required for final mixing. Motor graders are generally unsatisfactory for mixing lime with heavy clays.

4-2.2.3.2 One-stage Mixing.

Both blade and rotary mixing, or a combination, have been used successfully in projects involving granular base materials. However, rotary mixers are preferred for more uniform mixing, finer pulverization, and faster operation. They are generally required for highly plastic soils that do not readily pulverize and for reconstructing worn-out roads to pulverize the old asphalt.

4-2.2.3.3 Blade Mixing.

When blade mixing is used in conjunction with dry lime, the material is generally bladed into two windrows, one on each side of the roadway. Lime is then spread on the inside of each windrow or down the centerline of the road. The soil is then bladed to cover the lime. After the lime is covered, the soil is mixed dry by blading across the roadway. After dry mixing is completed, water is added to slightly above the optimum moisture content and additional mixing is performed. To ensure thorough mixing by this method, handle the material on the moldboard at least three times. When blade mixing is used with the slurry method, the mixing is done in thin lifts that are bladed to windrows. One practice is to start with the material in a center windrow then blade aside a thin layer after the addition of each increment of slurry, thereby forming side windrows. The windrowed material is then bladed back across the roadway and compacted, provided that its moisture content is at optimum. A second practice is to start with a side windrow then blade in a thin 2-inch (50 mm) layer across the roadway, add an increment of lime, and blade this layer to a windrow on the opposite side of the road. This procedure is repeated several times until all the material is mixed and bladed to the new windrow. Because only half of the lime has been added at this time, the process is repeated, moving the material back to the other side. This procedure is slow but it may be necessary when rotary mixing equipment cannot be easily obtained.

4-2.2.3.4 Central Mixing.

Premixing lime with granular base materials is common on new construction projects, particularly where marginal gravels are used. Because the gravel has to be processed anyway to meet gradation specifications, it is a relatively simple matter for the contractor to install a lime bin, feeder, and pugmill at the screening plant. The general practice is to add the optimum moisture at the pugmill, thereby permitting immediate compaction after laydown.

4-2.2.3.5 Pulverization and Mixing Requirements.

Pulverization and mixing requirements are generally specified in terms of percentages passing the 1.5 inch (37.5 mm) or 1 inch (25 mm) screen and the No. 4 (4.75 mm) sieve. Typical requirements are 100 percent passing the 1 inch (25 mm) screen and 60 percent passing the No. 4 (4.75 mm) sieve, exclusive of nonslaking fractions. In certain expedient construction operations, formal requirements are eliminated and the "pulverization and mixing to the satisfaction of the engineer" clause is employed.

4-2.2.4 Compaction.

For maximum development of strength and durability, properly compact lime-soil mixtures to at least 95 percent of ASTM D698, *Standard Test Methods for Laboratory Compaction Characteristics of Soil Using Standard Effort (12,400 ft-lbf/ft^3 (600 kN-m/m^3))*, density for subbase and 90 percent for bases for roads and non-traffic areas. Frequently, agencies require 95 percent ASTM D1557 maximum density, particularly for airfield projects. Although such densities can be achieved for granular soil-lime mixtures, it is difficult to achieve this degree of compaction for lime-treated, fine-grained soils. If a thick soil-lime lift is to be compacted in one lift, some project specifications require 95 percent of ASTM D698 maximum density in the upper 6 to 9 inches (150 to 230 mm) while 90 to 92 percent is acceptable in the bottom portion of the lift. However, do not use deep mixing techniques routinely for airfield projects. To achieve maximum densities, compacting at near optimum moisture content with appropriate compactors is necessary. Granular soil-lime mixtures are generally compacted as soon as possible after mixing, although delays of up to two days are not detrimental, especially if the soil is not allowed to dry out and lime is not allowed to carbonate. Fine-grained soils can also be compacted soon after final mixing, although delays of up to four days are not detrimental. When longer delays (two weeks or more) cannot be avoided, it may be necessary to incorporate a small amount of additional lime into the mixture (0.5 percent) to compensate for losses due to carbonation and erosion. Various rollers and layer thicknesses have been used in lime stabilization. The most common practice is to compact in one lift by first using the sheepsfoot roller until it "walks out" and then use a multiple-wheel pneumatic rubber-tired roller. Occasionally, a flat wheel roller is used in finishing. Single-lift compaction can also be accomplished with vibrating impact rollers or heavy pneumatic rollers, and light pneumatic or steel rollers can be used for finishing. When light pneumatic rollers are used alone, compaction is generally done in thin lifts, usually less than 6 inches (150 mm). During compaction, light sprinkling may be required, particularly during hot, dry weather, to compensate for evaporation losses.

4-2.2.5 Curing.

Maximum development of strength and durability also depends on proper curing. Favorable temperature and moisture conditions and the passage of time are required for curing. Temperatures higher than 40 °F to 50 °F (4.4 °C to 10 °C) and moisture contents around optimum are conducive to curing. Although some project specifications require a three- to seven-day undisturbed curing period, other agencies permit the immediate placement of overlaying paving layers if the compacted soil-lime layer is not rutted or distorted by the equipment. This overlying course maintains the moisture content of the compacted layer and is an adequate medium for curing. Two types of curing can be employed: moist and asphaltic membrane. In the first, the surface is kept damp by sprinkling, with light rollers being used to keep the surface knitted together. In membrane curing, the stabilized soil is sealed with asphalt at a rate of 0.10 to 0.25 gal/sq yd (0.45 to 1.13 liter/sq m). The membrane may need to be applied in multiple applications, depending on how much can be applied to the surface at one time without running off.

4-3 CONSTRUCTION WITH LIME-FLY ASH (LF) AND LIME-CEMENT-FLY ASH (LCF).

Construction procedures for LF and LCF are similar to those used for lime stabilization. Although both field in-place and central plant mixing may be used with LF and LCF, the latter procedure is recommended to obtain adequate proportioning and mixing. With LCF, note that the presence of cement requires the stabilized mixture be compacted as soon as possible.

4-4 CONSTRUCTION WITH BITUMEN OR POLYMER EMULSION.

Bituminous stabilization can involve either hot-mix or cold-mix materials. Bitumen and aggregate or soil can be blended in place or in a central plant. Construction procedures presented in this UFC are for cold-mix materials that are mixed in place (asphalt or polymer emulsions) or in a central plant. Construction procedures for hot-mix hot-laid materials are similar to those used for asphalt concrete. Follow applicable standard construction procedures when these materials are involved. Foamed bitumen stabilization is an in-place technique that involves injecting water into hot bitumen to create a foaming effect that efficiently coats soil particles. The use of cutback asphalts (asphalt mixed with solvent such as diesel or naphtha) as stabilizing materials are generally not acceptable due to environmental and health safety concerns. Procedures described below are applicable to a variety of liquid stabilizers.

4-4.1 Equipment for Mixed-in-Place Materials.

Some pieces of equipment used for mixed-in-place bituminous stabilization are similar to those used in standard construction and will not be described here. These include water distributors, compaction equipment, graders, and windrow sizers. Only equipment especially associated with or having special features applicable to liquid stabilization will be discussed.

4-4.1.1 Mixing Equipment.

4-4.1.1.1 Travel Plants.

Travel plants are a less common method of stabilization. Travel plants are self-propelled pugmill plants that proportion and mix aggregates and asphalt as they move along the road. There are two general types of travel plants: one that moves through a prepared aggregate windrow on the roadbed, adds and mixes the asphalt as it goes, and discharges a mixed windrow to the rear of the machine ready for aeration and spreading, and one that receives aggregate into its hopper from haul trucks, adds and mixes asphalt, and spreads the mix to the rear as it moves along the roadbed. Certain features and performance capabilities are common to all travel plants, enabling them to operate effectively and produce a mix meeting design and specification criteria.

4-4.1.1.2 Rotary-type Mixers.

Rotary or mechanical onsite mixing is the most common form of stabilization and is accomplished by what is essentially a mobile mixing chamber mounted on a self-propelled machine. A reclaimer-stabilizer machine is the most versatile mixing machine as it can mill asphalt and mix most soils. Within the chamber, usually about 6 to 8 feet (1.8 to 2.4 m) wide and open at the bottom, is a rotating drum with cutting blades or milling teeth that revolve at relatively high speed. A dedicated soil mixer can also be used but has only tines for mixing and is much less powerful. As the machine moves ahead, it strikes off behind it a uniform course of soil. Most single-shaft mixers are equipped with a liquid injection system (LIS) that adds water or emulsion by spraying it directly into the mixing chamber as the machine moves ahead, with the flow rate of liquid being synchronized with the travel speed to reach a prescribed dosage. This is an excellent method for achieving proper mixing of liquid and soil. If not equipped with an LIS, use the mixer in conjunction with a liquid distributor that sprays the liquid onto the aggregate or soil immediately ahead of the mobile mixer. Both types of machines have the common capability of effecting a smooth bottom cut and then blending the material into the specified mixture. Ensure machines with an LIS have the capability for accurate metering and blending of liquid into the in-place materials in synchronization with a continuous forward movement, have spray bars that will distribute the liquid uniformly across the mixer's width, and are equipped for controlling the depth of cutting. Foamed asphalt stabilization is accomplished using a reclaimer-stabilizer machine specially outfitted for injecting foamed asphalt into the mixing chamber.

4-4.1.1.3 Motor Graders.

Blade mixing is the onsite mixing of materials on the roadbed by a motor grader. This is also a common form of in-place mixing, albeit slow and less efficient than mixing machines. The stabilizing material (generally a slow-setting asphalt or polymer emulsion) is applied directly ahead of the motor grader by an asphalt distributor or other spray device. For most effective blade mixing, equip the motor grader with a blade at least 10 feet (3 m) long and a wheelbase of at least 15 feet (4.6 m). Equip motor graders used for final layout and finishing of the surface with smooth, rather than treaded, pneumatic tires. Scarifier or plow attachments may be mounted before, behind, or both before and behind the blade. This method is not generally recommended for bitumen or polymer emulsion mixing due to the adhesive nature of the additives and the propensity to form pockets of unmixed additive.

4-4.1.1.4 Liquid Distributor.

The liquid distributor is a key piece of equipment in cold mix construction with liquid additives, particularly when rotary mixers without built-in liquid injection systems are used or when blade mixing is utilized. The liquid distributor, either truck or trailer-mounted, may consist of an insulated tank, self-contained heating system, a pump, and a spray bar and nozzles through which the liquid is applied under pressure onto the prepared aggregate materials. The most common liquid distributors are made for asphalts and range in performance and capability. It is important to keep an adequate supply of asphalt or polymer emulsion at or near the jobsite to avoid delays. In rural areas, it may be advisable to have a bulk supply truck at the project.

4-4.2 Mixed-in-Place Construction.

4-4.2.1 Windrows.

Several types of cold-mix construction require the aggregates be placed in windrows prior to mixing and spreading. If windrows are to be used, clear the area of all vegetation to a width to accommodate both windrow and traffic while the mixture cures. Because the thickness of the new pavement is directly proportional to the amount of aggregate in the windrow(s), accurate control and measurement of the volume of the windrowed material is necessary. Usually, there is not enough loose material on the road surface to use in the road mix. In this case, it is best to blade the loose material onto the shoulder rather than perform the several operations necessary to blend it with the material brought in from other sources. However, sometimes incorporating the existing material on the roadbed into the mixture is considered practical if it is uniform and the necessary quantity is available. When this is done, the loose aggregate is first bladed into a windrow and measured. Next, it is made to meet grading specifications by adding other aggregates as necessary. Finally, the windrow is built up to the required volume with implanted material that meets the specifications. If two or more materials are to be combined on the road to be surfaced, place each in its own windrow. These windrows are then thoroughly mixed together before asphalt is added.

4-4.2.2 Determining Liquid Stabilizer Application Rate.

Before mixing operations begin, determine the correct asphalt or polymer emulsion application rate and forward speed of the spray bar-equipped mixer or liquid distributor for the quantity of aggregate in the windrow. Also, when using emulsified asphalt or polymer, it is necessary to moisten the aggregate before applying the emulsion.

For polymer emulsions, ensure the starting soil moisture content is well below optimum. If not, the additional moisture present in the emulsion will result in a moisture content above optimum, leading to lower density during compaction. Although this is also true for asphalt emulsions, the asphalt coating is capable of lubricating the soil for compaction. Therefore, aerating the material to moisture contents below optimum is acceptable for asphalt emulsion stabilization but not for a polymer emulsion.

4-4.2.3 Control of Liquid Stabilizers.

Liquid stabilizer is added to the aggregate from an asphalt distributor or by a travel mixer. Whichever method is used, close control of quantity, dilution, and viscosity is required to ensure a proper mixture. Maintaining the correct and consistent viscosity is critical to ensure the liquid material is fluid enough to move easily through the spray nozzles at the correct flow rate, adequately coat the aggregate particles, and reach the target moisture content necessary for compaction of the stabilized soil. Cutback asphalts, and occasionally emulsified asphalts, even though already fluid, may require heating to bring them to a viscosity suitable for spraying. If the proper grade of asphalt has been used and the mixing is done correctly, the cutback or emulsified asphalt will remain fluid until the completion of mixing. As the actual temperature of the mixture is controlled by that of the aggregate, take care to see that mixing is not attempted at aggregate temperatures below 50 °F (10 °C).

4-4.2.4 Mixing.

4-4.2.4.1 Travel Plant Mixing.

Travel-plant mixing offers the advantage of closer control of the mixing operation than possible with other common mixing methods. With the windrow-type travel plant, the machine moves along the windrow, picking up the aggregate, mixing it with asphalt in the pugmill, and depositing the mixture in a windrow, ready for aerating or spreading. For this type of plant, match the liquid application rate accurately with the width and thickness of the course, the forward speed of the mixer, and the density of the in-place aggregate. As the thickness is specified, the density is fixed and the liquid application rate is set; the variable is the forward speed. If the aggregate windrow is such that all of the liquid cannot be incorporated in one mixing pass, split it into two or more windrows and the proper amount of liquid added to each windrow as it is mixed. Further mixing of the windrowed material may be necessary after adding the liquid. Unless the travel mixer can be used as a multiple-pass mixer, this additional mixing is usually accomplished with a motor grader. This ensures all of the windrowed material is incorporated into the mix. It also aerates the mixture for the removal of diluents if cutback asphalt is used. The number of passes with the motor grader required for this purpose varies with job conditions. After the mixing and aeration procedure is completed, move the windrow to one side of the area to be surfaced in preparation for spreading.

4-4.2.4.2 Rotary Mixing.

- Liquid Stabilizers.

  As with windrow travel plants, rotary mixers equipped with built-in liquid injection systems require the liquid application rates be accurately matched with the width and thickness of the course, the forward speed of the mixer, the target design stabilizer content, and the optimum moisture content to reach the target density of the in-place aggregate. However, when utilizing a rotary mixer not equipped with a spraybar, a liquid distributor may be used to apply liquid to the aggregate/soil ahead of the mixer. Incremental applications of liquid and passes of the mixer are usually necessary to achieve the specified mixture. Most rotary mixers are now equipped with a spray system. Note that when using water-based liquid stabilizers, ensure the soil moisture content is well below optimum. To reach the design stabilizer content and the optimum moisture content for the mixed soil, properly dilute the mix. Prepare the soil to proper grade and cross-section. If possible, pre-compaction of the soil can help ensure the target design stabilizer content and proper layer thickness are reached. Usually, mixing is accomplished in a single pass of a rotary mixer for efficiency. This requires strict control of mixing speed and pump rates to achieve the desired dosage rate of stabilizer and moisture.

- Foamed Asphalt Stabilization.

  Foamed asphalt stabilization is an efficient and economical method for stabilizing soil. Water is injected into a stream of hot asphalt, causing the asphalt to foam. The hot foam is then immediately sprayed onto the soil inside the mixing chamber of a reclaimer-stabilizer machine. The foaming action provides an efficient coating of asphalt, effectively waterproofing the soil particles. It is best used on sandy and gravelly soils and is gaining popularity for full-depth reclamation of old asphalt pavements.

4-4.2.4.3 Blade Mixing.

Use a slow-setting stabilizer-applied liquid with blade mixing. The imported or in-place material is shaped into a measured windrow, either through a spreader box or by running through a windrow shaper. The windrow is then flattened with the blade to about the width of the distributor spraybar. The liquid is applied by successive passes of the asphalt distributor over the flattened windrow. After each pass of the distributor, the mixture is worked back and forth across the roadbed with the blade. Prior to each succeeding application of asphalt, the mixture is reformed into a flattened windrow. The material in the windrow is subjected to as many mixings, spreading, shapings, and flattenings as needed to disperse the asphalt thoroughly throughout the mixture and effectively coat the aggregate particles. During mixing, the vertical angle of the moldboard may require adjustment from time to time to achieve a complete rolling action of the windrow as it is worked. Carry as much material in a roll as possible ahead of the blade since pressure from the weight of the aggregate facilitates mixing. During mixing, take care to ensure that neither extra material be taken from the mixing table and incorporated into the windrow nor any of the windrow be lost over the edge of the mixing table or left on the mixing table without being treated. When the blade-mixing technique is used, the formation of "additive balls," or concentrated clusters of fine aggregate saturated and coated with excessive amounts of liquid additive, can make a mix difficult to spread and compact. For bitumen, asphalt emulsions, or cutback asphalts, this condition can be corrected by windrowing the mixture into a tight windrow and allowing it to cure for a few days. After mixing and aeration have been completed, the windrow is moved to one side of the roadbed in readiness for subsequent spreading. If it is left for any length of time, cut periodic breaks in the windrow to ensure drainage of rainwater from the roadbed. Unfortunately, the formation of “additive balls” with polymer emulsions is more difficult to correct since polymer emulsions harden as the emulsion water evaporates. For polymer emulsions, obtain a rotary mixer if the blade-mixing technique produces significant “additive balls” after reasonable attempts to blade-mix the additive with the soil.

4-4.2.5 Aeration.

4-4.2.5.1 Emulsified Asphalts and Polymers.

Begin compaction of emulsified liquids immediately before, or at the same time as, the emulsion starts to break (indicated by a marked color change from brown to black).

About this time, the moisture content of the mixture acts as a lubricant between the aggregate particles but is reduced to the point where it does not fill the void spaces, thus allowing their reduction under compactive forces. Also, by this time the mixture is able to support the roller without undue displacement or pickup onto the roller surface. Begin compaction of polymer emulsions immediately after mixing.

4-4.2.5.2 Cutback Asphalt Mixes.

When using cutback asphalt, correct aeration will be achieved when the volatile content is reduced to about 50 percent of that contained in the original asphaltic material and the moisture content does not exceed 2 percent by weight of the total mixture. Before compaction for cutback asphalt, allow most of the diluents that have made the mix workable to evaporate. In most cases, this occurs during mixing and spreading and very little additional aeration is required but extra manipulation on the roadbed is occasionally needed to help speed the process and dissipate the excess diluents. Until the mix is aerated, it usually will not support rollers without excessive shoving. Generally, the mixture is aerated when it becomes tacky and appears to "crawl." Fine-grained and well-graded mixtures will require longer aeration than open-graded and coarse-grained mixtures, all else being equal. Also, if an asphalt cold-mix base course is to be surfaced within a short length of time, aerate the surface before compaction more completely than if the course is not to be surfaced for a longer period of time; the surface acts as a seal, greatly retarding the removal of diluents.

4-4.2.6 Spreading and Compacting.

With mixing and aeration completed, spreading (if necessary) and compacting the cold mix follows. Achieving a finished section and smooth riding surface conforming to the plans is the objective of these final two construction steps. Always spread the mixture to a uniform thickness (whether in a single pass or in several thinner layers) so no thin spots exist in the final mat. Mixtures that do not require aeration may be spread to the required thickness immediately after mixing and then compacted with pneumatic-tired vibratory or steel-tired rollers. Mixtures that require aeration, however, are generally deposited upon the roadbed in windrows and then spread from these windrows. The windrow may be placed along the centerline of the road or along one side if the mixture is to be spread by blade. Because there is a tendency to leave a hump in the road when blade-spreading from a center-line windrow, it is considered better practice to place the windrow to the side for spreading. Accomplish spreading by blade in successive layers, with no layer thinner than approximately 1.5 times the diameter of the maximum particle size. As each layer is spread, compact the layer immediately with a pneumatic-tired roller as soon as the layer will bear the effort without shoving. Because the tires of the motor grader compact the freshly spread mix, their tracks will appear as ridges in the finished mat unless there is adequate rolling between the spreading of each successive layer. Eliminate ridge marks by rolling directly behind the motor grader. If, at any time during compaction, the asphalt mixture exhibits undue rutting or shoving, stop rolling. After one course is thoroughly compacted and cured, other courses may be placed over it. Repeat this operation as many times as necessary to bring the pavement to proper grade and crown. For a smooth riding surface, use the motor grader to trim and level as the rollers complete compaction of the upper layer. After the mat has been shaped to its final required cross-section, then finish roll, preferably with a steel-wheeled roller, until all roller marks are eliminated. A completed course may have to be temporarily opened to traffic. In this event, to prevent tire pickup, it may be advisable to seal the surface by applying a dilution of slow-setting emulsified asphalt and potable water (in equal parts) at a rate of approximately 0.10 gal/sq yd (0.45 liter/sq m). Allow this to cure until no pickup occurs. For immediate passage of traffic, sanding may be desirable to avoid pickup.

4-4.3 Central Plant Mix Construction.

4-4.3.1 Preparation of Mixture.

In batch-type plants, mixing is usually accomplished by a twin-shafted pugmill having a capacity of not less than 2,000 lb (907 kg). The correct amounts of asphalt and aggregate, generally determined by weight, are fed into the pugmill. The batch is then mixed and discharged into a haul truck before another batch is mixed. In the continuous-mixing plant, the devices feeding asphalt, aggregate, and water, if needed, are interlocked to automatically maintain the correct proportions. Typically, automatic feeders measure and govern the flow of aggregates in relation to the output of a positive displacement asphalt-metering pump. A spray nozzle arrangement at the mixer distributes the asphalt over the aggregate. As the proportioned materials move through the pugmill, completely mixed material, ready for spreading, is discharged for subsequent hauling to the road site.

4-4.3.2 Aerating Plant Mix.

Mixtures that require aerating are generally deposited upon the roadbed in windrows and then spread from these windrows. The cold mix is spread with a motor grader and aerated by blading it back and forth or aerated by rotary tiller mixing equipment.

4-4.3.3 Spreading and Compacting Plant Mix.

If aeration is not required, as is generally the case with plant-mixed emulsified asphalt mixes, the mixture is most effectively spread with asphalt pavers having automatic controls. For deep lifts, however, other equipment such as the Jersey Spreader type, towed spreaders, cutter-trimmer-spreaders, or motor graders may be used. Similar to mixed-in-place, central plant cold mixes gain stability as the diluents, which have made the mix workable, evaporate. It is important not to hinder this process; therefore, lift thicknesses are limited by the rate that the mixture loses its diluents. The most important factors affecting this loss are the type of asphalt, diluent content, gradation, and temperature of the aggregate; wind velocity; ambient temperature; and humidity. Because of these variables, local experience is likely to be the best guide in determining allowable placement thicknesses. Spread the mixture uniformly on the roadbed, beginning at the point farthest from the mixing plant. Hauling over freshly placed material is not permitted except when required for completion of the work.

4-5 CONSTRUCTION WITH FIBERS.

Equipment for placing fibers has not reached a commercial stage. Generally, fibers are placed manually by spacing bags of discrete fibers in a grid pattern or by lanes, similar to the way bagged cement and lime are placed. Like cement, spread the fibers uniformly within the area. Using the backside of a rake will help, as the rake tines drag the fibers. Placing fibers on days with winds above 15 miles per hour (24 kilometers per hour) is not recommended. Wetting the fibers after spreading will help hold them in place, if necessary. Fibers are difficult to efficiently mix and may require multiple passes of a rotary mixer to achieve even dispersal throughout the soil. Fibrillated fibers may also require multiple passes of a rotary mixer to “open” the fibrils. If using cement or lime, spread the dry material first then follow with the fibers.

It is very important to start with the soil well-prepared and properly graded to minimize or even eliminate any post-mixing soil work. After mixing, working the fibrous soil can be very difficult. It is not recommended to grade or move the material unless absolutely necessary. Before compaction, it can be moved with graders and rakes and mildly graded, but once compacted, grading the surface results in tears and rips that make repair problematic. After compaction, the material is best handled by remixing with a rotary mixer to loosen it before working the soil.

CHAPTER 5 QUALITY CONTROL

5-1 PURPOSE

Quality control is essential to ensure the final product will be adequate for its intended use and ensure the contractor has performed in accordance with the plans and specifications, as this is a basis for payment. This chapter identifies those control factors that are most important in soil stabilization construction with cement, lime, lime-fly ash, bituminous additives, and polymer emulsions.

5-2 CEMENT STABILIZATION.

The most important factors from a quality control standpoint in cement stabilization are pulverization, cement content, moisture content, uniformity of mixing, time sequence of operations, compaction, and curing. These are described in detail below.

5-2.1 Pulverization.

Pulverization is generally not a problem in cement construction unless clayey or silty soils are being stabilized. A sieve analysis is performed on the soil during the pulverization process, with the No. 4 (4.75 mm) sieve used as a control. The percent pulverization can then be determined by calculation. Proper moisture control is also essential to achieve the required pulverization. Most specifications require the soil material be pulverized so at the time of compaction 100 percent of the soil-cement mixture will pass a 1 inch (25 mm) sieve and a minimum of 80 percent will pass a No. 4 (4.75 mm) sieve, exclusive of any gravel or stone. Ensure gravel or stone are no more than a 2 inch (50 mm) maximum size or the cement cannot effectively stabilize the soil. Perform the final pulverization test at the conclusion of mixing operations.

5-2.2 Cement Content.

Cement content is typically expressed in terms of a percentage of the dry weight of the soil being treated. Occasionally, cement content is expressed in terms of volume; however, this is less frequent due to the complication it adds in calculating quantities for batching. Be aware of quantities of cement required per linear foot or per square yard of pavement. Spot checks can be performed to assure the proper quantity of cement is being applied by using a canvas of known area or, as an overall check, the area over which a known tonnage has been spread.

5-2.3 Moisture Content.

The optimum moisture content for the soil-additive mixture determined in the laboratory is used as an initial guide when construction begins. Make allowance for the in situ moisture content of the soil when construction starts. The optimum moisture content and maximum density can then be established for field control purposes. Mixing water requirements can be determined on the raw soil or on the soil-cement mix before adding the mixing water. Nuclear methods can be used to determine moisture content at the time construction starts and during processing. In general, field compaction equipment imparts more energy into the soil than laboratory equipment and the field optimum moisture content may be slightly lower than that reported in laboratory results.

5-2.4 Uniformity of Mixing.

A visual inspection is performed to assure the uniformity of the mixture throughout the treated depth. Check uniformity across the width of the pavement and to the desired depth of treatment. Trenches can be dug and then visually inspected. A satisfactory mix will exhibit a uniform color throughout, whereas a streaked appearance indicates a non-uniform mix. Pay special attention to the edges of the pavement.

5-2.5 Compaction.

Equipment used for compaction is the same used if no cement were present in the soil and is therefore dependent upon soil type. Two methods can be used to determine compacted density: sand-cone (ASTM D1556, *Standard Test Method for Density and Unit Weight of Soil in Place by Sand-Cone Method*) and nuclear (ASTM D6938, *Standard Test Methods for In-Place Density and Water Content of Soil and Soil-Aggregate by Nuclear Methods (Shallow Depth)*). It is important to determine the depth of compaction and pay special attention to compaction at the edges.

5-2.6 Curing.

To assure proper curing, a bituminous or polymer emulsion or liquid curing compound is frequently applied over the stabilized areas. Ensure the surface of the soil cement is free of dry, loose material and in a moist condition. It is important the soil-cement mixture be kept continuously moist until the membrane is applied. The recommended application rate is 0.15 to 0.30 gal/sq yd (0.68 to 1.36 liter/sq m).

5-3 LIME STABILIZATION.

The most important factors to control during soil-lime construction are pulverization and scarification, lime content, uniformity of mixing, time sequence of operations, compaction, and curing.

5-3.1 Pulverization and Scarification.

Before application of lime, the soil is scarified and pulverized. To assure the adequacy of this phase of construction, a sieve analysis is performed. Most specifications are based upon a designated amount of material passing the 1 inch (25 mm) and No. 4 (4.75 mm) sieves. The depth of scarification or pulverization is also of importance as it relates to the specified depth of lime treatment. For heavy clays, adequate pulverization can best be achieved by pretreatment with lime, but if this method is used, agglomerated soil-lime fractions may appear. These fractions can be easily broken down with a simple kneading action and are not necessarily indicative of improper pulverization.

5-3.2 Lime Content.

When lime is applied to the pulverized soil, the rate at which it is being spread can be determined by placing a canvas of known area on the ground and, after the lime has been spread, weighing the lime on the canvas. Charts can be made available to field personnel to determine if this rate of application is satisfactory for the specified lime content. To accurately determine the quantity of lime slurry required to provide the desired amount of lime solids, it is necessary to know the slurry composition. This can be done by checking the specific gravity of the slurry, either by a hydrometer or volumetric-weight procedure.

5-3.3 Uniformity of Mixing*.*

The major goal is to obtain uniform lime content throughout the depth of treated soil. This presents one of the most difficult factors to control in the field. It has been reported that mixed soil with lime has more or less the same outward appearance as mixed soil without lime. The use of phenolphthalein indicator solution for control in the field has been recommended. This method, while not sophisticated enough to provide an exact measure of lime content for depth of treatment, will give an indication of the presence of the minimum lime content required for soil treatment. The soil will turn a reddish pink color when sprayed with the indicator solution, indicating that free lime is available in the soil (pH = 12.4). Alternatively, soil samples can be collected at various locations and depths and subjected to pH tests using field portable equipment.

5-3.4 Compaction*.*

The most important compaction factor is the proper control of moisture and density. Conventional procedures such as sand cone (ASTM D1556) and nuclear methods (ASTM D6938) have been used for determining the density of compacted soil-lime mixtures. Moisture content can be determined by either oven-dry methods (ASTM D2216, *Standard Test Methods for Laboratory Determination of Water (Moisture) Content of Soil and Rock by Mass*) or nuclear methods (ASTM D6938). The influence of time between mixing and compacting has been demonstrated to have a pronounced effect on the properties of treated soil. Begin compaction as soon as possible after final mixing has been completed. The National Lime Association recommends an absolute maximum delay of one week. The use of phenolphthalein indicator solution has also been recommended for lime content control testing, as stated in paragraph 5-3.3. The solution can be used to distinguish between areas that have been properly treated and those that have received only a slight surface dusting by wind action. This will aid in identifying areas to perform density testing.

5-3.5 Curing*.*

Curing is essential to assure the soil-lime mixture will achieve the final properties desired. Curing is accomplished by one of two methods: (1) moist curing, involving a light sprinkling of water and rolling; or (2) membrane curing, which involves sealing the compacted layer with a bituminous seal coat or liquid curing compound. Regardless of the method used, properly protect the entire compacted layer to ensure the lime will not become nonreactive through carbonation. Inadequate sprinkling, which allows the stabilized soil surface to dry, will promote carbonation.

5-4 LIME-FLY ASH (LF) AND LIME-CEMENT-FLY ASH (LCF).

The nature of LF and LCF stabilization is similar to that for lime only. Consequently, the same factors involved for quality control are suggested.

5-5 BITUMINOUS AND POLYMER STABILIZATION.

The factors that seem most important to control during construction with bituminous and polymer stabilization are moisture content, viscosity of the liquid, additive content, uniformity of mixing, aeration, compaction, and curing.

5-5.1 Moisture Content.

The moisture of the soil to be stabilized is of concern. Moisture content can be determined by conventional methods, such as oven-drying (ASTM D2216), or by nuclear methods (ASTM D6938). The Asphalt Institute recommends surface moisture of up to 3 percent or more for use with emulsified asphalt and a moisture content of less than 3 percent for cutback asphalt. The gradation of the aggregate is significant to moisture content. With densely graded mixes, more water is needed for mixing than compaction. Generally, a surface moisture content that is too high will delay compaction of the mixture. Higher PI soils require higher moisture content. For polymer emulsions, ensure the starting soil moisture content is well below optimum. If not, the additional moisture present in the emulsion will result in a moisture content above optimum, leading to lower density during compaction. Although this is also true for asphalt emulsions, the asphalt coating is capable of lubricating the soil for compaction. Therefore, aerating the material to moisture contents below optimum is acceptable for asphalt-emulsion stabilization but not for polymer emulsion.

5-5.2 Viscosity of Asphalt.

The Asphalt Institute recommends avoiding cold-mix construction at temperatures below 50 °F (10 °C). The asphalt will rapidly reach the temperature of the aggregate to which it is applied and, at the lower temperature, difficulty mixing will be encountered. On occasion, heating is necessary with cutback asphalts to assure the soil aggregate particles are thoroughly coated. For emulsions, ensure the temperature is above the minimum film-forming temperature, a basic property of all emulsions.

5-5.3 Asphalt and Polymer Content.

Information that will enable field personnel to determine a satisfactory application rate can be provided to them. Maintain the asphalt content at optimum or slightly below for the specified mix. Excessive quantities of asphalt may cause difficulty in compaction and result in plastic deformation in service during hot weather.

Similarly, maintain the actual polymer content at or slightly below optimum for the design mix. The actual polymer content is computed based upon the percent solids of the polymer emulsion. In addition, check the polymer emulsion for consistency in terms of percent solids of the delivered product at random.

5-5.4 Uniformity of Mixing.

Visual inspection can be used to determine the uniformity of the mixture. With emulsified asphalts, a color change from brown to black indicates the emulsion has broken. The Asphalt Institute recommends control of three variables to assure uniformity for mixed-in-place construction: travel speed of application equipment;

volume of aggregate being treated; and flow rate (volume per unit time) of emulsified asphalt being applied. In many cases, an asphalt content above design is necessary to assure uniform mixing. The inspection of polymer-stabilized soil is less obvious; take extreme care to ensure the material is mixed thoroughly and to full depth.

5-5.5 Aeration.

Prior to compaction, allow the diluents that facilitated the cold-mix operation to evaporate. If the mix is not aerated, it cannot be compacted to acceptable limits. The Asphalt Institute has determined that the mixture has aerated when it becomes tacky and appears to "crawl." Most aerating occurs during the mixing and spreading stage but occasionally additional work on the roadbed is necessary. The Asphalt Institute has reported that overmixing in central plant mixes can cause emulsified asphalts to break early, resulting in a mix that is difficult to work with in the field.

5-5.6 Compaction.

Begin compaction when the aeration of the mix is completed. The Asphalt Institute recommends that rolling begin when an emulsified asphalt mixture begins to break (color change from brown to black). Early compaction can cause undue rutting or shoving of the mixture due to overstressing under the roller. The density of emulsion-stabilized bases has often been found to be higher than that obtained on unstabilized bases for the same compaction effort.

5-5.7 Curing.

Curing presents the greatest problem in asphalt soil stabilization. The Asphalt Institute has determined that the rate of curing is dependent upon many variables: the quantity of asphalt applied, the prevailing humidity and wind, the amount of rain and sunlight, and the ambient temperature. Allow initial curing in order to support compaction equipment. This initial curing, which allows the evaporation of diluents, occurs during the aeration stage. If compaction is started too early, the pavement will be sealed, delaying dehydration, which lengthens the time before design strength is reached. The heat of the day may cause the mixture to soften, which prohibits equipment from placing successive lifts until the following day. This emphasizes the need to allow curing time when lift construction is employed. The Asphalt Institute recommends a two- to five-day curing period under recommended conditions when emulsified bases are being constructed. Cement has been used to accelerate curing. Polymeric emulsions cure by evaporation of the dilution water. Thus, the use of a curing membrane is not recommended.

APPENDIX A BEST PRACTICES

A-1 THICKNESS CRITERIA-STABILIZED SOIL LAYERS

A-1.1 Equivalency Factors.

The use of stabilized soil layers within a flexible pavement provides the opportunity to reduce the overall thickness of the pavement structure required to support a given load. To design a pavement containing stabilized soil layers requires applying equivalency factors to a layer or layers of a conventionally designed pavement. To qualify for application of equivalency factors, ensure the stabilized layer meets appropriate strength and durability requirements set forth in this UFC. An equivalency factor represents the number of inches (millimeters) of a conventional base or subbase that can be replaced by 1 inch (25 mm) of stabilized material. Equivalency factors for stabilized materials are determined as shown in Table A-1. Limit the cement content to 4 percent by weight or less to prevent excessive reflective cracking. Selecting an equivalency factor from the table is dependent upon the classification of the soil to be stabilized.

Table A-1 Equivalency Factors for Stabilized Material

Material	Equivalency Factors	
	Base	Subbase
Asphalt-stabilized		
All-bituminous concrete	1.15	2.30
GW, GP, GM, GC	1.00	2.00
SW, SP, SM, SC	(*)	1.50
Cement-stabilized		
GW, GP, SW, SP	1.15	2.30
GM, GC	1.00	2.00
ML, MH, CL, CH	(*)	1.70
SC, SM	(*)	1.50
Lime-stabilized		
ML, MH, CL, CH	(*)	1.00
SC, SM, GM, GC	(*)	1.10
Lime, Cement, Fly Ash-Stabilized		
ML, MH, CL, CH	(*)	1.30
SC, SM, GM, GC	(*)	1.40
Unbound crushed stone	1.00	2.00
Unbound aggregate	(*)	1.00
* Not used for base course material.		

A-1.2 Thickness Design for Stabilized Soil Layers.

To use the equivalency factors requires that a conventional flexible pavement be designed to support the design load conditions. If it is desired to use a stabilized base or subbase course, the thickness of the conventional base or subbase is divided by the equivalency factor for the applicable stabilized soil.

A-1.2.1 Example 1.

Assume a conventional flexible pavement has been designed that requires a total thickness of 16 inches (406 mm) above the subgrade. The minimum thicknesses of the AC and the base are 2 and 4 inches (51 and 102 mm), respectively, and the thickness of the subbase is 10 inches (254 mm). It is desired to replace the base and the subbase with a cement-stabilized gravelly soil (GP) having an unconfined compressive strength of 890 psi (6.14 MPa). The material qualifies for application as a base course since its strength is greater than 750 psi (5.17 MPa), as required by this UFC. From Table A-1, the equivalency factor for a base is 1.15. Therefore, 4 inches ÷ 1.15 = 3.48 inches (102 mm ÷ 1.15 = 88.7 mm) of stabilized base course. Since the minimum required thickness is 4 inches (102 mm), the excess of stabilized base course of 4 inches – 3.48 inches = 0.52 inches (102 mm – 88.7 mm = 13.3 mm) is computed as the equivalent thickness of non-stabilized subbase material, which is equal to 0.52 inches * 2.3 = 1.12 inches (13.3 mm * 2.3 = 30.6 mm). This equivalent subbase thickness is accounted for in the stabilized base; therefore, the needed non-stabilized subbase is thinner than 10 inches (254 mm) and equal to 10 inches – 1.12 inches = 8.88 inches (254 mm – 21.2 mm = 232.8 mm). The next step includes calculating the equivalent thickness of the subbase stabilized material as 8.88 inches ÷ 2.3 = 3.86 inches (223.4 mm ÷ 2.3 = 97.1 mm). The required minimum thickness for the stabilized subbase is 4 inches (102 mm). Therefore, the total thickness of the cement-stabilized pavement is 2 inches (51 mm) of AC, 4 inches (102 mm) of cement-stabilized gravelly soil base, and 4 inches (102 mm) of cement-stabilized gravelly soil subbase.

A-1.2.2 Example 2.

Assume a conventional flexible pavement has been designed that requires 3.5 inches (89 mm) of AC surface, 4 inches (102 mm) of crushed stone base, and 18 inches (458 mm) of subbase. It is desired to construct an all-bituminous pavement (ABC). The equivalency factor from Table A-1 for a base course is 1.15 and for a subbase, 2.30. The thickness of AC required to replace the base is 4 inches ÷ 1.15 = 3.48 inches (102 mm ÷ 1.15 = 88.7 mm). Since the minimum required thickness is 4 inches (102 mm), the excess of stabilized base course of 4 inches – 3.48 inches = 0.52 inches (102 mm – 88.7 mm = 13.3 mm) is computed as the equivalent thickness of non-stabilized subbase material, which is equal to 0.52 inches * 2.3 = 1.12 inches (13.3 mm * 2.3 = 30.6 mm). This equivalent subbase thickness is accounted in the stabilized base; therefore, the needed non-stabilized subbase is thinner than 18 inches (459 mm) and equal to 18 inches – 1.12 inches = 16.88 inches (458 mm – 21.2 mm = 437 mm). The next step computes the equivalent thickness of subbase-stabilized material as 16.88 inches ÷ 2.3 = 7.34 inches (437 mm ÷ 2.3 = 190 mm). The total thickness of the ABC pavement is 3.5 inches + 4 inches + 7.34 inches = 14.84 inches ~15 inches (89 + 102 + 190 = 381 mm ~390 mm)

A-2 PH TEST ON SOIL-CEMENT MIXTURES

A-2.1 Materials.

Portland cement will be used for soil stabilization.

A-2.2 Apparatus.

Apparatus are the pH meter (equip the pH meter with an electrode having a pH range of 14), 150-ml plastic bottles with screw-top lids, 500-ml plastic beakers, distilled water, balance, oven, and moisture cans.

A-2.3 Procedure.

A-2.3.1 Standardization. Standardize the pH meter with a buffer solution having a pH of 12.00.

A-2.3.2 Representative Samples. Weight to the nearest 0.01 g representative samples of air-dried soil passing the No. 40 (0.425 mm) sieve and equal to 25.0 g of oven-dried soil.

A-2.3.3 Soil Samples. Pour the soil samples into 150-ml plastic bottles with screw-top lids.

A-2.3.4 Portland cement. Add 2.5 g of portland cement.

A-2.3.5 Mixture. Thoroughly mix soil and portland cement.

A-2.3.6 Distilled Water. Add distilled water to make a thick paste. (Caution: Too much water will reduce the pH and produce an incorrect result.)

A-2.3.7 Blending. Stir the soil-cement and water until thorough blending is achieved.

A-2.3.8 Transferal. After 15 minutes, transfer part of the paste to a plastic beaker and measure the pH.

A-2.3.9 Interference. If the pH is 12.1 or greater, the soil organic matter content should not interfere with the cement-stabilizing mechanism.

A-3 DETERMINATION OF SULFATE IN SOILS - GRAVIMETRIC AND TURBIDIMETRIC METHOD

A-3.1 Gravimetric Method.

A-3.1.1 Scope.

Applicable to all soil types with the possible exception of soils containing certain organic compounds, this method permits the detection of as little as 0.05 percent sulfates as SO_4.

A-3.1.2 Reagents.

Reagents include barium chloride ($BaCl_2$), 10 percent solution of $BaCl_2 \bullet 2H_2O$ (Add 1 ml 2 percent HCI to each 100 ml of solution to prevent formation of carbonate.); hydrochloric acid, 2 percent solution (0.55 Normal); magnesium chloride, 10 percent solution of $MgCl_2 \bullet 6H_2O$; demineralized water; and silver nitrate, 0.1 Normal solution.

A-3.1.3 Apparatus.

Apparatus used are a 100-ml beaker, a burner and ring stand, a 500-ml filtering flask, a 90-ml Buchner funnel, 90-ml Whatman No. 40 filter paper, 90 ml Whatman No. 42 filter paper, Saran Wrap, a crucible or heavy-grade aluminum foil, ignition, an analytical balance, and an aspirator or other vacuum source.

A-3.1.4 Procedure.

A-3.1.4.1 Select a representative sample of air-dried soil weighing approximately 10 g. Weigh to the nearest 0.01 g. (Note: When sulfate content is anticipated to be less than 0.1 percent, a sample weighing 20 g or more may be used.) (Measure the moisture content of the air-dried soil for later determination of dry weight of the soil.)

A-3.1.4.2 Boil for 1.5 hours in a beaker with mixture of 300-ml water and 15-ml HCl.

A-3.1.4.3 Filter through Whatman No. 40 paper, wash with hot water, and dilute combined filtrate and washings to 50 ml.

A-3.1.4.4 Take 100 ml of this solution and add $MgCl_2$ solution until no more precipitate is formed.

A-3.1.4.5 Filter through Whatman No. 42 paper, wash with hot water, and dilute combined filtrates and washings to 200 ml.

A-3.1.4.6 Heat 100 ml of this solution to boiling and add $BaCl_2$ solution very slowly until no more precipitate is formed. Continue boiling for about five minutes and let stand overnight in a warm place, covering the beaker with Saran Wrap.

A-3.1.4.7 Filter through Whatman No. 42 paper. Wash with hot water until free from chlorides (filtrate should show no precipitate when a drop of $AgNO_3$ solution is added or continue washing).

A-3.1.4.8 Dry filter paper in crucible or on sheet of aluminum foil. Ignite paper. Weight residue on analytical balance as $BaSO_4$.

A-3.1.5 Calculation.

$$Percent\ SO_4 = \frac{Weight\ of\ residue}{Oven\ dry\ weight\ of\ initial\ sample} \times 411.6$$

Where:

$$\text{Oven-dry weight of initial sample} = 1 + \frac{\frac{air-dry\ \ weight\ of\ initial\ sample}{air-dry\ moisture\ content\ (percent)}}{100\ percent}$$

Note: If precipitated from cold solution, barium sulfate is so finely dispersed that it cannot be retained when filtering by the above method. Precipitation from a warm, dilute solution will increase crystal size. Due to the absorption (occlusion) of soluble salts during the precipitation by $BaSO_4$, a small error is introduced. This error can be minimized by permitting the precipitate to digest in a warm, dilute solution for a number of hours. This allows the more soluble small crystals of $BaSO_4$ to dissolve and recrystallize on the larger crystals.

A-3.2 Turbidimetric Method.

A-3.2.1 Reagents.

Reagents include $BaCl_2$ crystals (grind analytical reagent-grade $BaCl_2$ to pass a 1-mm sieve), ammonium acetate solution (0.5 N) (add dilute hydrochloric acid until the solution has a pH of 4.2), and distilled water.

A-3.2.2 Apparatus.

Apparatus used are a moisture can, an oven, a 200-ml beaker, a burner and ring stand, a filtering flask, a 90-ml Buchner funnel, 90 ml Whatman No. 40 filter paper, a vacuum source, a spectrophotometer and standard tubes (Bausch and Lomb Spectronic 200 or equivalent), and a pH meter.

A-3.2.3 Procedure.

A-3.2.3.1 Take a representative sample of air-dried soil weighing approximately 10 g and weight to the nearest 0.01 g. (Measure the moisture content of the air-dried soil for later determination of dry weight of the soil.)

A-3.2.3.2 Add the ammonium acetate solution to the soil until the ratio of soil to solution is approximately 1:5 by weight.

A-3.2.3.3 Boil for about five minutes.

A-3.2.3.4 Filter through Whatman No. 40 filter paper. If the extracting solution is not clear, filter again.

A-3.2.3.5 Take 10 ml of extracting solution (this may vary, depending on the concentration of sulfate in the solution) and dilute with distilled water to about 40 ml. Add about 0.2 g of $BaCl_2$ crystals and dilute to make the volume exactly equal to 50 ml. Stir for one minute.

A-3.2.3.6 Immediately after the stirring period has ended, pour a portion of the solution into the standard tube and insert the tube into the cell of the spectrophotometer. Measure the turbidity at 30-second intervals for four minutes. Maximum turbidity is usually obtained within two minutes and the readings remain constant thereafter for three to ten minutes. Consider the turbidity to be the maximum reading obtained in the four-minute interval.

A-3.2.3.7 Compare the turbidity reading with a standard curve and compute the sulfate concentration (as SO_4) in the original extracting solution. (The standard curve is secured by carrying out the procedure with standard potassium sulfate solutions.)

A-3.2.3.8 Correct for the apparent turbidity of the samples by running blanks in which no $BaCl_2$ is added.

A-3.2.4 Sample Calculation.

Given:		
	Weight of air-dried sample	= 10.12 g
	Water content	= 9.36 percent
	Weight of dry soil	= 9.27 g
	Total volume of extracting solution	= 39.1 ml

10 ml of extracting solution was diluted to 50 ml after addition of $BaCl_2$ (see paragraph A-3.2.3, step 5). The solution gave a transmission reading of 81. From the standard curve, a transmission reading of 81 corresponds to 16.0 parts per million. (See Figure A-1.)

Concentration of original extracting solution = 16.0 × 5 = 80.0 parts per million

$$Percent\ SO_4 = \frac{80.0 \times 39.1 \times 100}{1{,}000 \times 1{,}000 \times 9.27} \times 0.0338\ percent$$

A-3.2.5 Determination of Standard Curve.

A-3.2.5.1 Prepare sulfate solutions of 0, 4, 8, 12, 16, 20, 25, 30, 35, 40, 45, and 50 parts per million in separate test tubes. The sulfate solution is made from potassium sulfate salt dissolved in 0.5 Normal ammonium acetate (with pH adjusted to 4.2).

A-3.2.5.2 Continue steps 5 and 6 in the procedure (paragraph A-3.2.3).

A-3.2.5.3 Draw a standard curve as shown in Figure A-1 by plotting transmission readings for known concentrations of sulfate solutions.

Figure A-1 Example Standard Curve for Spectrophotometer

B-2 TERMS

Additive Stabilization: Stabilization is achieved by adding the proper percentages of additives to the soil. Selecting the type and determining the percentage of additive to be used is dependent upon the soil classification, conservation of deleterious materials such as sulfates and organics, and the degree of improvement in soil quality desired. Non-traditional additives such as polymer, fiber, lignin derivatives, enzymes, acids, etc. will be addressed where appropriate; however, due to the specialized nature of many of these materials, defining specific criteria for all additives is beyond the scope of this UFC. Generally, smaller amounts of additives are required when only modification of soil properties such as gradation, workability, and plasticity is desired. When significant strength and durability improvement is desired, greater quantities of additive are needed. After the additive has been mixed with the soil at the optimum moisture content, spreading and compaction are achieved by conventional means.

Additives: Manufactured commercial products that, when added to the soil in the proper quantities, improve some engineering characteristics of the soil such as strength, texture, workability, and plasticity are termed “traditional” additives and include materials such as lime, cement, fly ash, and asphalt emulsions. “Non-traditional” additives such as polymer emulsions, fiber, lignin derivatives, enzymes, acids, and other materials used to improve soil qualities are more recent entries into the commercial market. Additives addressed in this UFC are portland cement, lime, fly ash, bitumen, polymer emulsion, fiber, and select combinations of these.

Durability: Durability refers to the resistance of the soil to weathering, primarily by the action of water and abrasion after wet-dry and freezing and thawing cycles (ASTM D559 and D560).

Mechanical Stabilization: Mechanical stabilization is accomplished by mixing or blending soils of two or more gradations to obtain a material meeting the required specification. The soil blending may take place at the construction site, a central plant, or a borrow area. The blended material is then spread and compacted to required densities at the optimum moisture content by conventional means. Compaction and fiber addition are also means of mechanical stabilization. Compaction consists of the mechanical rearrangement of soil particles into a denser configuration, typically resulting in increased strength and/or durability. The addition of fibers into a soil can mechanically stabilize the soil by creating interlock between particles.

Modification: Modification refers to the stabilization process that results in improvement in some material property of the soil such as the plasticity index (PI) but does not, by design, result in a significant increase in soil strength and durability.

Optimum Moisture Content: The optimum moisture content of soil is the water content, measured in percentage by unit weight, at which a maximum dry unit weight can be achieved after a given compactive effort. (See ASTM D1557 for further information.) A higher or lower moisture content will result in a lower maximum dry unit weight after compaction.

Soils: Soils are naturally occurring materials used for the construction of all except the surface layers of pavements (i.e., concrete and asphalt) and subject to classification tests (ASTM D2487) to provide a general concept of their engineering characteristics.

Stabilization: Stabilization is the process of blending and mixing materials with a soil to improve engineering properties of the soil. The process may include the blending of soils to achieve a desired gradation or the mixing of additives that may alter the chemistry, gradation, texture, plasticity, or water absorption or act as a binder for cementation of the soil. Stabilization results in a significant increase in the strength and/or durability of the stabilized material.

Strength: In the context of this UFC, “strength” refers to the unconfined compressive tests measured using ASTM D1633.

Record of Changes (changes are indicated by **1**\ ... /**1**/)

Change No.	**Date**	**Location**
1	5 May 2020	Updated Tables 3-5 and 8-4, Figures 8-23, 8-25, and 8-46, and paragraphs 6-5.7, 7-9, 7-12.1, 7-10.2.5, 8-5.4.4, 8-5.9, B1-2.1.4, B11-5.1, B13-2.2, and B13-2.21.2.10. Added new paragraph B13-2.2.2.5 on perimeter fencing in the MFZ. Replaced all references to AFI 32-1042, AFI 32-1043, and AFI 32-1044 with superseding AFMAN 32-1040. Updated references in Appendix A.

This UFC supersedes UFC 3-260-01, dated 17 November 2008.

FOREWORD

The Unified Facilities Criteria (UFC) system is prescribed by MIL-STD 3007 and provides planning, design, construction, sustainment, restoration, and modernization criteria, and applies to the Military Departments, the Defense Agencies, and the DoD Field Activities in accordance with USD (AT&L) Memorandum dated 29 May 2002. UFC will be used for all DoD projects and work for other customers where appropriate. All construction outside of the United States is also governed by Status of Forces Agreements (SOFA), Host Nation Funded Construction Agreements (HNFA), and in some instances, Bilateral Infrastructure Agreements (BIA). Therefore, the acquisition team must ensure compliance with the more stringent of the UFC, the SOFA, the HNFA, and the BIA, as applicable.

UFC are living documents and will be periodically reviewed, updated, and made available to users as part of the Services' responsibility for providing technical criteria for military construction. Headquarters, U.S. Army Corps of Engineers (HQUSACE), Naval Facilities Engineering Command (NAVFAC), and Air Force Civil Engineer Center (AFCEC) are responsible for administration of the UFC system. Defense agencies should contact the preparing service for document interpretation and improvements. Technical content of UFC is the responsibility of the cognizant DoD working group. Recommended changes with supporting rationale should be sent to the respective service proponent office by the following electronic form: Criteria Change Request (CCR). The form is also accessible from the Internet sites listed below.

UFC are effective upon issuance and are distributed only in electronic media from the following source:

Whole Building Design Guide web site http://dod.wbdg.org/.

Refer to UFC 1-200-01, *DoD Building Code (General Building Requirements)*, for implementation of new issuances on projects.

UNIFIED FACILITIES CRITERIA (UFC)
REVISION SUMMARY SHEET

Document: UFC 3-260-01, *Airfield and Heliport Planning and Design*

Superseding: UFC 3-260-01, dated 17 November 2008

Description of Changes: This update to UFC 3-260-01:

- Updates Chapter 1, *General Requirements* to clarify text per review comments. In particular, clarified applicability to existing facilities in Para 1-3.
- Updates Chapter 2, *Aviation Facilities Planning* to clarify text per comments. In particular, a) added paragraph 2-5.5 regarding stormwater management facilities near airfields; b) unified nomenclature to apply to all DoD services; c) updated Navy exceptions from criteria in Para 2-11; d) added paragraph 2-12 regarding design requirements for buried utility structures on airfields.
- Updates Chapter 3, *Runways (Fixed-Wing) and Imaginary Surfaces* to clarify text per review comments. In particular, a) clarified MV-22 applicability in paragraph 3-3.3; b) revised Table 3-1 to update for current aircraft; c) added paragraph 3-9 regarding runway end siting requirements; c) updated figures to improve resolution; d) deleted design requirements for underground structures in paragraphs 3-9.1 and 3-9.2;
- Updates Chapter 4, *Rotary-Wing Runways, Helipads, Landing Lanes, and Hoverpoints* to clarify text per review comments. In particular, a) clarified MV-22 applicability in paragraph 4-3.4; b) added paragraph 4-4.4 describing elevated helipads.
- Updates Chapter 5, *Taxiways* to clarify text per review comments. In particular, deletes paragraph 5-8.2 and Figure 5-6. This aligns Navy intersection fillet design criteria with previously published Army and Air Force criteria.
- Updates Chapter 6, *Aprons and Other Pavements* to clarify text per review comments. In particular, a) adds criteria for CH-53 helicopters including parking layout; b) adds criteria for protective barriers or shelters on parking spaces for rotary-wing aircraft in paragraph 6-7.4.3; c) adds paragraph 6-7.6 providing considerations for hot refueling operations for rotary-wing aircraft; d) adds Aircraft Wash Racks content passed from UFC 4-211-02; e) updated Compass Calibration Pad requirements.
- Updates Chapter 7 to incorporate Air Force ETL 09-6, *C-130 and C-17 Landing Zone (LZ) Dimensional, Marking and Lighting Criteria*.
- Deletes Chapter 8, Aircraft Hangar Pavements.
- Adds new Chapter 8, *Fixed-Wing Short Takeoff and Vertical Landing (STOVL) Facilities.* This chapter incorporates information from Air Force ETL 14-4, *Vertical Landing Zone (VLZ) And Other Airfield Pavement Design and Construction Using High Temperature Concrete* and *F-35 Lightning II STOVL Airfield Facilities and Airspace Criteria Engineering Technical Letter (ETL), document No: 2PSS00040, Rev 1 dated 30 July 2010.* In addition, added F-35B related content and standard drawings for LHD and VL Pad facilities.

- Adds new Chapter 9, *Unmanned Aircraft Systems (UAS)*. This chapter incorporates Army ETL 1110-3-510 *Aviation Complex Planning and Design Criteria for Unmanned Aircraft Systems (UAS)*.
- Updates Glossary to include new acronyms and new terms.
- Moves Glossary to Appendix C to follow UFC template format.
- Updates Appendix A, References, to update hyperlinks.
- Updates Appendix B, Section 1 to incorporate Army, Air Force and Navy revisions to clarify waiver procedures for each service.
- Updates Appendix B, Section 2, deleting Tables B2-1 thru B2-7 and instead providing facility space planning cross references for each service.
- Updates Appendix B, Section 3 by deleting all text and tables, but providing cross references to DoD, Air Force and Navy source documents
- Updates Appendix B, Section 5 to delete Part 77 text and include only cross-references to the Part 77 document.
- Updates Appendix B, Section 6 to change reference for Aircraft Characteristics to Army Technical Reports.
- Updates Appendix B, Section 7.
- Updates Appendix B, Section 10, Compass Calibration Pad siting, survey and marking guidance.
- Updates Appendix B, Section 11 to remove descriptions of static grounding points and cross-referencing to UFC 3-575-01.
- Deleted Appendix B, Section 12. Replaced with content from AF ETL 07-3: *Jet Engine Thrust Standoff Requirements for Airfield Asphalt Edge Pavements.*
- Updates Appendix B, Section 13 to incorporate Army and Air Force revisions, adding new systems and deleting old systems.
- Updates Appendix B, Section 14 to incorporate some features of FAA Advisory Circular 150/5370-2F.
- Updates Appendix B, Section 15 to incorporate Air Force ETL 01-10, *Design and Construction of High Capacity Trim Pad Anchoring Systems*.
- Deletes Appendix B, Section 16.
- Updates and Renumbers Appendix B, Section 17 now be Section 16 and to delete detailed facility requirements and provide cross-reference to UFC 4-133-01.
- Updates and Renumbers Appendix B, Section 18 now be Section 17.

Reasons for Changes:

- Incorporate new guidance scattered throughout Army and Air Force Engineering Technical Letters.
- Incorporate guidance for STOVL facilities to be used by aircraft such as F-35B.
- Clarified MV-22 Content.
- Incorporate UAS Content.
- Response to Criteria Change Requests (CCR).

- Response to review comments made by a wide variety of UFC users among the DoD agencies, including engineers, planners, airfield managers, and air traffic controllers.
- Improvement to readability of figures and addition of information via new tables and figures

Impact: There are negligible cost impacts; however, these benefits should be realized:

- Reduced confusion in interpreting guidance.
- Tri-service criteria for C-130 and C-17 Landing Zones.
- Consistent and clear tri-service criteria for STOVL facilities.
- Consistent and clear tri-service criteria for UAS facilities.
- Improved waiver processing guidelines

Non-Unification Issues: Due to differences in mission, aircraft, tactics, mishap potential and mishap rates for specific aircraft, not all criteria within this UFC are unified. The primary elements of criteria that are not unified are clear zone and accident potential zone (APZ) shapes and sizes, separation distances between runways and taxiways, and size and implementation dates for certain protected air space elements. Maintaining these differences allows the Services to avoid costs associated with non-mission-driven changes in airfield configuration and mapping, and acquisition of real property or avigation easements.

- Planning: The processes vary among the Services due to differing organizational structures and are delineated in separate Service-specific directives.
- Clear zone and APZ shapes and sizes: These areas are different for each Service and class of runway because they are based on the types of aircraft that use the runways and Service-specific accident potential.
- Distances between fixed and rotary-wing runways: The distance is greater for Air Force and Navy/Marine Corps runways due to the frequency of operations by high-performance aircraft.
- Increased width of landing lanes for Navy/Marine Corps: The width is increased to prevent rotor wash damage to landing lane shoulders and subsequent potential foreign object damage (FOD) from large rotary-wing aircraft.
- No Navy/Marine Corps requirement for paved shoulders on Class A taxiways: Same rationale as for the width of Class A taxiways above.
- Reduced site distance for Air Force taxiways: Enables the Army and Navy/Marine Corps to operate with uncontrolled taxiways.
- Increased clearance from taxiway centerlines to fixed or mobile obstacles: The Air Force routinely operates C-5 aircraft on all Air Force airfields. Use of the reduced clearances slows taxi speeds and hinders expedient operations.
- Towway width differences: The Navy/Marine Corps base towway width on three general aircraft types; the Air Force and Army base towway width on mission aircraft.

- Clearance from towway centerline to fixed or mobile obstacles: The Navy/Marine Corps require distance be based on towway type; the Air Force and Army require clearance be based on mission aircraft.
- Vertical clearance from towway pavement surface to fixed or mobile obstacles: The Navy/Marine Corps require distance be based on towway type; the Air Force and Army require clearance be based on mission aircraft.
- Differences in apron spacing for parking aircraft: The Navy/Marine Corps apron spacing requirements are developed for each aircraft in the inventory. Air Force and Army requirements are based on aircraft wingspan.
- Differences in Air Force and Army apron clearance distance: The Army requires a 38-meter (125-foot) clearance distance for all Class B aircraft aprons. This distance is sufficient to accommodate C-5 aircraft. The Air Force formerly used the same criteria but recently began basing the required distance on the most demanding aircraft that uses the apron. This is because all aprons will not accommodate C-5 aircraft.
- Differences in apron layout for rotary-wing aircraft: Formerly, Air Force and Army rotary-wing criteria were slightly different. The Air Force has adopted Army rotary-wing criteria as optional and will standardize these criteria in the next revision of AFH 32-1084, *Facility Requirements*.

CHAPTER 1
GENERAL REQUIREMENTS

1-1 BACKGROUND.

This Unified Facilities Criteria (UFC), UFC 3-260-01, provides requirements for evaluating, planning, programming, and designing airfields and heliports. The requirements contained in this UFC apply to Army, Navy, and Air Force facilities unless specifically referenced to a single service. This UFC is not intended as a substitution for thorough review during design by individual Program Managers, Engineers and Operations Staff in the appropriate service.

The desired goal of this UFC is to maintain consistency in Airfields and Heliports requirements across the Army, Navy and Air Force. This UFC is not intended as an operational manual.

Each service has unique requirements to fulfill specific missions. This document will highlight any key differences that impact the airfield or heliport layout and design. Where one Service's criteria vary from the other Services' criteria, it is noted in the text.

1-2 PURPOSE AND SCOPE.

1-2.1 Purpose.

This manual provides standardized airfield, heliport, and airspace criteria for the geometric layout, design, and construction of runways, helipads, taxiways, aprons, landing zones (LZs), short take-off and vertical landing (STOVL) facilities, unmanned aircraft system (UAS) facilities and related permanent facilities to meet sustained operations.

1-2.2 Scope.

This manual prescribes dimensional and geometric layout criteria for safe standards for airfields, landing zones, heliports and helipads, and related permanent facilities, as well as the navigational airspace surrounding these facilities. Manned aircraft facilities are addressed in Chapters 1 through 6. Landing Zones used by C-130 and C-17 aircraft are addressed in Chapter 7. Airfield facilities used by Short Take-off Vertical Landing (STOVL) aircraft are addressed in Chapter 8. Airfield facilities for Unmanned Aircraft Systems (UAS) are addressed in Chapter 9. Criteria in this manual pertain to all Department of Defense (DoD) military facilities in the United States, its territories, trusts, and possessions, and unless otherwise noted, to DoD facilities overseas on which the United States has vested base rights. For DoD facilities overseas; if a written agreement exists between the host nation and the DoD that requires application of either North Atlantic Treaty Organization (NATO), International Civil Aviation Organization (ICAO), or Federal Aviation Administration (FAA) standards, those standards will apply as stipulated within the agreement; however, DoD proponents will apply the criteria within this manual to the maximum extent practicable. United States Air Force (USAF) bases within the European theater may be authorized by Headquarters United States Forces in Europe (HQ USAFE) to use NATO criteria (See USAFEI 32-1007). Tenant organizations on civil airports in the continental United States (CONUS) will use these criteria to the extent practicable; otherwise, FAA criteria will apply. Specifically, on airfield areas that are joint-use or with restrictions and clear zones generated by joint-use areas, the FAA criteria contained in FAA Advisory Circular (AC) 150/5300-13 is applicable. For areas where airfield surfaces are National Guard Bureau (NGB), Army Reserve or Air Force Reserve controlled, whether fee-owned or exclusive use leased, the criteria contained in this manual are applicable.

1-2.2.1 Terminal Instrument Procedures (TERPS).

In addition to a local TERPS review, modifications to existing facilities, temporary construction, airfield surface modifications, maintenance or construction requiring equipment on or near the airfield flying environment, and construction of new facilities must be closely coordinated with the Air Force major command (MAJCOM), US Army Aeronautical Services Agency (USAASA) and United States Army Aeronautical Services Detachment, Europe (USAASDE), and Naval Flight Information Group (NAVFIG) to determine the impact to existing and planned instrument approach and departure procedures . The criteria in this manual do not address instrument flight procedures. TERPS evaluations and processes are described in FAA Order 8260.3 and Air Force Instruction (AFI) 11-230. TERPS criteria shall be considered when designing or modifying airfields and facilities on airfields that are used under instrument flight rules (IFR).

1-2.2.2 Objects Affecting Navigable Airspace.

Modifications to existing facilities and construction of new facilities must consider effects on navigable airspace IAW Federal Aviation Regulation (FAR) Part 77 and may require that an FAA Form 7460-1 and/or 7460-2 be filed with the administrator. See Appendix B, Section 5, to determine when the FAA Form 7460-1 must be filed. FAA Form 7460-2 is used to notify the FAA of progress or abandonment, as requested, on the form. The FAA Service Area routinely includes this form with a determination when such information will be required. The information is used for charting purposes, to change affected aeronautical procedures, and to notify pilots of the location of the structure. Go to https://oeaaa.faa.gov/oeaaa/external/portal.jsp for more information on these forms and instructions for using E-file to submit the form to FAA. The criteria for determining obstructions to navigable airspace have been identified in this manual. The designer must consult this manual during the design process to identify obstructions to airspace and file FAA Form 7460-1 when required. The Construction Proponent/Community Planner will coordinate with the airfield/airspace manager and aviation safety officer before filing the form with the FAA. For facilities outside the United States (US) and its trust territories, host nation criteria apply off base. If the criteria in this manual are more stringent, this manual should be used to the maximum extent practical.

1-2.2.3 Navigational Aids (NAVAIDS) and Lighting.

NAVAIDS and airfield lighting are integral parts of an airfield and must be considered in the planning and design of airfields and heliports. NAVAID location, airfield lighting, and the grading requirements of a NAVAID must be considered when locating and designing runways, taxiways, aprons, and other airfield facilities.

1-2.2.4 Special Tilt-Rotor Aircraft Considerations (V-22).

The V-22 is a tilt-rotor aircraft that can operate both as a fixed-wing aircraft or a rotary-wing aircraft. At permanent shore establishments, the V-22 will be considered a fixed-wing aircraft for the purposes of determining facilities requirements. The runway will be planned according to critical field length. Chapter 3 contains V-22 fixed-wing criteria with noted exceptions. Additionally, rotary-wing facilities such as helipads may be utilized for V-22 operations. Chapter 4 contains V-22 rotary-wing criteria with noted exceptions. V-22 facilities require upgraded high temperature materials where stationary operations are expected for extended periods of times. V-22 apron requirements are provided in Chapter 6.

1-3 APPLICABILITY.

1-3.1 Existing Facilities.

Existing airfield facilities built under a previous standard need not be immediately modified nor upgraded to conform to the criteria in this manual if these facilities meet current mission requirements. This includes cases where runways may lack paved shoulders or other physical features because they were not previously required or authorized. However, when a change in the facility mission occurs, new features are added, or the facility is repaired (when repair is accomplished by replacement), the airfield facilities must be re-evaluated and upgraded where deficient using current criteria and the new mission requirements to eliminate the deficiency. A change in the facility mission can be a new aircraft or weapons platform, revised facility use, facility re-purposing, or other change that may present a new risk, assumption, or loading not previously considered or evaluated for the existing facility.

The criteria in this UFC apply to DoD aviation facilities located in the US, its territories, trusts and possessions. Where a DoD aviation facility is a tenant on a civil airport see paragraph 1-3.5.

Where a DoD aviation installation complex is host to a civilian aviation operation, the criteria in this UFC applies. Apply this criteria to the extent practicable at overseas locations where the DoD have vested rights. While the criteria in this UFC is not intended for use in theater of operations situations, it may be used as a guideline when prolonged use is anticipated and no other standard has been designated. Once upgraded, facilities must be maintained at a level that will sustain compliance with current standards. DoD personnel must identify the status of features and facilities on airfield maps as exempt (because they were constructed under a previous, less stringent standard), as a permissible deviation (authorized as a deviation to airfield criteria and sited appropriately), or as a violation, with or without approved waiver. For the Air Force only, Building Restriction Lines (BRLs) encompass vertical facilities along the flight line that are exempt because they were constructed under previous standards. For other items or features, annotate the airfield map to identify the status of the facility or feature and the date of construction or waiver number. See Appendix B, Section 17, for the guidelines used to establish the BRL.

1-3.2 Modification of Existing Facilities.

When existing airfield facilities are modified, construction must conform to the criteria established in this manual unless the criteria is waived in accordance with paragraph 1-7. Modified portions of facilities must be maintained at a level that will sustain compliance with the current standards. Exception: For the USAF, parallel taxiways constructed less than 305 meters (m) (1,000 feet (ft)) from the runway centerline may be resurfaced or extended without a waiver if the extension is less than 50 percent of the total taxiway length and the location does not impact TERPS criteria.

1-3.3 New Construction.

The criteria established in this manual apply to all new facilities. All new construction will comply with the criteria established in this manual unless the appropriate waivers are obtained as outlined in Appendix B, Section 1. For the USAF, new facilities within the appropriate category code may be constructed without a waiver if they are behind and beneath the boundaries of the BRL (see Appendix B, Section 17). All site plans for new facilities that will be sited within this area will clearly delineate the limits (including elevation) of the BRL and the relationship to the proposed facility. New facilities must be maintained at a level that will sustain compliance with the current standards.

1-3.4 Metric Application.

Geometric design criteria established in this manual are expressed in SI units (metric) and inch-pound units (English). These metric values are based on aircraft-specific requirements rather than direct conversion and rounding. This results in apparent inconsistencies between metric and inch-pound (English) dimensions. For example, 150-ft-wide runways are shown as 46 m, and 150-ft-wide aircraft wash racks are shown as 45 m. Runways need the extra meter in width for aircraft operational purposes; wash racks do not. English dimensions apply to new airfield construction at US facilities. At OCONUS facilities, apply dimensional units customarily used for construction at the facility. To avoid changes to existing airfield obstruction maps and compromises to flight safety, airfield and heliport imaginary surfaces and safe wingtip clearance dimensions are shown as a direct conversion from inch-pound to SI units.

1-3.5 Military Activities on Civil Owned Airfields.

DoD installations on municipal airports or FAA-controlled airfields must apply FAA criteria to facilities such as runways and taxiways that are jointly used by civilian and military aircraft. The portions of facilities that are for military use only, such as aircraft parking aprons, must apply DoD criteria.

1-3.6 USAFE Installations.

HQ USAFE Instruction (USAFEI) 32-1007 provides guidance for when NATO criteria may be used in lieu of the standards provided in this manual.

1-3.7 Gravel Runways at Radar Sites.

As much as possible, the criteria from Chapter 7 will be applied to the gravel runways currently in use at radar sites throughout Alaska. It is understood that many of these runways were constructed in such a way that terrain constraints allow traffic in only one direction, and that slope and obstacle clearances can be well outside normal criteria.

1-4 GENERAL BUILDING REQUIREMENTS.

Comply with UFC 1-200-01, General Building Requirements. UFC 1-200-01 provides applicability of model building codes and government unique criteria for typical design disciplines and building systems, as well as for accessibility, antiterrorism, security, high performance and sustainability requirements, explosive and other safety. Use this UFC in addition to UFC 1-200-01 and government criteria referenced therein.

1-4.1 Explosives Safety.

This document does not contain requirements for explosives safety. Facilities that involve DoD Ammunition and Explosives (AE) storage, handling, maintenance, manufacture or disposal, as well as facilities within the explosives safety quantity distance (ESQD) arcs of AE facilities, must comply with the requirements found in DoD 6055.09-M, as well as implementing Service criteria found in DA PAM 385-64 (Army), NAVSEA OP 5 (Navy and Marine Corps), and AFMAN 91-201 (Air Force). DoD facilities exposed to potential explosion effects from AE belonging to other nations are also required to meet DoD and Service explosives safety criteria. See also Appendix B Section 9.

1-4.2 Physical Security.

That part of security concerned with physical measures designed to safeguard personnel; to prevent or delay unauthorized access to equipment, installations, material, and documents; and to safeguard them against espionage, sabotage, damage, and theft.

Regulatory requirements for security of assets can have a significant impact on the planning and design of airfields and heliports. The arms, ammunition, explosives, and electronic devices associated with aircraft, as well as the aircraft themselves, require varying types and levels of protection. Operational security of the airfield is also a consideration.

Protective features such as barriers, fences, lighting, access control, intrusion detection, and assessment must be integrated into the airfield planning and design process to minimize problems with aircraft operations and safety requirements. This is discussed further in Chapter 2 and in unified facilities criteria UFC 4-020-01, DoD Security Engineering Facilities Planning Manual. The protective measures will be included in the design based on risk and threat analyses with an appropriate level of protection, or will comply with security-related requirements.

1-5 SERVICE REQUIREMENTS.

When criteria differ among the various Services, the criteria for the specific Service are noted. For the USAF, all work orders processed for work within the airfield environment must be signed by the airfield manager before work may proceed in accordance with paragraph 1-8, "USAF Work Order Coordination and Authorization."

1-6 THEATER OF OPERATIONS.

Standards for theater-of-operations facilities are contained in US Army TM 3-34.48-2. For C-17 and C-130 landing zones see Chapter 7 of this manual.

1-7 WAIVERS TO CRITERIA.

Mil-STD 3007 contains the overarching process for "waivers" or "exemptions" to this and all UFCs even though this UFC details additional waiver processes for operational and safety authorities. The term "waiver" herein may refer to either a temporary "waiver" or permanent "exemption" with regard to Mil-STD 3007. Each DoD Service component is responsible for setting the administrative procedures necessary to process and grant formal design or operational waivers. "Waivers" in general herein is a term that also indicates intent to seek approval for some non-compliance to criteria in this UFC. This document is intended for new construction; however, it is acknowledged that other authorities may reference it for other supplemental uses and purposes. Although this is not an operational document, these other authorities may require their own respective waiver processes. Waivers to the criteria contained in this manual will be processed in accordance with Appendix B, Section 1. If a waiver affects instrument approach and departure procedures as defined in TERPS (FAA Order 8260.3/ TM 95-226/OPNAVINST 3722.16C), the DoD Service component processing the waiver must also coordinate its action with the applicable TERPS approving authority. Certain existing facilities may require the supported aircraft activity to have an operational waiver to continue to operate, such as to land/takeoff on a shorter runway, operate on a taxiway that is not wide enough, or operate with reduced wingtip clearances for interior hangars or sunshades. These are operational/safety waivers and not design criteria waivers for new construction. Design criteria waivers address design considerations of new facilities while operational/safety waivers address airfield safety/risk considerations and operational mitigations. The Service authority owning the airfield and/or the mission aircraft will determine the requirements needed to safely operate on the existing facilities as described in Appendix B, Section 1.

1-8 USAF WORK ORDER COORDINATION AND AUTHORIZATION.

All work orders processed for work in the airfield environment must first be coordinated with communications, civil engineering, safety, security forces, and TERPS, and then signed by the airfield manager before work may proceed. The airfield manager (AM) and flight safety must be notified no less than five working days prior to beginning construction/work on the airfield. This does not apply to emergency repairs.

1-9 FAA NOTICE OF PROPOSED CONSTRUCTION OR ALTERATION.

Construction of new airfields, heliports, helipad or hoverpoints, or modifications to existing facilities affecting the use of airspace or changes in aircraft densities may require notification to the FAA Administrator. When a new runway, heliport, helipad or hoverpoint is planned or an existing landing surface will be extended or modified, in addition to local permitting requirements, file FAA Form 7480-1 in accordance with FAA Order 7400.2 via https://oeaaa.faa.gov/oeaaa/external/portal.jsp. Additionally, the FAA must be notified of all construction that affects air navigation at DoD airfields and civil airports in the US and its territories. FAA Form 7460-1 must be submitted to the FAA at least 45 days prior to the start of construction, in accordance with Federal Aviation Regulations (FAR), Part 77, subpart B. Airspace surface penetrations will be noted. Applications may be obtained and are filed with the appropriate FAA Service Area. For DoD facilities overseas, similar requirements by the host country, NATO, or ICAO may be applicable.

1-10 CONSTRUCTION PHASING PLAN.

A construction phasing plan, as discussed in Appendix B, Section 14, must be included in the contract documents. This is a mandatory requirement for USAF and Army installations whether work will be accomplished by contract or in-house (see Appendix B, Section 14). Also see the procedures for obtaining temporary waivers for construction in Appendix B, Section 1.

1-11 ZONING.

Existing facilities should be modified, and new facilities will be sited and constructed consistent with Service-specific AICUZ compatible land use standards and in a manner that will encourage local municipalities to adopt land use plans and zoning regulations to protect people, property and the installation's flying mission. Land uses compatible with flight operations are defined in DoD Instruction (DoDI) 4165.57 and Service-specific AICUZ directives.

1-12 REFERENCES.

Appendix A contains a list of documents referenced in this manual.

1-13 GLOSSARY.

Appendix C contains acronyms, abbreviations and terms.

1-14 USE OF TERMS.

These terms, when used in this manual, indicate the specific requirements listed here:

- Will or Must: Indicates a mandatory and/or required action.
- Should: Indicates a recommended, advisory, and/or desirable action.
- May or Can: Indicates a permissible action.

CHAPTER 2
AVIATION FACILITIES PLANNING

2-1 APPLICABILITY.

The criteria in this chapter apply to DoD aviation facilities planning, but may be supplemented by additional service-specific guidance. Navy aviation planning is covered in NAVFAC publication UFC 2-000-05N. Aviation facilities planning for the Air Force is discussed in AFIs 32-7062, 32-7063, 32-1024, and Air Force Manual (AFMAN) 32-1084. In some cases, Army, Air Force and Navy agencies reference documents have been noted.

2-1.1 Manual Usage.

Integration of aviation facilities planning with other DoD planning processes entails broad considerations. For example, the National Environmental Policy Act of 1969 (NEPA) has significantly affected aviation facilities planning by requiring that environmental impacts be considered early and throughout the planning process. In using this manual, planners should recognize that planning an aviation facility requires not only planning for runways, taxiways, aprons, and buildings, but also considering environmental factors, land use considerations, airspace constraints, and surrounding infrastructure.

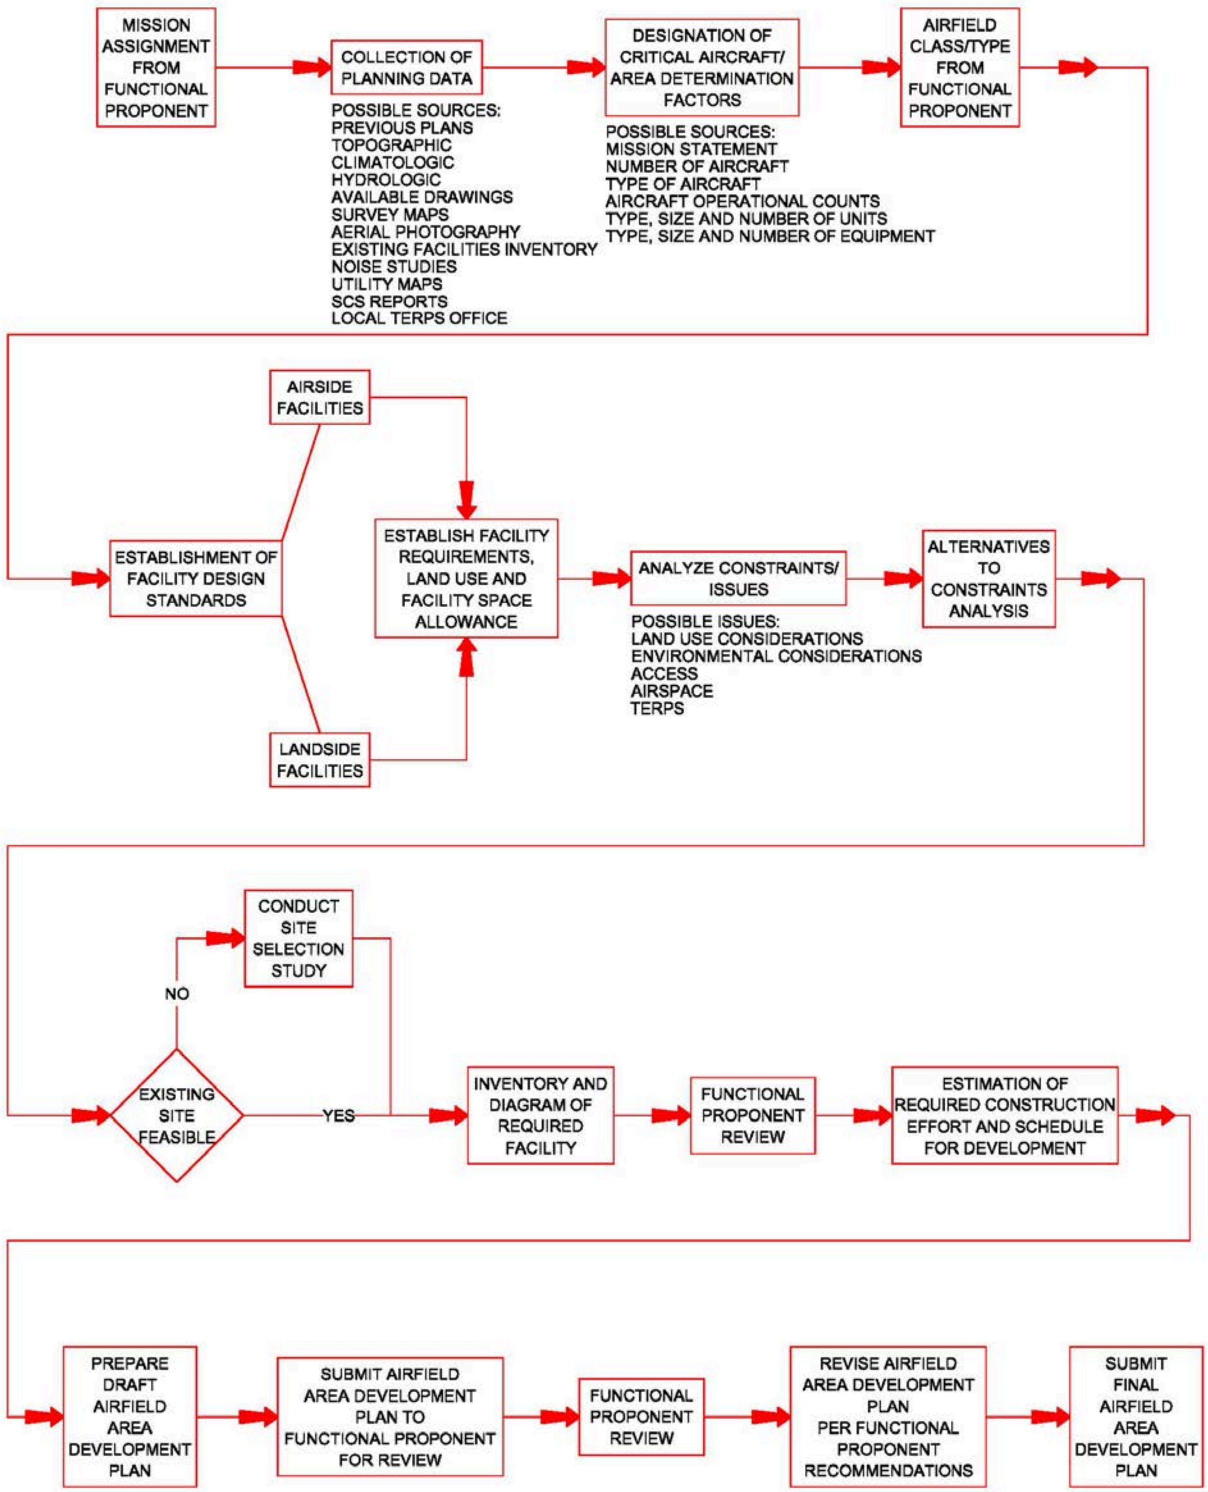
2-1.2 Planning Process.

Aviation facilities planning involves collecting data, forecasting demand, determining facility requirements, analyzing alternatives, and preparing plans and schedules for facility development. The aviation facilities planning process must consider the mission and use of the aviation facility and its effect on the general public. The planning process cannot be completed without knowing the facility's primary mission and assigned organization and types of aircraft. Figure 2-1 provides general steps in the aviation facilities planning process.

2-1.3 Planning Elements.

The elements of an aviation facility's planning process will vary in complexity and degree of application, depending on the size, location, function, and problems of the facility. The technical steps described in this manual should be undertaken only to the extent necessary to produce a well-planned aviation facility. Each DoD installation with an airfield should have an airfield Area Development Plan (ADP) to address airfield development, i.e., projects (such as pavement, lighting, grading, tree removal), waivers, and obstruction removal. The ADP is a part of the base comprehensive plan.

Figure 2-1. Aviation Facilities Planning Process



2-1.4 Guidance.

This chapter is structured and organized to provide guidance to planners intending to plan, design, or modify an aviation facility to comply with standardized criteria.

2-1.5 Additional Planning Factors.

As discussed in Chapter 1, additional planning factors such as pavement design, airfield marking, and TERPS must be considered when planning aviation facilities.

2-1.6 Space Allowances.

The primary source for determining authorized space allowances for Army aviation facilities is the Facility Planning System (FPS) contained in the Real Property Planning and Analysis System (RPLANS). Space allowances are presented in UFC 2-000-05N for Navy facilities and AFMAN 32-1084 for Air Force facilities.

2-2 JUSTIFICATION.

2-2.1.1 Aviation Facilities Planning.

Aviation facilities must be planned, programmed, and constructed in accordance with the Area Development Plan process. An ADP is developed and approved through an established planning process as discussed in paragraph 2-4. The master plan process requires assessing alternatives to determine the best alternative, or the best combination of alternatives, to overcome deficiencies at an aviation facility. Consideration must be given to construction alternatives (to construct new, modify, or upgrade a substandard facility) combined with operational alternatives (rescheduling and sharing facilities, changing training or mission) to determine the best plan for meeting facility requirements. As a minimum, each alternative considered must identify the changes to the mission, personnel, weapons systems and equipment, and any other impact to the facility. Construction of a new aviation facility is authorized when: (1) operational alternatives have been assessed and the conclusion is that the alternatives are not viable or executable options; or (2) existing facilities have been assessed as inadequate to meet the mission, and new airside and/or landside facilities are not feasible.

2-2.2 Existing Facility Assessment.

When the mission to be supported changes, a determination must be made if a facility built to a previous design standard meets or exceeds the current design standard and is no longer needed by the current mission, such as wider/longer runway/taxiway/apron or multiple runways (crosswind/parallel, etc.) than currently required. In these cases, the long term cost of keeping the excess pavement as is, must be documented and analyzed to determine if keeping the facility or bringing the facility into current required design standards is safer and/or cost effective in the long term.

2-2.2.1 Navy/Marine Corps

Approval from Headquarters Naval Facilities Engineering Command (NAVFACENGCOM) must be obtained before revising safety clearances at existing airfield pavements to conform to new standards herein. NAVFACENGCOM will coordinate the approval with the Naval Air Systems Command (NAVAIR) and Chief of Naval Operations (CNO)/Commandant Marine Corps (CMC), as required.

2-2.3 Joint Use Facilities.

Use of existing facilities on a civil airfield, or the airfield of another Service, should be considered when feasible.

2-3 GENERAL PLANNING CONSIDERATIONS.

2-3.1 Goals and Objectives.

The goals and objectives of planning an aviation facility, as set forth in this manual, are to ensure sustained, safe, economical, and efficient aircraft operations and aviation support activities. Planners must consider both the present and potential uses of the aviation facility during peacetime, mobilization, and emergency operations. Engineers/planners should assist operations personnel with the planning and programming, definition and scope, site selection, and design of the facility. See UFC 2-100-01, Installation Master Planning, for additional guidance.

2-3.2 Requirements.

Each functional proponent is responsible for providing the appropriate operational information to be used in the planning of an aviation facility. In addition, planning should be coordinated with all users (operations, air traffic control, and safety) of the aviation facility, including the FAA, to determine immediate and long-range uses of the aviation facility.

2-3.2.1 Operational Information.

Functional proponents will provide, at a minimum, the existing and projected operational information needed for planning aviation facilities:

- Mission statements
- Aircraft operational counts, traffic levels, and traffic density
- Type, size, and number of units/organizations and personnel
- Type, size, and number of equipment (e.g., aircraft, weapons systems, vehicles)
- Once these items are established, land requirements to support the aircraft mission can be established.

2-3.2.2 Engineering Information.

Engineering information provided will include, as a minimum: graphical maps and plans, facility condition assessments, and tabulation of existing facilities.

2-3.3 Safety.

The planning and design of an aviation facility will emphasize safety for aircraft operations. This includes unobstructed airspace and safe and efficient ground movements. Protect air space by promoting conscientious land use planning, such as compatible zoning and land easement acquisition.

2-3.3.1 Wildlife Hazards Mitigation.

Planning and design must comply with installation specific bird and animal strike hazard or other wildlife hazards mitigation plans and FAA/AC150/5200-33B to minimize aircraft wildlife strikes.

- For Navy and Marine Corps: Use the Installation specific Wildlife Hazards Mitigation Plan (WHMP) in accordance with CNICINST 3750.1.
- For Army: The requirements for a Wildlife Hazard Management Plan as spelled out in AR 95-2 shall be adhered to.
- For Air Force: Use AFI 91-212 Bird/Wildlife Aircraft Strike Hazard (BASH) Management Program. New proposed storm water features on airfields will be coordinated with and through the local Bird Hazard Working Group during the design stage.

2-3.4 Design Aircraft.

Typically, aviation facilities are designed for a specific aircraft known as the "critical" or "design" aircraft, which is the most operationally and/or physically demanding aircraft to make substantial use of the facility. The critical or design aircraft is used to establish the dimensional requirements for safety parameters such as approach protection zones; lateral clearance for runways, taxiways and parking positions; and obstacle clearance. In many cases, the "geometric" design aircraft (most demanding based on size or performance) may not be the same aircraft as the "pavement" design aircraft (most demanding for pavement load design).

2-3.5 Airspace and Land Area.

Aviation facilities need substantial air space and land area for safe and efficient operations and to accommodate future growth or changes in mission support.

2-3.5.1 Ownership of Clear Zones and Accident Potential Zones.

When planning a new aviation facility or expanding an existing one, clear zones should, to the maximum extent possible, be either owned or protected through restrictive use easements. Ownership/control of the APZ should follow guidance in DoDI 4165.57.

2-3.5.2 Land Use within the Clear Zone and Accident Potential Zones.

The AICUZ Program is the governing authority for land use in clear zones and accident potential zones (APZ). Requirements for land use in clear zones and APZs are provided in DoDI 4165.57 and Service-specific AICUZ directives. Additional restrictions for the graded area of the clear zone are provided in this manual.

2-3.5.3 Explosives.

Where explosives or hazardous materials are handled at or near aircraft, safety and separation clearances are required. The clearances are based on quantity-distance criteria as discussed in Appendix B, Section 9.

2-3.5.4 Landside Safety Clearances.

Horizontal and vertical operational safety clearances must be applied to landside facilities and will dictate the general arrangement and sizing of facilities and their relationship to airside facilities. Landside facilities will vary in accordance with the role of the mission. There are, however, general considerations that apply in most cases, such as:

- Adherence to standards in support of safety in aircraft operations
- Non-interference with line of sight or other operational restrictions
- Use of existing facilities
- Flexibility in being able to accommodate changes in aircraft types or missions
- Efficiency in ground access
- Priority accorded aeronautical activities where available land is limited

2-3.5.5 Helipads.

Helipads are authorized at locations where aircraft are not permanently assigned but have a need for access based on supporting a continuing and recurrent aviation mission. For example, hospitals, depot facilities, and headquarters buildings are authorized one or more helipads. These facilities must be included in the approved airfield master plan.

2-3.5.6 Facilities Used by Multiple Services.

At airfields used by multiple Services, the planning and design of facilities will be coordinated between the appropriate Services. The lead for coordination is the appropriate facilities/engineering echelon of the Service that owns the facilities.

2-3.5.7 Air Force Airfield Obstruction Mapping.

The requirements and specifications for mapping are contained in AFI 32-7062.

2-4 PLANNING STUDIES.

2-4.1 Master Plan.

Knowledge of existing facilities, mission, and aircraft, combined with a realistic assumption of future requirements, is essential to the development of master plans. Principles and guidelines for developing master plans at an aviation facility are contained in UFC 2-100-01, Installation Master Planning, and these publications:

- Army: AR 210-20, Real Property Master Planning for Army Installations
- Air Force: AFI 32-7062
- Navy/Marines: NAVFAC, Naval Shore Infrastructure, Installation Development Plan Consistency Guide

2-4.2 Land Use Studies.

Long-range land use planning is a primary strategy for protecting a facility from problems that arise from aviation-generated noise and incompatible land uses. Aircraft noise can adversely affect the quality of the human environment. Federal agencies are required to work with local, regional, state, and other Federal agencies to foster compatible land uses, both on and off the boundaries of the aviation facility. The Air Installations Compatible Use Zones (AICUZ) and Installation Compatible Use Zone (ICUZ) programs promote land use compatibility through active land use planning.

2-4.3 Environmental Studies.

Development of an aviation facility, including expansion of an existing aviation facility, requires compliance with a variety of laws, regulations, and policies. The National Environmental Policy Act (NEPA) requires all Federal agencies to consider the potential environmental impacts of certain proposed projects and activities, as directed by DoD Directive (DoDD) 6050.7. Implementation of these regulations is defined for each Service in these documents: Army: AR 200-1, Environmental Protection and Enhancement; Air Force: Title 32, Code of Federal Regulations, Part 989 (32 CFR 989); and Navy and Marine Corps: OPNAVINST 5090.1B (MCO 5090.2). Four broad categories of environmental review for a proposed action exist. The decision to conduct one study or another depends on the type of project and the potential consequences of project to various environmental categories. Criteria for determining which type of study should be undertaken are defined in the environmental directives and regulations for each Service. Environmental studies should be prepared and reviewed locally. When additional assistance or guidance is necessary, this support may be obtained through various agencies such as the USA Army Air Traffic Services Command (ATSCOM)the US Army Corps of Engineers Transportation Systems Center (USACE TSC), the US Army Corps of Engineers District Offices, NAVFAC Headquarters and Engineering Field Divisions, and the Air Force Civil Engineer Center (HQ AFCEC).

2-4.3.1 Environmental Assessment (EA).

The EA serves to analyze and document the extent of the environmental consequences of a proposed action. It evaluates issues such as existing and future noise, land use, water quality, air quality, and cultural and natural resources. The conclusion of the assessment will result in either a Finding of No Significant Impact (FONSI), or, if the consequences are significant and cannot be mitigated to insignificance, the decision to conduct an Environmental Impact Statement (EIS). This decision is typically made by the authority approving the study.

2-4.3.2 Environmental Impact Statement (EIS).

An EIS is the document that identifies the type and extent of environmental consequences created if the proposed project is undertaken. The primary purpose of the EIS is to ensure that NEPA policies and goals are incorporated into the actions of the Federal government. The EIS defines the impact and details what measures will be taken to minimize, offset, mitigate, or avoid any adverse effects on the existing environmental condition. Upon completion of an EIS, the decision maker will file a Record of Decision (ROD), which finalizes the environmental investigation and establishes consent to either abandon or complete the project within the scope of measures outlined in the EIS.

2-4.3.3 Categorical Exclusion (CATEX).

A CATEX is defined as a category of proposed action(s) that does not individually or cumulatively have the potential for significant effect on the environment and does not, therefore, require further environmental analysis in an EA or EIS. A list of actions that are categorically excluded is contained in the regulatory directives for each service.

2-4.3.4 Exemption By Law and Emergencies.

In specific situations, Congress may exempt the DoD from compliance with NEPA for particular actions. Emergency situations do not exempt the DoD from complying with NEPA but do allow emergency response while complying with NEPA.

2-4.4 Aircraft Noise Studies.

AICUZ and ICUZ are programs initiated to implement Federal laws concerning land compatibility from the perspective of environmental noise impacts. The ICUZ program is the Army's extension of the AICUZ program, which was initiated by the DoD and undertaken primarily by Air Force and Navy aviation facilities. Noise studies conducted under these programs describe the airfield noise environment and provide the installation with noise contour maps for use in managing noise and planning for compatible land use.

2-4.4.1 Analysis.

Due to the widely varied aircraft, aircraft power plants, airfield traffic volume, and airfield traffic patterns, aviation noise at installations depends on both aircraft types and operational procedures. Aircraft noise studies should be prepared for aviation facilities to quantify noise levels and possible adverse environmental effects, ensure that noise reduction procedures are investigated, and plan land for uses that are compatible with higher levels of noise. While many areas of an aviation facility tolerate higher noise levels, many aviation landside facilities and adjoining properties do not. Noise contours developed under the AICUZ and ICUZ studies are used to graphically illustrate noise levels and provide a basis for land use management and impact mitigation. The primary means of noise assessment is mathematical modeling and computer simulation. Guidance regarding when to conduct noise studies is contained in the environmental and AICUZ directive for each Service.

2-4.5 Instrumented Runway Studies.

The requirement to conduct an instrumented runway study is issued by the functional proponent. It is important to recognize that instrument landing capability provides for aircraft approaches at very low altitude ceilings or visibility distance minimums. Consequently, these lower approach minimums demand greater safety clearances, larger approach surfaces, and greater separation from potential obstacles or obstructions to air navigation.

2-5 SITING AVIATION FACILITIES.

NOTE: While the general siting principles below are applicable to Navy aviation facilities, see UFC 2-000-05N for Navy-specific data and contacts.

2-5.1 Location.

The general location of an aviation facility is governed by many factors, including base conversions, overall defense strategies, geographic advantages, mission realignment, security, and personnel recruitment. These large-scale considerations are beyond the scope of this manual. The information in this chapter provides guidelines for siting aviation facilities where the general location has been previously defined.

2-5.2 Site Selection.

2-5.2.1 Site Conditions.

Site conditions must be considered when selecting a site for an aviation facility. The site considerations include, but are not limited to: topography, vegetative cover, existing construction, weather elements, wind direction, soil conditions, flood hazard, natural and man-made obstructions, adjacent land use, availability of usable airspace, accessibility of roads and utilities, and future expansion capability.

2-5.2.2 Future Development.

Adequate land for future aviation growth must be considered when planning an aviation facility. An urgent requirement for immediate construction should not compromise the plan for future development merely because a usable, but not completely satisfactory, site is available. Hasty acceptance of an inferior site can preclude the orderly expansion and development of permanent facilities. Initial land acquisition (fee or lease) or an aviation easement of adequate area will prove to be the greatest asset in protecting the valuable airfield investment.

2-5.2.3 Sites not on DoD Property.

Site selection for a new airfield or heliport not located on a DoD- or Service-controlled property must follow FAA planning criteria and each Service's established planning processes and procedures for master planning as previously discussed in paragraph 2-4.1. Siting the aviation facility requires an investigation into the types of ground transportation that will be required, are presently available, or are capable of being implemented. All modes of access and transportation should be considered, including other airports/airfields, highways, railroads, local roadways, and internal roads. The facility's internal circulation plan should be examined to determine linear routes of movement by vehicles and pedestrians to ensure that an adequate access plan is achievable.

2-5.3 Airspace Approval.

See Chapter 1, Paragraph 1-9.

2-5.4 Airfield Safety Clearances.

2-5.4.1 Dimensional Criteria.

The dimensions for airfield facilities, airfield lateral safety clearances, and airspace imaginary surfaces are provided in this UFC.

2-5.4.2 Air Force Missions at Army Facilities.

Airfield safety clearances applicable to Army airfields that support Air Force cargo aircraft missions will be based on an Army Class B airfield. This will be coordinated between the Army and the Air Force.

2-5.4.3 Prohibited Land Uses.

AICUZ compatible land use standards prohibit certain land uses within the clear zone and APZs (APZ I and APZ II). These land uses include storage and handling of munitions and hazardous materials, and live-fire weapons ranges. See DoDI 4165.57 and Service-specific AICUZ directives for more information.

2-5.4.4 Wake Turbulence.

The problem of wake turbulence may be expected at airfields where there is a mix of light and heavy aircraft. At these airfields, some taxiway and holding apron design modifications may help to alleviate the hazards. Although research is underway to improve detection and elimination of the wake, at the present time the most effective means of avoiding turbulent conditions is provided by air traffic control personnel monitoring and regulating both air and ground movement of aircraft. Planners can assist this effort by providing controllers with line-of-site observation to all critical aircraft operational areas and making allowances for aircraft spacing and clearances in turbulence-prone areas. Additional information on this subject is available in FAA AC 90-23.

2-5.5 Storm Water Management Facilities.

Use UFC 3-201-01 for airfield drainage design and manage stormwater in ways that will not compromise airfield safety. Design stormwater elements to minimize the attraction of hazardous wildlife by reducing open standing water such as retention ponds and stormwater wetlands to the maximum extent practicable. Some techniques that may be used to achieve these goals include:

- Increasing the separation distance between stormwater elements and the runway
- Using underground detention
- Using detention ponds with a maximum 48-hour detention period

For Army: No new above ground detention or retention ponds shall be sited within 1500' of the runway centerline as extended through the ends of the clear zones without prior approval from USACE-TSC.

2-5.6 Renewable Energy Systems.

When siting renewable power generation facilities (e.g. photovoltaic cell arrays) in close proximity to airfields, issues like airspace coordination, glare and low-altitude testing and training route interference must be considered. See UFC 3-440-01, Facility-Scale Renewable Energy Systems and UFC 3-540-08, Utility-Scale Renewable Energy Systems for additional information and requirements. For Air Force, see AFI 32-7063 for additional guidance on hazards to aircraft flight zone.

2-6 AIRSIDE AND LANDSIDE FACILITIES.

An aviation facility consists of four land use areas, further described in paragraphs 2-7 through 2-10.

a. Airside Facilities – facilities associated with the movement and parking of aircraft.

- Landing and takeoff surfaces
- Aircraft ground movement and parking areas

b. Landside Facilities – facilities not associated with the movement and parking of aircraft but are required for the facilities' mission.

- Aircraft maintenance areas
- Aviation operations support areas

2-7 LANDING AND TAKEOFF SURFACES.

2-7.1 Runways and Helipads.

Takeoff and landing surfaces are based on either a runway or helipad. The landing/takeoff surface consists of not only the runway and helipad surface, shoulders, and overruns, but also the approach slope surfaces, safety clearances, and other imaginary airspace surfaces.

2-7.2 Number of Runways.

Aviation facilities normally have only one runway. Additional runways may be necessary to accommodate operational demands, minimize adverse wind conditions, or overcome environmental impacts. A parallel runway may be provided based on operational requirements. Methodologies for calculating runway capacity in terms of annual service volume (ASV) and hourly IFR or visual flight rules (VFR) capacity are provided in FAA AC 150/5060-5. Planning efforts to analyze the need for more than one runway should be initiated when it is determined that traffic demand for the primary runway will reach 60 percent of its established capacity (FAA guidance). For USAF facilities, also see AFMAN 32-1084, Facility Requirements, Facility Analysis Category (FAC) 1111, Runways.

2-7.3 Number of Helipads.

At times at airfields or heliports, a large number of helicopters are parked on mass aprons or are in the process of takeoff and landing. When this occurs, there is usually a requirement to provide landing and takeoff facilities that permit more rapid launch and recovery operations than can otherwise be provided by a single runway or helipad. This increased efficiency can be obtained by providing one or more of the following options, but is not necessarily limited to:

- Multiple helipads, hoverpoints, or runways
- Rotary-wing runways in excess of 490 m (1600 ft) long

- Landing lane(s)

2-7.4 Runway and Helipad Location.

Runway and helipad location and orientation are paramount to airport safety, efficiency, economics, practicality, and environmental impact. The degree of concern given to each factor influencing runway or helipad location depends greatly on meteorological conditions, adjacent land use and land availability, airspace availability, runway/helipad type/instrumentation, environmental factors, terrain features/topography, and obstructions to air navigation.

2-7.4.1 Obstructions to Air Navigation.

Runways and helipads must have approaches that are free and clear of obstructions. Runways and helipads must be planned so that the ultimate development of the airfield provides unobstructed navigation. A survey of obstructions will be undertaken to identify those objects that may affect aircraft operations. Protection of airspace can be accomplished through land purchase, easement, zoning coordination, and application of appropriate military directives.

2-7.4.2 Airspace Availability.

Existing and planned instrument approach and departure procedures, Class D Airspace, and special use airspace and traffic patterns influence airfield layouts and runway and helipad locations. Construction projects for new airfields and heliports or construction projects on existing airfields have the potential to affect airspace. These projects require notification to the FAA to examine feasibility for conformance with and acceptability into the national airspace system.

2-7.4.3 Runway and Helipad Orientation.

Wind direction and velocity is a major consideration for siting runways and helipads. To be functional, efficient, and safe, a runway or helipad should be oriented in alignment with the prevailing winds, to the greatest extent practical, to provide favorable wind coverage. Wind data, obtained from local sources, for a period of not less than five years, should be used as a basis for developing the wind rose to be shown on the airfield general site plan. Appendix B, Section 4, provides guidance for the research, assessment, and application of wind data.

2-7.5 Runway and Helipad Separation.

The lateral separation of a runway from a parallel runway, parallel taxiway, or helipad/hoverpoint is based on the type of aircraft the runway serves. Runway and helipad separation criteria are presented in Chapters 3 and 4 of this manual.

2-7.6 Runway Instrumentation.

Navigational Aids (NAVAIDS) require land areas of specific size, shape, and grade to function properly and remain clear of safety areas.

2-7.6.1 NAVAIDS, Vault, and Buildings.

NAVAIDS assist the pilot in flight and during landing. The type of air NAVAIDS that are installed at an aviation facility is based on the instrumented runway studies, as previously discussed in 2-4.5. A lighting equipment vault is provided for airfields and heliport facilities with NAVAIDS, and may be required at remote or stand-alone landing sites. A (NAVAID) building will be provided for airfields with NAVAIDS. Each type of NAVAID equipment is usually housed in a separate facility. Technical advice and guidance for air NAVAIDS should be obtained from service-specific support and siting agencies.

2-8 AIRCRAFT GROUND MOVEMENT AND PARKING AREAS.

Aircraft ground movement and parking areas consist of taxiways and aircraft parking aprons.

2-8.1 Taxiways.

Taxiways provide for free ground movement to and from the runways, helipads, and maintenance, cargo/passenger, and other areas of the aviation facility. The objective of taxiway system planning is to create a smooth traffic flow. This system allows unobstructed ground visibility; a minimum number of changes in aircraft taxiing speed; and, ideally, the shortest distance between the runways or helipads and apron areas.

2-8.1.1 Taxiway System.

The taxiway system is comprised of entrance and exit taxiways; bypass, crossover taxiways; apron taxiways and taxilanes; hangar access taxiways; and partial-parallel, full-parallel, and dual-parallel taxiways. The design and layout dimensions for various taxiways are provided in Chapter 5.

2-8.1.2 Taxiway Capacity.

At airfields with high levels of activity, the capacity of the taxiway system can become the limiting operational factor. Runway capacity and access efficiency can be enhanced or improved by the installation of parallel taxiways. A full-length parallel taxiway may be provided for a single runway, with appropriate connecting lateral taxiways to permit rapid entrance and exit of traffic between the apron and the runway. At facilities with low air traffic density, a partial parallel taxiway or mid-length exit taxiway may suit local requirements; however, develop plans so that a full parallel taxiway may be constructed in the future when such a taxiway can be justified.

2-8.1.3 Runway Exit Criteria.

The number, type, and location of exit taxiways is a function of the required runway capacity. Exit taxiways are typically provided at the ends and in the center and midpoint on the runway. Additional locations may be provided as necessary to allow landing aircraft to exit the runway quickly. Chapter 5 provides additional information on exit taxiways.

2-8.1.4 Dual-Use Facility Taxiways.

For taxiways at airfields supporting both fixed-wing and rotary-wing operations, the appropriate fixed-wing criteria will be applied.

2-8.1.5 Paved Taxiway Shoulders.

Paved taxiway shoulders are provided to reduce the effects of jet blast on areas adjacent to the taxiway. Paved taxiway shoulders help reduce ingestion of foreign object debris (FOD) into jet intakes. Paved shoulders will be provided on taxiways in accordance with the requirements in Chapter 5.

2-8.2 Aircraft Parking Aprons.

Aircraft parking aprons are the paved areas required for aircraft parking, loading, unloading, and servicing. They include the necessary maneuvering area for access and exit to parking positions. Aprons will be designed to permit safe and controlled movement of aircraft under their own power. Aircraft apron dimensions and size are based on mission requirements. Additional information concerning Air Force aprons is provided in AFMAN 32-1084, FAC 1131, Aprons. For Navy, see UFC 3-000-05N and paragraph 6-2 APRON REQUIREMENTS for additional guidance.

2-8.2.1 Requirement.

Aprons are individually designed to support specific aircraft and missions at specific facilities. The size of a parking apron depends on the type and number of aircraft authorized. Chapter 6 provides additional information on apron requirements.

2-8.2.2 Location.

Aircraft parking aprons typically are located between the parallel taxiway and the hangar line. Apron location with regard to airfield layout will adhere to the operations and safety clearances provided in Chapter 6 of this manual.

2-8.2.3 Capacity.

Aircraft parking capacity for the Army is discussed in the Facility Planning System (FPS) contained in the Real Property Planning and Analysis System (RPLANS)DAPAM 415-28; in UFC 2-000-05N for the Navy; and in AFMAN 32-1084 for the Air Force.

2-8.2.4 Clearances.

Lateral clearances for parking aprons are provided from all sides of aprons to fixed and/or mobile objects. Additional information on lateral clearances for aprons is discussed in Chapter 6.

2-8.2.5 Access Taxilanes, Entrances, and Exits.

The dimensions for access taxilanes on aircraft parking aprons are provided in Chapter 6. The minimum number of exit/entrance taxiways provided for any parking apron should be two.

2-8.2.6 Aircraft Parking Schemes.

On a typical mass parking apron, aircraft should be parked in rows. The recommended tactical/fighter aircraft parking arrangement is to park aircraft at a 45-degree angle. This is the most economical parking method for achieving the clearance needed to dissipate jet blast temperatures and velocities to levels that will not endanger aircraft or personnel. (For the Navy, these are 38 degrees Celsius (100 degrees Fahrenheit) and 56 km per hour (km/h) (35 miles per hour (mph)) at break-away (intermediate power)). Typical parking arrangements and associated clearances are provided in Chapter 6.

2-8.2.7 Departure Sequencing.

Aircraft egress patterns from aircraft parking positions to the apron exit taxiways should be considered to prevent congestion at the apron exits. For example, aircraft departing from one row of parking positions should taxi to one exit taxiway, allowing other rows to simultaneously taxi to a different exit.

2-8.2.8 Apron/Other Pavement Types.

Special use aprons may exist on an aviation facility. Chapter 6 provides further information on these aprons/pavements.

2-9 AIRCRAFT MAINTENANCE AREA (OTHER THAN PAVEMENTS).

An aircraft maintenance area is required when aircraft maintenance must be performed regularly at an aviation facility. Space requirements for maintenance facilities are based on aircraft type.

2-9.1 Aircraft Maintenance Facilities.

The aircraft maintenance facility includes but is not limited to: aircraft maintenance hangars, special purpose hangars, hangar access aprons, weapons system support shops, aircraft system testing and repair shops, aircraft parts storage, corrosion control facilities, and special purpose maintenance pads. The aircraft maintenance area includes utilities, roadways, fencing, and security facilities and lighting.

2-9.2 Aviation Maintenance Buildings and Hangars.

For aviation maintenance building information for the Army, see the Facility Planning System (FPS) contained in the Real Property Planning and Analysis System (RPLANS); for the Air Force, see AFMAN 32-1084; for the Navy see UFC 2-000-05N.

2-9.2.1 Maintenance Hangars.

Maintenance hangars are required to support those aircraft maintenance, repair, and inspection activities that can be more effectively accomplished while the aircraft is under complete cover. The size requirement for maintenance hangars is determined by the number of aircraft assigned. See UFC 4-211-01 for hangars.

2-9.2.2 Security and Storage Hangars.

These hangars are limited in use and do not require the features normally found in maintenance hangars.

2-9.2.3 Avionics Maintenance Shop.

Avionics maintenance space should normally be provided within the maintenance hangar; however, a separate building for consolidated avionics repair may be provided at aviation facilities with multiple units.

2-9.2.4 Engine Repair and Engine Test Facilities.

Engine repair and test facilities are provided at air bases with aircraft engine removal, repair, and testing requirements. Siting of engine test facilities will consider the impacts of jet blast, jet blast protection, and noise suppression.

2-9.2.5 Parts Storage.

Covered storage of aircraft parts should be provided at all aviation facilities and located close enough to the maintenance area to allow easy access to end users.

2-9.3 Maintenance Aprons.

These aprons should be sized according to the dimensions discussed in Chapter 6.

2-9.4 Apron Lighting.

Apron area lighting (floodlights) is provided where aircraft movement, loading or unloading, and security are required at night, and during poor visibility. The type of lighting is based on the amount of apron space or number of aircraft positions that receive active use during nighttime operations.

2-9.5 Security.

The hangar line typically represents the boundary of the airfield operations area. Maintenance buildings should be closely collocated to discourage unauthorized access and enhance facility security.

2-10 AVIATION OPERATIONS SUPPORT AREA.

2-10.1 Aviation Operations Support Facilities.

Aviation operations support facilities include those facilities that directly support the flying mission. Operations support includes air traffic control, aircraft rescue and firefighting, fueling facilities, the airfield operations center (airfield management facility), squadron operations/aircraft maintenance units, and air mobility operations groups.

2-10.2 Location.

Aviation operations support facilities should be located along the hangar line, with the central area typically being allocated to airfield operations (airfield management facility), air traffic control, aircraft rescue and firefighting, and flight simulation. Aircraft maintenance facilities should be located on one side of the runway to allow simplified access among maintenance areas, aircraft, and support areas.

2-10.3 Orientation of Facilities.

Facilities located either parallel or perpendicular to the runway make the most efficient use of space. Diagonal and curved areas tend to divide the area and result in awkward or unusable spaces.

2-10.4 Multiple Supporting Facilities.

When multiple aviation units are located at one facility, their integrity may be retained by locating such units adjacent to each other.

2-10.5 Transient Facilities.

Provisions should be made for transient and very important person (VIP) aprons and buildings. These facilities should be located near the supporting facilities discussed in paragraph 2-10.1.

2-10.6 Other Support Facilities.

When required, other support facilities, such as aviation fuel storage and dispensing, heating plants, water storage, consolidated parts storage, and motor pool facilities, should be sited on the far side of an access road paralleling the hangar line.

2-10.6.1 Air Traffic Control Facilities.

The siting and height of the Air Traffic Control Tower (ATCT) are determined in accordance with Appendix B, Section 16. For Army and Air Force, other air traffic control facilities will be sited in accordance with Appendix B, Section 13. For Navy, other air traffic control facilities will be sited in compliance with surfaces described in Chapters 3 and 4.

2-10.6.2 Radar Approach Control Facilities.

Some airfields are equipped with radar capability. When the functional proponent determines the need for radar capability, space for radar equipment will be provided. Space for radar equipment should be provided in the air traffic control tower building and/or RAPCON. See UFC 4-133-01, Air Traffic Control and Air Operations Facilities for facility design requirements.

2-10.6.3 Aircraft Rescue and Fire Facilities.

Airfield facilities and flight operations will be supported by fire and rescue equipment. The aircraft rescue and fire facilities must be located strategically to allow aircraft firefighting vehicles to meet response time requirements to all areas of the airfield. Coordinate the airfield fire and rescue facility and special rescue equipment with the facility protection mission and master plan. It may be economically sound to develop a consolidated or expanded facility to support both airside and landside facilities. The site of the fire and rescue station must permit ready access of equipment to the aircraft operational areas and the road system serving the airfield facilities. A site centrally located, close to the midpoint of the runway, and near the Airfield Operations Building (AOB) and the ATCT is preferred.

2-10.6.4 Rescue and Ambulance Helicopters.

With the increasing use of helicopters for emergency rescue and air ambulance service, consider providing an alert helicopter parking space near the fire and rescue station. This space may be located as part of the fire and rescue station or in a designated area on an adjacent aircraft parking apron.

2-10.6.5 Hospital Helipad.

A helipad should normally be sited in close proximity to each hospital to permit helicopter access for emergency use. Subject to necessary flight clearances and other hospital site factors, the hospital helipad should permit reasonably direct access to and from the hospital emergency entrance.

2-10.6.6 Miscellaneous Buildings.

These buildings should be provided as part of an aviation facility:

- Airfield operations building (airfield management facility)

- Aviation unit operations building (Army); squadron operations building (Air Force)
- Representative weather observation stations (RWOS)
- Authorization and space allowances should be determined in accordance with directives for each Service.

2-10.7 Aircraft Fuel Storage and Dispensing.

2-10.7.1 Location.

Aircraft fuel storage and dispensing facilities will be provided at all aviation facilities. Operating fuel storage tanks will be provided wherever dispensing facilities are remote from bulk storage. Bulk fuel storage areas require locations that are accessible by tanker truck, tanker rail car, or by waterfront. Both bulk storage and operating storage areas must provide for the loading and parking of fuel vehicles to service aircraft. Where hydrant fueling systems are authorized, bulk fuel storage locations must take into account systems design requirements (e.g., the distance from the fueling apron to the storage tanks).

2-10.7.2 Safety.

Fuel storage and operating areas have requirements for minimum clearances from buildings, aircraft parking, roadways, radar, and other structures/areas, as established in Service directives. Aviation fuel storage and operating areas also require lighting, fencing, and security alarms. All liquid fuel storage facility sitings must address spill containment and leak protection/detection.

2-10.8 Service Roadways to Support Airfield Activities.

2-10.8.1 General.

Uncontrolled vehicle roads will not be planned to violate airfield imaginary surfaces and safety clearance distances. Roads should be located so that surface vehicles will not be hazards to air navigation and air navigation equipment. All roads within the movement area will be controlled by the ATCT. See Appendix B, Section 13, Para B13-2.20.2.9.

2-10.8.2 Rescue and Firefighting Roadways.

Rescue and firefighting access roads are usually needed to provide unimpeded two-way access for rescue and firefighting equipment to potential accident areas. Connecting these access roads to the extent practical with airfield operational surfaces and other airfield roads will enhance fire and rescue operations. Dedicated rescue and firefighting access roads are all-weather roads designed to support vehicles traveling at normal response speeds.

2-10.8.3 Fuel Truck Access.

Fuel truck access points to aircraft parking aprons should be located to provide minimal disruptions and hazards to active aircraft operating areas. Fuel truck access from the facility boundary to the fuel storage areas should be separate from other vehicular traffic. Fuel trucks should be parked as close to the flight line as is reasonably possible.

2-10.8.4 Explosives and Munitions Transfer to Arm/Disarm Pads.

Transfer of explosives and munitions from storage areas to arm/disarm pads should occur on dedicated transfer roads. Transfer roads should be used exclusively for explosives and munitions transfer vehicles.

2-11 NAVY/MARINE CORPS EXCEPTIONS FROM CRITERIA NOT REQUIRING NAVFAC DESIGN WAIVERS/EXEMPTIONS FROM UFC 3-260-01 OR NAVAIR AIRFIELD SAFETY WAIVERS.

Siting and design for airfield facilities and equipment must conform to appropriate design and siting criteria, and must be necessary for support of assigned mission aircraft, or multiple waivers (design and safety) may be required. (See Appendix B, Section 1, Para B1-3 for waiver types and procedures.) If the equipment renders satisfactory service at locations that do not penetrate airfield safety surfaces, such locations should be selected to enhance the overall efficiency and safety of airfield operations. This section lists certain airfield facilities that are considered exceptions to certain criteria (such as violating safety surfaces) only if they are sited in those zones in accordance with guidance in this UFC. This is due to their nature of inherently needing to be locating within certain zones for functional reasons that may create a criteria conflict. Even so, siting guidance in this UFC for these facilities must be satisfied or a design or safety waiver is still required. All structures placed or constructed within the airfield environment must be made frangible (to the maximum extent practicable) or placed below grade. Consult NAVAIR for Airfield Safety Waiver requirements for airfield facilities and equipment that are not specifically listed in this section. THE FOLLOWING FACILITIES DO NOT REQUIRE AN AIRFIELD SAFETY WAIVER or NAVFAC DESIGN WAIVER IF SITED IN ACCORDANCE WITH THIS UFC WHERE GUIDANCE IS PROVIDED:

2-11.1 Visual Air Navigational Facilities.

This term identifies, as a type of facility, all lights, signs and other devices located on, and in the vicinity of, an airfield that provide a visual reference to pilots for guidance when operating aircraft in the air and on the ground. Examples of visual air navigation facilities are Precision Approach Path Indicator (PAPI), Visual Slope Indicator (VASI), Optical Lighting Systems (OLS), runway distance remaining (RDR) signs, taxiway guidance and orientation signs, beacons, approach lighting, wind direction indicators, obstruction lights, and electric transformers in support of airfield lighting. For detailed construction and siting criteria, see UFC 3-535-01.

2-11.2 Radar/Communications Facilities.

When properly sited by Space and Naval Warfare Systems Center (SPAWARS) the exempted systems include Fixed Base Airport Surveillance Radar (ASR), Fixed Base Digital Airport Surveillance Radar (DASR), Tactical Air Navigation System (TACAN), Precision Approach Radar (PAR), Instrument Landing System (ILS), radar reflectors, and VHF/UHF radio facility (transmitter receiver site may include shelter), expeditionary equipment (TACAN, ASR, PAR) temporarily located for an event.

2-11.3 Other Facilities and Equipment.

Other facilities that are excepted from waiver requirements include Arm-Dearm Pads, Automated Surface Observing System (ASOS), Portable Landing Signal Officer (LSO), and Runway Duty Officer (RDO) facilities positioned on the primary surface during an event and permanent LSO facilities positioned adjacent to dedicated simulated Landing, Helicopter, Assault (LHA)/Landing, Helicopter, Deck (LHD) facility, Concrete bollards positioned to protect fire hydrants and extinguishers if located on the aircraft parking apron and next to the hangar. Airfield service roads located for access to NAVAIDs, aircraft arresting systems, weather sensors, and other similar areas on the airfield. Signage and traffic signals associated with the airfield service roads.

2-12 AIRFIELD UTILITY STRUCTURES.

All buried utility structures (manholes, handholes, drainage structures, etc.) constructed within runways, taxiways, towways, helipads, aprons, overruns or shoulders (paved or unpaved) will, at a minimum, be designed as provided in the following paragraphs. Regardless of location on the airfield, the top surface of foundations, manhole covers, handhole covers, and frames will be flush with the grade. Maintenance action is required if the drop-off at any edge of the structure exceeds 76 mm (3 in).

2-12.1 Load Bearing Pavements and Paved Shoulder Areas.

- For manhole covers and inlet grates and frames, design for a 45,000 kg (100,000 lb) wheel load with 1.72 MPa (250 psi) tire pressure. Higher tire pressures should be assumed if the using aircraft will have tire pressure greater than 1.72 MPa (250 psi).
- For structures with their shortest span equal to or less than 0.6 m (2 ft), design based on a single wheel load of 45,000 kg (100,000 lb) at a contact pressure of 1.72 MPa (250 psi), or a uniform live load over the entire structure of 1.72 MPa (250 psi), whichever is greater.
- For structures with their shortest span greater than 0.6 m (2 ft), design based on the maximum number of wheels that can fit onto the span, considering the most critical assigned aircraft operating at its maximum gross weight. In no case, however, should the design be based on computed stress conditions less than those created by a wheel load of 45,000 kg (100,000 lb) at a contact pressure of 1.72 MPa (250 psi).

2-12.2 Unpaved Shoulder Areas.

- For manhole covers and inlet grates and frames, design for a 45,000 kg (100,000 lb) wheel load with 1.72 MPa (250 psi) tire pressure. Higher tire pressures should be assumed if the using aircraft will have tire pressure greater than 1.72 MPa (250 psi).
- For structures with their shortest span equal to or less than 0.6 m (2 ft), design based on a single wheel load of 22,667 kg (50,000 lb) at a contact pressure of 1.72 MPa (250 psi), or a uniform live load over the entire structure of 1.72 MPa (250 psi), whichever is greater.
- For structures with their shortest span greater than 0.6 m (2 ft), design based on the maximum number of wheels that can fit onto the span, considering the most critical assigned aircraft operating at its maximum gross weight. In no case, however, should the design be based on computed stress conditions less than those created by a wheel load of 22,667 kg (50,000 lb) at a contact pressure of 1.72 MPa (250 psi).

2-12.3 Other Airfield Areas.

- Beyond the paved or unpaved shoulder areas of runways, taxiways, towways, helipads, aprons or overruns, underground structures are not designed to support aircraft wheel loads; however, they will be designed to support standard truck loads (AASHTO H20/HS20).

This Page Intentionally Blank

CHAPTER 3
RUNWAYS (FIXED-WING) AND IMAGINARY SURFACES

3-1 CONTENTS.

This chapter presents design standards and considerations for fixed-wing runways and associated imaginary surfaces.

3-2 REQUIREMENTS.

The landing and takeoff design considerations for an airfield include mission requirements, expected type and volume of air traffic, traffic patterns such as the arrangement of multidirectional approaches and takeoffs, ultimate runway length, runway orientation required by local wind conditions, local terrain, restrictions due to airspace obstacles or the surrounding community, noise impact, and aircraft accident potential. When planning to construct a new runway or to lengthen an existing runway, in addition to local permitting requirements, file FAA Form 7480-1 in accordance with FAA Order 7400.2.

3-3 RUNWAY CLASSIFICATION.

Runways are classified as either Class A or Class B based on aircraft type as shown in Table 3-1. This table uses the same runway classification system established by the Office of the Secretary of Defense as a means of defining accident potential areas (zones) for the AICUZ program. These runway classes are not to be confused with aircraft approach categories and aircraft wingspan in other DoD or FAA documents, aircraft weight classifications, or pavement traffic areas. The aircraft listed in Table 3-1 are examples of aircraft that fall into these classifications and may not be all-inclusive.

3-3.1 Class A Runways.

Class A runways are primarily intended for small, light aircraft. These runways do not have the potential or foreseeable requirement for development for use by high-performance and large, heavy aircraft. Ordinarily, these runways are less than 2,440 m (8,000 ft) long and less than 10% of their operations involve aircraft in the Class B category; however, this is not intended to limit the number of C-130 and C-17 operations conducted on any Class A airfield.

3-3.2 Class B Runways.

Class B runways are primarily intended for high-performance and large, heavy aircraft, as shown in Table 3-1. For airfield safety clearances applicable to USAF missions on US Army airfields, see paragraph 2-5.4.2.

3-3.3 Special Tilt-Rotor Aircraft Considerations (V-22).

The V-22 is a tilt-rotor aircraft that can operate both as a fixed-wing aircraft or a rotary-wing aircraft. When the V-22 operates on a fixed-wing airfield, this chapter applies with noted V-22 exceptions. See paragraph 1.2.2.4 for general V-22 planning considerations.

Table 3-1. Runway Classification by Aircraft Type

Runway Classification by Aircraft Type				
Class A Runways		**Class B Runways**		
C-1 C-2 C-12 C-20 C-21 C-22 C-23 C-26 C-37 C-38 E-1 E-2 MQ-1	OV-10 T-3 T-6 (Navy) T-28 T-34 T-41 T-44 U-21 UC-35 UV-18 V-22 DASH-7 DASH-8	A-4 A-6 EA-6B A-10 AV-8 B-1 B-2 B-52 C-5 C-9 KC-10 KC-135 KC-46 C-17 C-27J C-32 C-40 C-130 C-135 C-137	E-3 E-4 E-6 E-8 EA-18 R/F-4 F-5 F-15 F-16 E/F/A-18 F-22 F-35	P-3 P-8 RQ-4 RQ-9 MQ-4 S-3 T-1 T-2 T-6 (Air Force) T-38 T-43 T-45 TR-1 U-2 VC-25

NOTES:

1. Only symbols for basic mission aircraft or basic mission aircraft plus type are used. Designations represent entire series. Runway classes in this table are not related to aircraft approach categories, aircraft weight, aircraft wingspan, or to pavement design classes or types.
2. These are examples of aircraft that fall into these classifications, and may not be all-inclusive.
3. Rotary aircraft are not addressed in this table.
4. For F-35B aircraft operating as STOVL, see Chapter 8.
5. For US Army rotary-wing aircraft, see Chapter 4.

3-3.4 Landing Zones (formerly called Short Fields and Training Assault Landing Zones).

Landing zones are special use fields. Design criteria for these airfields are provided in Chapter 7 of this manual.

3-4 RUNWAY SYSTEMS.

3-4.1 Single Runway.

A single runway is the least flexible and lowest capacity system. The capacity of a single runway system will vary from approximately 40 to 50 operations per hour under IFR conditions and up to 75 operations per hour under VFR conditions.

3-4.2 Parallel Runways.

Parallel runways are the most commonly used system for increased capacity. In some cases, parallel runways may be staggered, with the runway ends offset from each other and with terminal or service facilities located between the runways. When parallel runways are separated by less than the IFR separation distance shown in Item 15 of Table 3-2, the second runway will increase capacity at the airfield under VFR conditions, but due to the close distance, capacity at the airfield will not be increased under IFR conditions.

3-4.3 Crosswind Runways.

Crosswind runways may be either the open-V or the intersecting type of runway. The crosswind system is adaptable to a wider variety of wind conditions than the parallel system. When winds are calm, both runways may be used simultaneously. An open-V system has a greater capacity than an intersecting system.

Table 3-2. Runways

Table 3-2. Runways				
Item		Class A Runway	Class B Runway	
No.	Description	Requirement		Remarks
1	Length	See Table 3-3	See Remarks	For Army airfields. For Army Class B runways, runway length will be determined by the ACOMs/ASCCs/DRUs/or ARNG in conjunction with HQDA, G4 by identifying the most critical aircraft in support of USTRANSCOM global transportation requirements.
		See Remarks	See Remarks	For Air Force airfields, runway length will be determined by the MAJCOM/A3 for the most critical aircraft to be supported
		See Remarks	See Remarks	For Navy and Marine Corps airfields, see UFC 2-000-05N for computation of runway lengths.
2	Width	30 m (100 ft)	46 m (150 ft)	Army airfields and Air Force airfields, not otherwise specified.
		N/A	90 m (300 ft)	B-52 aircraft. AFI 11-202 V3 allows that B-52 aircraft may routinely operate on 60 m (200 ft) wide runways.
		23 m (75 ft)	60 m (200 ft)	Navy and Marine Corps airfields. Runway width for T-34 and T-44 will be 45 m (150 ft).
3		15 m (50 ft)	60 m (200 ft)	Army and Air Force airfields

Table 3-2. Runways				
Item		Class A Runway	Class B Runway	
No.	Description	Requirement		Remarks
	Total width of shoulder (paved and unpaved)	7.5 m (25 ft)	46 m (150 ft)	Navy and Marine Corps airfields
4	Paved shoulder width	7.5 m (25 ft)	7.5 m (25 ft)	Army and Air Force Manned Aircraft with exception for Trainer, Fighter and B-52 aircraft indicated below. For Air Force, pave shoulders to provide a combined hard surface width (runway and paved shoulders) of not less than 60 m (200 feet) with at least 0.6 m (2 ft) of paved surface beyond the edge lights.
		N/A	3 m (10 ft)	Air Force airfields designed for Trainer, Fighter and B-52 aircraft. (Pave shoulders to provide a combined hard surface width (runway and paved shoulders) of 52 m (170 feet) for fighters and trainers and 98 m (320 feet) for B-52 mission runways, with at least 0.6 m (2 ft) of paved surface beyond the edge lights.
		3 m (10 ft)	3 m (10 ft)	Navy and Marine Corps airfields
5	Longitudinal grades of runway and shoulders	Maximum 1.0%		Grades may be both positive and negative but must not exceed the limit specified. Grade restrictions are exclusive of other pavements and shoulders. Where other pavements tie into runways, comply with grading requirements for towways, taxiways, or aprons as applicable, but hold grade changes to the minimum practicable to facilitate drainage. Exception for shoulders (paved and unpaved): a 3.33% maximum is permitted where arresting systems and visual glide slope indicators (VGSIs) are installed relative to the longitudinal slope of the runway and shoulders. Grade deviations must be held to a minimum for VGSI installations but may be used when necessary to limit the overall height of the light housings above grade.
6	Longitudinal runway grade changes	No grade change is to occur less than 300 m (1,000 ft) from	No grade change is to occur less than 900 m (3,000 ft) from	Where economically feasible, the runway will have a constant centerline gradient from end to end. Where terrain dictates the need for centerline grade changes, the distance between two successive point of

Table 3-2. Runways				
Item		Class A Runway	Class B Runway	
No.	Description	Requirement		Remarks
		the runway end	the runway end	intersection (PI) will be not less than 300 m (1,000 ft) and two successive distances between PIs will not be the same.
7	Rate of longitudinal runway grade changes	Max 0.167% per 30 linear meters (100 linear feet) of runway		Army and Air Force Maximum rate of longitudinal grade change is produced by vertical curves having 180-m (600-ft) lengths for each % of algebraic difference between the two grades.
		Max 0.10% per 30 linear meters (100 linear feet) of runway		Navy and Marine Corps Maximum rate of longitudinal grade change is produced by vertical curves having 300-m (1,000-ft) lengths for each% of algebraic difference between the two grades.
		See Remarks		Exceptions: 0.4% per 30 linear meters (100 ft) for edge of runways at runway intersections
8	Longitudinal sight distance	Min 1,500 m (5,000 ft)		Any two points 2.4 m (8 ft) above the pavement must be mutually visible (visible by each other) for the distance indicated. For runways shorter than 1,500 m (5,000 ft), height above runway will be reduced proportionally.
9	Transverse grade of runway	Min 1.0% Max 1.5%		New runway pavements will be centerline crowned. Existing runway pavements with insufficient transverse gradients for rapid drainage should provide increasing gradients when overlaid or reconstructed.
				Slope pavement downwards from centerline of runway. 1.5% slope is optimum transverse grade of runway. Selected transverse grade is to remain constant for length and width of runway, except at or adjacent to runway intersections where pavement surfaces must be warped to match abutting pavements. For Navy and Marine Corps, this exception also applies to aircraft arresting system cables where the transverse slope may be reduced to 0.75% in the center section to allow achieving the

Table 3-2. Runways				
Item		Class A Runway	Class B Runway	
No.	Description	Requirement		Remarks
				proper pendant height above the runway crown. See paragraph 3-17.2.2 for modifications to transverse grade in the area of the aircraft arresting system pendant.
10	Transverse grade of paved shoulder	2% min 3% max		Paved portion of shoulder. Slope downward from runway pavement. Reversals are not allowed. Exception allowed in the tape sweep area for USAF aircraft arresting systems. At runway edge sheaves, paved shoulder slope should match runway cross slope on centerline crowned runways. Designers will warp the adjacent tape sweep area pavement surfaces to direct drainage away from the aircraft arresting system components as much as possible. Pavement within the tape sweep area of arresting systems will meet the design and grade criteria in USAF Typical Installation Drawing 67F2013A.
11	Transverse grade of unpaved shoulder	(a) 40-mm (1.5-in) drop-off at edge of paved shoulder, +/- 13 mm (0.5 in) (b) 2% min, 4% max.		Unpaved portion of shoulder Slope downward from shoulder pavement. For additional information, see Figure 3-1. Reversals not allowed.
12	Runway lateral clearance zone	152.40 m (500 ft)	152.40 m (500 ft)	Army airfields
		152.40 m (500 ft)	304.80 m (1,000 ft)	Air Force, Navy, and Marine Corps
		152.4 m (500 ft)	228.6 m (750 ft)	Navy airfields constructed prior to 1981.
		(1) The runway lateral clearance zone's lateral limits coincide with the limits of the primary surface. The ends of the lateral clearance zone coincide with the runway ends. The ground surface within this area must be clear of fixed or mobile objects as defined in the glossary, and graded to the requirements of Table 3-2, items 13 and 14. The zone distance is measured perpendicularly each direction from the centerline of the runway and begins at the runway centerline. See Table 3-7 for other height restrictions and controls. (2) Fixed obstacles are those defined in the glossary. Navigational aids and meteorological equipment may be sited within these clearances where essential for their proper functioning. For Army and Air Force, this area to be clear of all obstacles except for properly sited permissible deviations		

Table 3-2. Runways				
Item		Class A Runway	Class B Runway	
No.	Description	Requirement		Remarks
		noted in Appendix B, Section 13. For Navy and Marine Corps, certain items that are listed in Appendix B, Section 1, Paragraph B1-3.4 are exempted. (3) Mobile obstacles are those defined in the glossary. Taxiing aircraft, emergency vehicles, and authorized maintenance vehicles are exempt from this restriction. (4) For Army and Air Force airfields, parallel taxiway (exclusive of shoulder width) will be located in excess of the lateral clearance distances (primary surface). For Navy and Marine Corps airfields, the centerline of a runway and a parallel taxiway will be a minimum of 152.4 m (500 ft) apart. For Class A Airfields, one half of the parallel taxiway may be located within the runway lateral clearance zone. (5) For Class A runways, except at Navy and Marine Corps airfields, above ground drainage structures, including headwall, are not permitted within 91.26 m (300 ft) of the runway centerline. For Class B runways, except at Navy and Marine Corps airfields, above ground drainage structures, including headwalls are not permitted within 114.3 m (375 ft) of the runway centerline. At Navy and Marine Corps airfields, above ground drainage structures will be individually reviewed. Drainage slopes of up to a 10 to 1 ratio are permitted for all runway classes, but swales with more gentle slopes are preferred. (6) Distance from runway centerline to helipads is discussed in Table 4-1. (7) For Military installations overseas (other than bases located in the United States, its territories, trusts, and possessions), apply to the maximum practical extent.		
13	Longitudinal grades within runway lateral clearance zone	Max 10.0%		Exclusive of pavement, shoulders, and cover over drainage structures. Slopes are to be as gradual as practicable. Avoid abrupt changes or sudden reversals. Rough grade to the extent necessary to minimize damage to aircraft.
14	Transverse grades within runway lateral clearance zone (in direction of surface drainage)	Min of 2.0% to Max 10.0%[4] Grades may be upwards or downwards		Exclusive of pavement, shoulders, and cover over drainage structures. Slopes are to be as gradual as practicable. Avoid abrupt changes or sudden reversals. Rough grade to the extent necessary to minimize damage to aircraft.
15	Distance between centerlines of parallel runways	213.36 m (700 ft)	304.80 m (1,000 ft)	VFR without intervening parallel taxiway between the parallel runways. One of the parallel runways must be a VFR only runway.
		632.46 m (2,075 ft)		VFR with intervening parallel taxiway.

Table 3-2. Runways				
Item		Class A Runway	Class B Runway	Remarks
No.	Description	Requirement		
		762.00 m (2,500 ft)		IFR using simultaneous operation (depart-depart) (depart-arrival)
		1,310.64 m (4,300 ft)		IFR using simultaneous approaches
				For separation distance between fixed-wing runways and rotary-wing facilities, see Table 4-1.
16	Width of USAF and Army mandatory frangibility zone (MFZ)	152.4 m (500 ft)		Centered on the runway centerline. All items sited within this area must be frangible (see Appendix B, Section 13).
17	Length of USAF and Army MFZ	Runway length plus 914.4 m (3,000 ft) at each end		Centered on the runway. All items sited within this area to the ends of the graded area of the clear zone must be frangible (also see Table 3-5 and Appendix B, Section 13). Items located beyond the graded area of the clear zone must be constructed to be frangible, low impact resistant structures, or semi-frangible (see Appendix B, Section 13).

NOTES:

1. Geometric design criteria in this manual are based on aircraft-specific requirements and are not direct conversions from inch-pound (English) dimensions.
2. Airfield and heliport imaginary surfaces and safe wingtip clearance dimensions are direct conversions from inch-pound to SI units.
3. English dimensions apply to new airfield construction at US facilities. Metric units apply to airfield construction where necessary for host nation construction practices. .
4. Bed of channel may be flat. When drainage channels are required, the channel bottom cross section may be flat but the channel must be sloped to drain

3-5 RUNWAY ORIENTATION/WIND DATA.

Runway orientation is the key to a safe, efficient, and usable aviation facility. Orientation is based on an analysis of wind data, terrain, local development, operational procedures, and other pertinent data. Procedures for analysis of wind data to determine runway orientation are discussed further in Appendix B, Section 4.

3-6 ADDITIONAL CONSIDERATIONS FOR RUNWAY ORIENTATION.

In addition to meteorological and wind conditions, the factors in paragraphs 3-6.1 through 3-6.7 must be considered.

3-6.1 Obstructions.

A specific airfield site and the proposed runway orientation must be known before a detailed survey can be made of obstructions that affect aircraft operations. Runways should be so oriented that approaches necessary for the ultimate development of the airfield are free of all obstructions.

3-6.2 Restricted Airspace.

Airspace through which aircraft operations are restricted, and possibly prohibited, is shown on sectional and local aeronautical charts. Runways should be so oriented that their approach and departure patterns do not encroach on restricted areas.

3-6.3 Built-Up Areas.

Airfield sites and runway alignment will be selected and operational procedures adopted that will least impact local inhabitants. Additional guidance for facilities is found in DoDI 4165.57.

3-6.4 Neighboring Airports.

Existing aircraft traffic patterns of airfields in the area may affect runway alignment.

3-6.5 Topography.

Avoid sites that require excessive cuts and fills. Evaluate the effects of topographical features on airspace zones, grading, drainage, and possible future runway extensions.

3-6.6 Soil Conditions.

Evaluate soil conditions at potential sites to minimize settlement problems, heaving from highly expansive soils, high groundwater problems, and construction costs Evaluate the project area for wetlands and potential historical/archeological sites. Analyze the soil for contaminants and plan for remediation or protection, as necessary.

3-6.7 Noise Analysis.

Noise analyses will be conducted to determine noise impacts to on-base and local communities and to identify noise-sensitive areas.

3-7 RUNWAY DESIGNATION.

Runways are identified by the whole number nearest one-tenth (1/10) the magnetic azimuth of the runway centerline. The magnetic azimuth of the runway centerline is measured clockwise from magnetic north when viewed from the direction of approach. For example, where the magnetic azimuth is 183 degrees, the runway designation marking would be 18; and for a magnetic azimuth of 117 degrees, the runway designation marking would be 12. For a magnetic azimuth ending in the number 5, such as 185 degrees, the runway designation marking can be either 18 or 19. Supplemental letters, where required for differentiation of parallel runways, are placed between the designation numbers and the threshold or threshold marking. For parallel runways, the supplemental letter is based on the runway location, left to right, when viewed from the direction of approach: for two parallel runways—"L," "R"; for three parallel runways—"L," "C," "R." A zero (0) is marked to precede single-digit numbers on Class B runways except those subject to NAVAIR 51-50AAA-2.

3-8 RUNWAY DIMENSIONS.

The paragraphs, tables, and figures in this section present the design criteria for runway dimensions at all aviation facilities except landing zones. The criteria presented in the figures are for all DoD components (Army, Air Force, Navy, and Marine Corps), except where deviations are noted.

3-8.1 Runway Dimension Criteria, Except Runway Length.

Table 3-2 presents all dimensional criteria, except runway length, for the layout and design of runways used primarily to support fixed-wing aircraft operations.

3-8.2 Runway Length Criteria.

3-8.2.1 Army.

For Army Class A runways, the runway length will be determined in accordance with Table 3-3. Army Class B runways are used to support USTRANSCOM global transportation requirements; therefore, runway length will be determined by the ACOMs/ASCCs/DRUs/or ARNG in conjunction with HQDA, G4 by identifying the most critical aircraft in support of USTRANSCOM requirements.

3-8.2.2 Air Force.

For Air Force Class A and Class B runways, the length will be determined by the MAJCOM.

3-8.2.3 Navy and Marine Corps.

Runway length computation for Navy and Marine Corps Class A and Class B runways is presented in UFC 2-000-05N.

3-8.3 Layout.

Typical sections and profiles for Army, Air Force, Navy, and Marine Corps airfield runways and the associated airspace surfaces are shown in Figures 3-1 through 3-22.

Table 3-3. Army Class A Runway Lengths

Temperature	Elevation				
	Sea Level	**304 meters (1,000 feet)**	**610 meters (2,000 feet)**	**1,524 meters (5,000 feet)**	**1,828 meters (6,000 feet)**
15ºC (60ºF)	1,615 m (5,300 ft)	1,676 m (5,500 ft)	1,768 m (5,800 ft)	2,042 m (6,700 ft)	2,164 m (7,100 ft)
30ºC (85ºF)	1,707 m (5,600 ft)	1,798 m (5,900 ft)	1,890 m (6,200 ft)	2,286 m (7,500 ft)	2,438 m (8,000 ft)
40ºC (105ºF)	1,798 m (5,900 ft)	1,890 m (6,200 ft)	2,042 m (6,700 ft)	2,469 m (8,100 ft)	2,682 m (8,800 ft)

NOTES:
1. Based on zero runway gradient and a clean, dry runway surface for the most critical aircraft in the Army's inventory to date (RC-12N).

3-9 RUNWAY END SITING REQUIREMENTS.

This paragraph provides guidance on the preliminary design for the establishment of runway thresholds and departure ends. Final design must be based on a detailed analysis and coordination with each service Flight Standards Agency and verified with Terminal Instrument Procedures (TERPS).

3-9.1 Runway Ends.

The runway ends are the physical ends of the rectangular surface that constitutes a runway. The end of the runway is normally the beginning of the takeoff roll and the end of the landing roll out.

3-9.2 Threshold.

The threshold is ideally located at the beginning of the runway. The threshold is located to provide proper clearance for landing aircraft over existing obstacles while on approach to landing. When an object is beyond the DoD's ability to remove, relocate, or reduce the height and the object obstructs the airspace required for aircraft to land at the beginning of the runway for takeoff, the threshold may be located farther down the runway. Such a threshold is called a "displaced threshold."

3-9.2.1 Displaced Threshold.

A displaced threshold may be designated on certain runways in order to avoid obstacles in the imaginary or TERPS surfaces. When it is determined that a runway requires a displaced threshold, the responsible airfield authority will evaluate each individual situation and set the displaced threshold and airspace imaginary surfaces.

3-9.2.2 Impacts to Runway Length.

Displacement of a threshold reduces the length of runway available for landings. The portion of the runway behind a displaced threshold may be available for takeoffs and, depending on the reason for displacement, may be available for takeoffs and landings from the opposite direction.

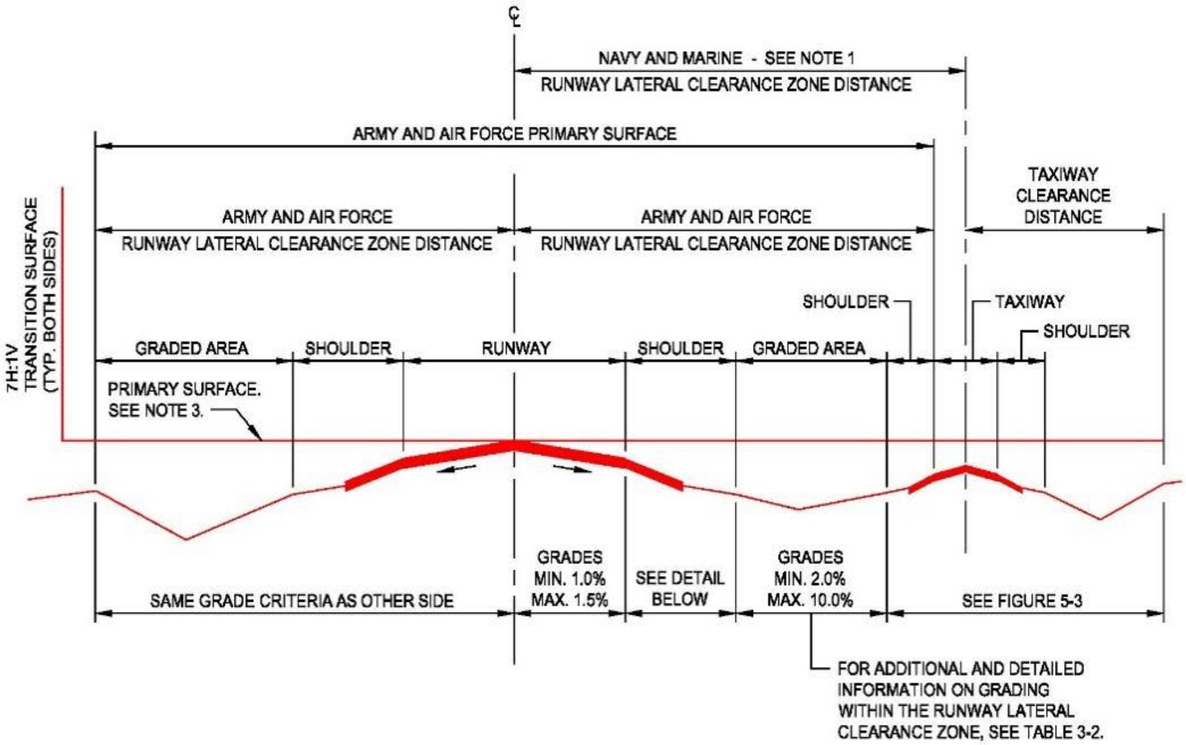
3-9.2.3 Other Impacts.

Displacement of the threshold often introduces disruptions to an otherwise orderly airport design. Approach lighting systems and NAVAIDs used for landing may need to be moved. Taxiways that remain in the new approach area (prior to the threshold) can create situations where taxiing aircraft penetrate the approach surface or the Clear Zone. Hold lines may also need to be moved to keep aircraft clear of these areas and runway capacity may be affected. While threshold displacement is often used to as a solution for constrained airspace, airfield designers need to carefully weigh the trade-offs of a displaced threshold. Displacing a threshold may also create a situation where the holdline must be placed on the parallel taxiway. This is undesirable as pilots do not normally expect to encounter a holdline on the parallel taxiway.

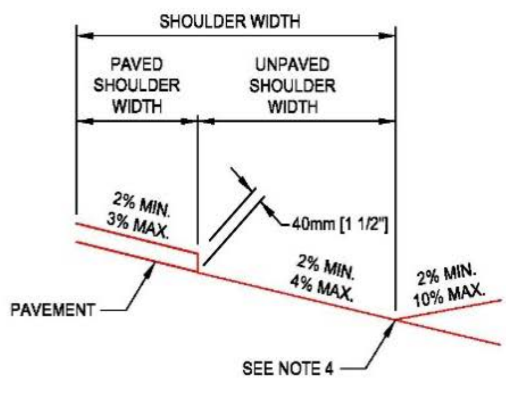
3-9.2.4 Cautions.

Threshold displacement should be undertaken only after full evaluation reveals that displacement is the best alternative. Coordination must be made with each Service Flight Standards Agency, TERPS, Engineering, and Operations.

Figure 3-1. Runway Transverse Sections and Primary Surface



RUNWAY TRANSVERSE SECTION
N.T.S.



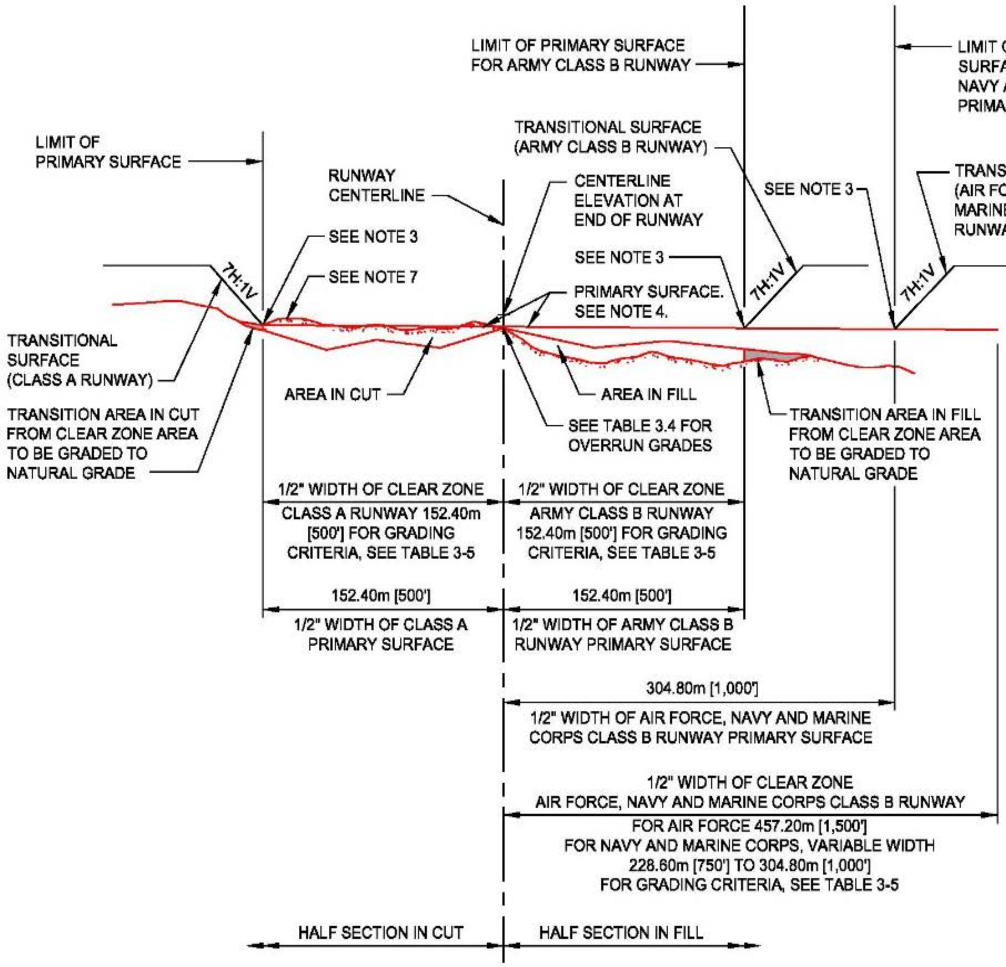
SHOULDER GRADE DETAIL
N.T.S.

NOTES

1. AT NAVY AND MARINE CORPS AIRFIELDS, THE CENTERLINES OF A RUNWAY AND A PARALLEL TAXIWAY SHALL BE A MINIMUM OF 152.4 METERS [500 FEET] APART. FOR CLASS A AIRFIELDS, ONE-HALF OF THE PARALLEL TAXIWAY MAY BE LOCATED WITHIN THE LATERAL CLEARANCE ZONE. SEE TABLE 3-2.
2. PROVIDE A 40mm [1-1/2"] DROP-OFF FROM PAVED SHOULDERS.
3. THE PRIMARY SURFACE WIDTH IS COINCIDENT WITH THE RUNWAY LATERAL CLEARANCE ZONE WIDTH. THE ELEVATION OF ANY POINT ON THE PRIMARY SURFACE IS THE SAME AS THE ELEVATION OF THE NEAREST POINT ON THE RUNWAY CENTERLINE.
4. WHEN A SLOPE REVERSAL IS REQUIRED AT THE TOE OF THE SHOULDER, THE DESIGNER MUST PROVIDE AN ADEQUATELY FLAT BOTTOM DITCH.

CLASS A AND CLASS B RUNWAYS

Figure 3-2. Clear Zone Transverse Section Detail



CLEAR ZONE TRANSVERSE SECTION DETAIL

N.T.S.

NOTES

1. TAKEN BEYOND END OF RUNWAY.
2. PRIMARY SURFACE APPLIES ONLY TO FIRST 60.96m [200'] BEYOND END OF RUNWAY.
3. THE STARTING ELEVATION FOR THE 7:1 TRANSITIONAL SURFACE IS THE ELEVATION OF THE PRIMARY SURFACE. REFER TO TABLE 3-7.
4. ELEVATION OF ANY POINT ON THE PRIMARY SURFACE IS THE SAME AS THE ELEVATION OF THE NEAREST POINT ON THE RUNWAY CROWN.
5. AT NAVY AND MARINE CORPS FACILITIES, THE PRIMARY SURFACE MAY BE 228.60m [750'].
6. DISTANCES ARE SYMETRICAL ABOUT CENTER OF RUNWAY.
7. NO PART OF THE AIRCRAFT OPERATIONS AREA WILL BE CONSIDERED AN OBSTRUCTION IF APPLICABLE GRADING CRITERIA ARE MET. GROUND SURFACES MAY PENETRATE THE PRIMARY SURFACE PROVIDED IT MEETS THE GRADING REQUIREMENTS. SEE PARAGRAPH 3.16.1.

NOTES

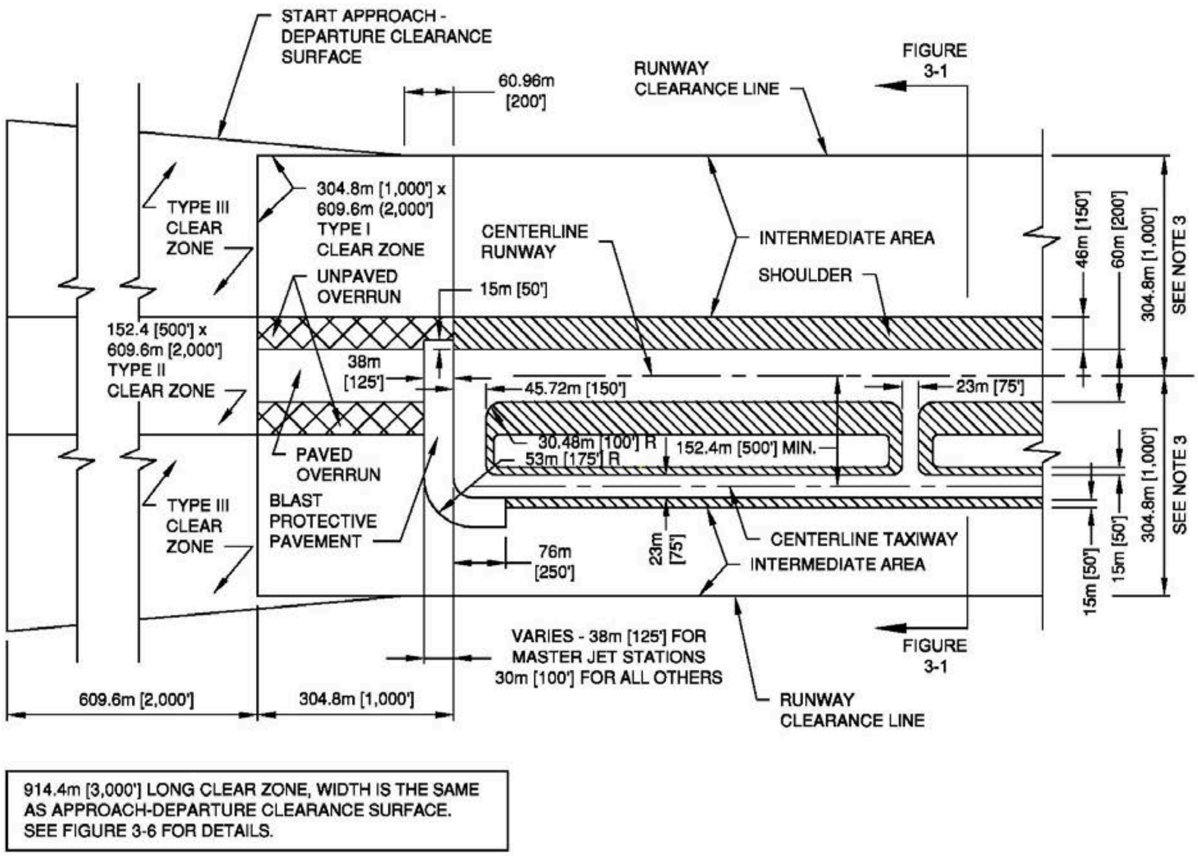
1. SEE UFC 2-000-05N FOR SPECIFICS ON CLEAR ZONE AND APPROACH-DEPARTURE CLEARANCE SURFACES.
2. MINIMUM OF 23m [75'] WIDTH. WIDTH SHALL BE INCREASED TO 46m [150'] AT TRAINING COMMAND RUNWAYS FOR T-34 AND T-44 AIRCRAFT.
3. FOR DIMENSIONS OF SPECIFIC ELEMENTS, SEE APPROPRIATE TABLES.
4. FOR RADII OF FILLETS, REFER TO FIGURES 5-4 AND 5-5.
5. FOR NAVY AND MARINE CORPS AIRFIELDS PARALLEL TAXIWAYS MAY BE LOCATED WITHIN THE PRIMARY SURFACE A MINIMUM DISTANCE OF 152.4m [500'] FROM CENTERLINE OF RUNWAY TO CENTERLINE OF TAXIWAY.
6. FOR GRADES WITHIN THE PRIMARY SURFACE, SEE TABLE 3-2.
7. FOR OVERRUN, SEE TABLE 3-4.

Figure 3-21. Plan, Single Runway, and Navy Class B

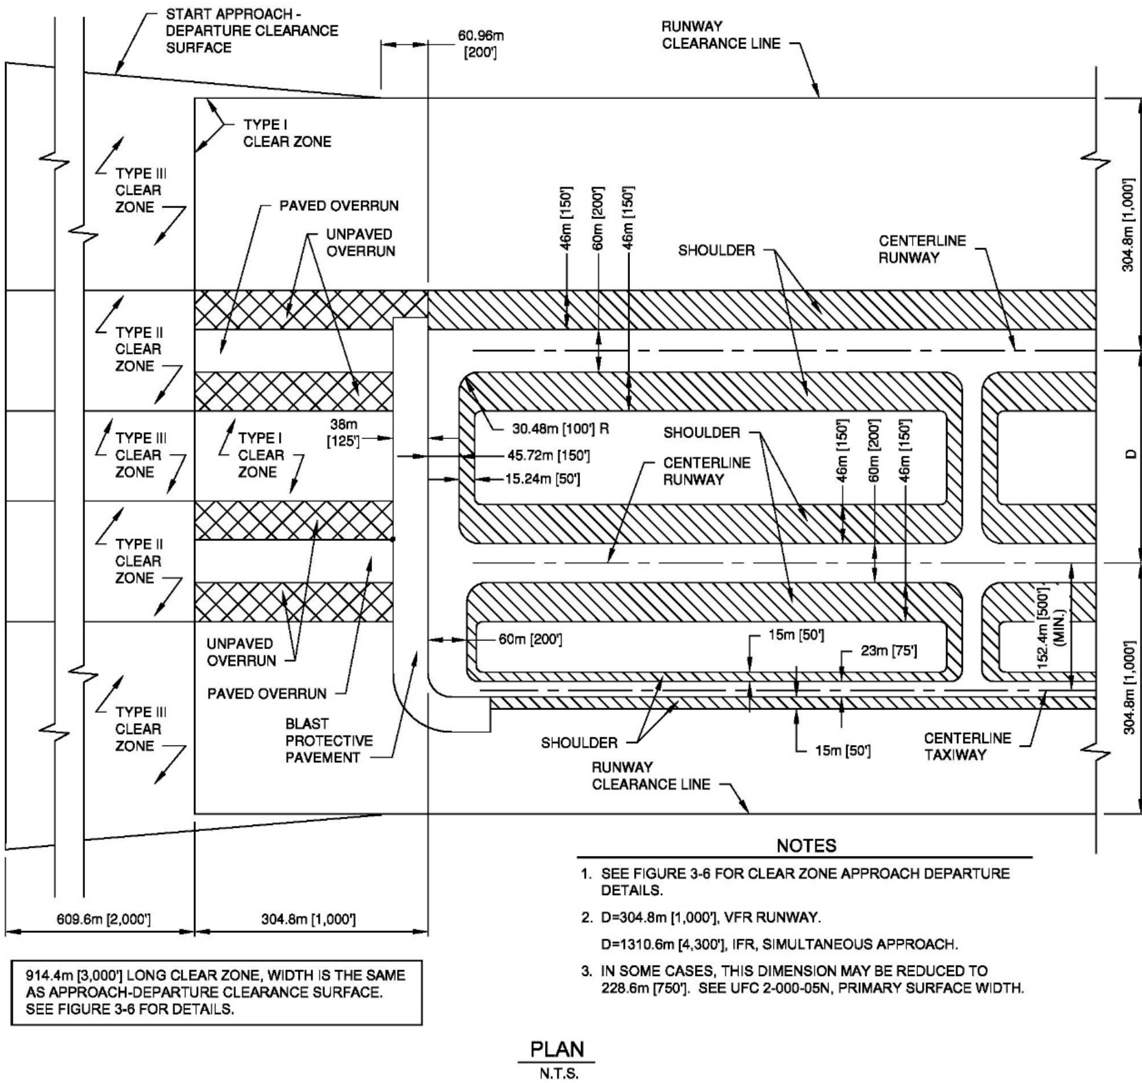


PLAN
N.T.S.

NOTES

1. SEE FIGURE 3-20 FOR SINGLE RUNWAY - CLASS A.
2. IN SOME CASES, THIS DIMENSION MAY BE REDUCED TO 228.6m [750']. SEE UFC 2-000-05N, PRIMARY SURFACE WIDTH.

Figure 3-22. Typical Layout, Navy Dual Class B Runways



3-10 SHOULDERS.

Unprotected areas adjacent to runways and overruns are susceptible to erosion caused by jet blast. Shoulders reduce the probability of serious damage to an aircraft to a minimum in the event that the aircraft runs off the runway pavement. The shoulder width, shown in Item 3 of Table 3-2, includes both paved and unpaved shoulders. Paved shoulders are required adjacent to all runways. The minimum paved shoulder width, shown in Table 3-2, allows the runway edge lights to be placed within the paved portion of the shoulder and to reduce foreign object damage (FOD) to aircraft. The unpaved shoulder will be graded to prevent water from ponding on the adjacent paved area (shoulder and runway). The drop-off next to the paved area prevents turf (which may build up over the years) from ponding water. See Paragraph 2-12 for requirements for designing buried utility structures in shoulders.

3-11 RUNWAY OVERRUNS.

Runway overruns keep the probability of serious damage to an aircraft to a minimum in the event that the aircraft runs off the runway end during a takeoff or landing, or lands short during a landing. Overruns are required for the landing and takeoff area. Table 3-4 shows the dimensional requirements for overruns. Overrun profiles are shown in Figure 3-3, and an overrun layout is shown in Figures 3-7, 3-10, 3-13, and 3-16. USAF and Army design and construction requirements are covered in UFC 3-260-02 (Chapter 10, under "Special Areas"). See Paragraph 2-12 for requirements for designing buried utility structures in overruns.

In certain situations, mission capability may be improved by increased runway length for takeoff. With responsible airfield authority approval, this can sometimes be accomplished by strengthening the paved overrun to support full aircraft traffic, thereby extending the allowable takeoff length, but not changing the approach or departure surfaces or runway thresholds. This situation will require displaced threshold markings to indicate the landing threshold and may require changes to lighting systems. See Paragraph 3-9.2 for displaced threshold guidance.

Table 3-4. Overruns

Table 3-4. Overruns				
Item		Class A Runway	Class B Runway	Remarks
No.	Description	Requirement		
1	Length	60 m (200 ft)	300 m (1,000 ft)	Army and Air Force airfields. Pave the entire length.
		300 m (1,000 ft)		Navy and Marine Corps airfields. Pave the entire length. At outlying fields for T-34 aircraft, the required overrun length is 150 m (500 ft).
2	Total width of overrun (paved and unpaved)	Sum of runway and shoulders		The outside edges of the overrun, equal in width to the runway shoulder, are graded but not paved.
3	Paved overrun width	Same as width of runway		Center on runway centerline extended
4	Longitudinal centerline grade	First 60 m (200 ft) same as last 300 m (1,000 ft) of runway. Remainder 1.5% Max.	First 90 m (300 ft) same as last 900 m (3,000 ft) of runway. Remainder: 1.5% Max	To avoid abrupt changes in grade between the first 90 m (300 ft) and remainder of overrun of a Class B runway, the maximum change of grade is 2.0% per 30 linear m (100 linear ft).
5	Transverse grade	Min 2.0% Max 3.0% 40 mm (1.5 in) drop-off at edge of paved overrun +/- 13 mm (0.5 in)		From centerline of overrun. Transition from the runway and runway shoulder grades to the overrun grades to be made within the first 45 m (150 ft) of overrun.

Note: Geometric design criteria in this manual are based on aircraft-specific requirements and are not direct conversions from inch-pound (English) dimensions. Inch-pound units are included only to permit reference to the previous standard.

3-12 RUNWAY CLEAR ZONES.

Runway clear zones are areas on the ground, located at the ends of each runway. They possess a high potential for accidents, and their use is restricted to be compatible with aircraft operations. Runway clear zones are required for the runway and should be owned or protected under a long-term lease. Table 3-5 shows the dimensional requirements for runway clear zones. Layout of the clear zones is shown in Figures 3-4, 3-5, 3-6, 3-7, 3-9, 3-10, 3-12, 3-13, 3-15, 3-16, 3-18, 3-20, 3-21, and 3-22. See Chapter 2, Para 2-12 for criteria for designing buried utility structures (manholes, handholes, drainage structures) in the Clear Zone.

3-12.1 Land Use in Clear Zones.

The purpose of the clear zone is to protect the safety of flight and safety of people on the ground. The entire clear zone area is a land use control area intended to protect people both flight safety and property on the ground. DoDI 4165.57 and individual Service component directives govern land use within this area.

3-12.2 Clear Zone Mandatory Frangibility Zone (MFZ).

For the USAF and Army, a MFZ extends through the land use control area to the end of the clear zone if on property owned or controlled by the USAF or Army, or to the base boundary if an avigation easement does not exist. Items that must be sited there due to their function must be made frangible, semi-frangible or low impact resistant to the maximum extent possible (see Appendix B, Section 13). Items that cannot be made frangible (such as highway guard rails) but must be located within this area for urgent and compelling reasons must be waived by the MAJCOM or USAASA in accordance with Appendix B, Section 1, before they are constructed. This is to ensure that all alternatives are considered before non-frangible structures are sited within this area. for additional information. Interaction with property owners whose land falls within the MFZ is encouraged. Owners should be encouraged to make items in these areas frangible where practicable. For Air Force, see AFI 32-7063 for additional information.

Table 3-5. Clear Zones

Table 3-5. Clear Zones[1]				
Item		Class A Runway	Class B Runway	Remarks
No.	Description	Requirement		
1	Length	914.40 m (3,000 ft)	914.40 m (3,000 ft)	Measured along the extended runway centerline beginning at the runway end[2]. Although desirable, clearing and grading of the entire area is not required. For acceptable land uses in the clear zone, see AFI 32-7063 and AFH 32-7084 for USAF, and, OPNAVINST 11010.36C/MCO 11010.16 (or latest version), for Navy and Marine Corps. For grading requirements, see items 4 and 5.
2	Width at start of clear zone (adjacent to the runway)	304.80 m (1,000 ft)	304.80 m (1,000 ft)	Army airfields. Exception to these widths is permissible based on Army analysis of highest accident potential area for specific runway use and acquisition constraints.
			914.80 m (3,000 ft)	Air Force airfields. Though desirable, clearing and grading of the entire area is not required. For acceptable land uses in the clear zone, see AFI 32-7063 and AFH 32-7084 for USAF.
			609.60 m (2,000 ft)	Navy and Marine Corps: (See OPNAVINST 11010.36C/MCO 11010.16 (or latest version) for historical guidance where this dimension is 457 m

Table 3-5. Clear Zones[1]

Item No.	Item Description	Class A Runway Requirement	Class B Runway Requirement	Remarks
				(1,500 ft) for airfields built before 1981. For grading requirements, see items 4 and 5.
		See Remarks		Width of the clear zone is centered on and measured at right angles to the extended runway centerline. Refer to Figures 3-4, 3-5, and 3-6.
3	Width at end of clear zone	304.80 m (1,000 ft)	304.80 m (1,000 ft)	Army airfields. Exception to these widths is permissible based on Army analysis of highest accident potential area for specific runway use and acquisition constraints.
			914.40 m (3,000 ft)	Air Force airfields
		304.80 m (1,000 ft)	848.56 m (2,784 ft)	Navy and Marine Corps: See OPNAVINST 11010.36C/MCO 11010.16 (or latest version) for historical guidance for airfields built before 1981. The clear zone has the same dimensions as the approach-departure surface, as shown in Table 3-7. The first 60.96 m (200 ft) of the clear zone is a uniform 609.60 m (2,000 ft) in width, and which point the variable width begins.
			704.7 m (2,312 ft)	Navy and Marine Corps runways constructed prior to 1981 with 457.2m (1500 ft) primary surface.
		See Remarks		Width of the clear zone is centered on and measured at right angles to the extended runway centerline. Refer to Figures 3-4 (US Army), 3-5 (USAF), and 3-6 (US Navy and Marine Corps).
4	Longitudinal grade of area to be graded	Max 10.0%		For Army and Air Force, the area to be graded is 300 m (1,000 ft) in length by the established width of the primary surface. Grades are exclusive of the overrun, but are to be shaped into the overrun grade. The maximum longitudinal grade change cannot exceed $\pm$ 2.0% per 30 m (100 ft). Grade restrictions are also exclusive of other pavements and shoulders. Where other pavements cross the graded area, comply with grading requirements for the specific pavement design (towways, taxiways, or aprons as applicable), but hold grade changes to the minimum practicable to facilitate drainage. For Navy and Marine Corps, the area to be graded will be based on the type of clear zone, as shown in Figures 3-16, 3-20, 3-21, and 3-22. For all Services, the graded area is to be cleared and grubbed of stumps and free of abrupt surface
5	Transverse grade of area to be graded (in direction of surface drainage prior to channelization)	Min 2.0% Max 10.0%		(see remarks for item 4)

Table 3-5. Clear Zones[1]				
Item		**Class A Runway**	**Class B Runway**	
No.	**Description**	**Requirement**		**Remarks**
				irregularities, ditches, and ponding areas. No aboveground structures (see note 3), objects, or roadways (except air traffic control controlled service roads to arresting gear or NAVAIDs) are permitted in the area to be graded, but gentle swales, subsurface drainage, covered culverts and underground structures are permissible. The transition from the graded area to the remainder of the clear zone is to be as gradual as feasible. For policy regarding permissible facilities, geographical features, and land use in the clear zone, refer to guidance furnished by each individual Service, and DoD AICUZ guidelines for clear zones and accident potential zones. (See Appendix B, Section 3.)
6	Width of USAF and Army MFZ	152.4 m (500 ft)		Centered on the extended runway centerline. **\1** All items sited in the clear zone must be frangible (see B13 for exceptions such as fencing). **/1/** Man-made items located beyond the Graded Area of the clear zone but within the MFZ must be constructed to be frangible, low impact-resistant structures, or semi-frangible to the maximum extent possible (see Appendix B, Section 13).
7	Length of USAF and Army MFZ	914.4 m (3000 ft)		

NOTES:

1. Applicable to aviation facilities installations of the military departments in the United States, its territories, trusts, and possessions. For military facilities overseas, other than in locations designated, apply to the maximum practical extent.
2. For the definition of runway end refer to the glossary.
3. Essential NAVAID structure exceptions are discussed in Appendix B, Section 13.
4. Airfield and heliport imaginary surfaces and safe wingtip clearance dimensions are direct conversions from inch-pound to SI units.

3-12.3 US Navy Clear Zones.

Clear zones possess a high potential for accidents, and are subject to severe land use restrictions. For compatible land use assessment purposes, the clear zone is considered as one contiguous geometric area. Land use in the clear zone is governed by DoDI 4165.57 and OPNAVINST 11010.36C/MCO 11010.16 (or latest version). For the purpose of clear zone design, associated graded areas and approach-departure clearance requirements, the Navy defines three clear zone types as follows:

3-12.3.1 Type I Clear Zone.

This zone is immediately adjacent to the end of the runway. It will be cleared, graded, and free of above-ground objects (except airfield lighting) and is to receive special ground treatment or pavement in the area designated as the runway overrun. This clear zone is required at both ends of all runways.

3-12.3.2 Type II Clear Zone.

This zone is used only for Class B runways and is an extension of the Type I clear zone except that the width is reduced. The Type II clear zone will be graded and cleared of all above-ground objects except airfield lighting.

3-12.3.3 Type III Clear Zone.

This zone is laterally adjacent to the Type II clear zone for Class B runways and is used in lieu of the Type II clear zone at Class A runways and basic training outlying fields used by the T-34 aircraft. Objects in this zone will not penetrate the approach-departure clearance surface. Trees, shrubs, bushes, or any other natural growth will be topped 3 m (10 ft) below the approach-departure clearance surface or to a lesser height if necessary to ensure the visibility of airfield lighting. Traverse ways (e.g., roads, railroads, canals) are permitted provided that they would not penetrate airfield imaginary surfaces after the height of the traverse way has been increased by the distances specified in UFC 2-000-05N.

3-13 ACCIDENT POTENTIAL ZONES (APZ).

APZs are areas on the ground located beyond the clear zone of each runway. They possess a potential for accidents, and land use in APZs is governed in accordance with DoDI 4165.57 and Service-specific AICUZ directives. Table 3-6 shows the dimensional requirements for runway APZs. Layout of APZs is shown in Figure 3-4 for the Army, Figure 3-5 for the Air Force, and Figure 3-6 for the Navy. Navy planners will use OPNAVINST 11010.36C/MCO 11010.16 (or latest version) to determine specific AICUZ requirements. For the Air Force, land use guidelines within the clear zone (beyond the graded area) and APZ I and APZ II are provided in AFI 32-7063 and AFH 32-7084.

3-14 AIRSPACE IMAGINARY SURFACES.

The area surrounding a runway that must be kept clear of objects that might damage an aircraft is bounded by imaginary surfaces that are defined in this manual. An object, either man-made or natural, that projects above an imaginary surface is an obstruction. Imaginary surfaces for fixed-wing airfields are shown in Figures 3-6 through 3-22 and are defined in the glossary. The applicable dimensions and slopes are provided in Table 3-7. These imaginary surfaces include:

- Primary surface
- Approach-departure surface
- Inner horizontal surface
- Conical surface
- Outer horizontal surface
- Transitional surface

- The graded portion of the clear zone

Table 3-6. Accident Potential Zones (APZs)

Table 3-6. Accident Potential Zones (APZs)				
Item		Class A Runway	Class B Runway	
No.	Description	Requirement		Remarks
1	APZ I length	762.00 m (2,500 ft)	1,524.00 m (5,000 ft)	APZ I starts at the end of the clear zone, and is centered and measured on the extended centerline.
2	APZ I width	304.80 m (1,000 ft)	304.80 m (1,000 ft)	Army airfields
			914.400 m (3,000 ft)	Air Force, Navy, and Marine Corps airfields
3	APZ II length	762.00 m (2,500 ft)	2,133.60 m (7,000 ft)	Standard APZ II starts at the end of the APZ I and is centered and measured on the extended runway centerline.
4	APZ II width	304.80 m (1,000 ft)	304.80 m (1,000 ft)	Army airfields
			914.40 m (3,000 ft)	Air Force, Navy, and Marine Corps airfields

NOTES:

1. Applicable to aviation facilities of the military departments in the United States, its territories, trusts, and possessions. For military facilities overseas, other than in locations designated, follow the guidance of the individual Service component.
2. For guidance on land use within the APZs, see land use compatibility guidelines in DoD AICUZ guidelines (Appendix B, Section 3). For USAF, see AFI 32-7063 and AFH 32-7084. For Navy and Marine Corps, see OPNAVINST 11010.36C/MCO 11010.16 (or latest version).
3. Airfield and heliport imaginary surfaces and safe wingtip clearance dimensions are shown as a direct conversion from inch-pound to SI units.

Table 3-7. Airspace Imaginary Surface

Table 3-7. Airspace Imaginary Surfaces						
Item			Class A Runway Requirement		Class B Runway Requirement	
No.	Description	Legend	VFR	IFR	VFR and IFR	Remarks
1	Primary surface width	A	304.80 m (1,000 ft)	304.80 m (1,000 ft)		
					304.80 m (1,000 ft)	Army airfields
					609.60 m (2,000 ft)	Air Force, Navy, and Marine Corps airfields
			See Remarks			Centered on the runway centerline. At US Navy and Marine Corps airfields where the lateral clearance was established according to the previous 228.60 m (750 ft) from centerline criterion, the 457.2-m (1500-ft) distance may remain. For USAF, the primary surface width was expanded 10 Nov 64. Facilities constructed under the previous standard are exempt. See Chapter 1 and Appendix B, Section 17. Parallel taxiways located within the primary surface under previous standards may remain but should be evaluated for continued use in the current location when major repairs are necessary. For Navy and Marine Corps, this surface was expanded on 12 May 1981.
2	Primary surface length	A	Runway Length + 60.96 m (200 ft) at each end			Primary surface extends 60.96 m (200 ft) beyond each end of the runway.
3	Primary surface elevation	A	The elevation of any point on the primary surface is the same as the elevation of the nearest point on the runway centerline.			
4	Clear zone surface (graded area)	B	See Table 3-5			Graded area only. For land use in the clear zone, apply AICUZ standards. For USAF, see AFI 32-7063 and AFH 32-7084; for US Army, see Appendix B, Section 3. For Navy and Marine Corps, see

Table 3-7. Airspace Imaginary Surfaces						
Item			Class A Runway Requirement		Class B Runway Requirement	
No.	Description	Legend	VFR	IFR	VFR and IFR	Remarks
10	Elevation of approach-departure surface at start of sloped portion	C	See Remarks			Same as the runway centerline elevation at the threshold.
11	Elevation of approach-departure surface at end of sloped portion	C	76.20 m (250 ft)	152.40 m (500 ft)	152.40 m (500 ft)	Above the established airfield elevation.
12	Start of horizontal portion of approach-departure surface	D	N/A	6,096.00 m (20,000 ft) See Note 4	7,620.00 m (25,000 ft) See Note 4	Measured from the end of the primary surface. The end of the primary surface (start of the approach-departure surface) is 60.96 m (200 ft) from the end of the runway.
13	Length of horizontal portion of approach-departure surface	D	N/A	9,144.00 m (30,000 ft)	7,620.00 m (25,000 ft)	Measured horizontally along the ground.
14	Width of approach-departure surface at start of horizontal portion	D	N/A	2,133.60 m (7,000 ft) See Note 4	2,743.20 m (9,000 ft) See Note 4	Centered along the runway centerline extended.
15	Width of approach-departure surface at end of horizontal portion	D	N/A	4,876.80 m (16,000 ft)	4,876.80 m (16,000 ft)	Centered along the runway centerline extended.
16	Elevation of horizontal portion of approach-departure surface	D	N/A	152.40 m (500 ft)	152.40 m (500 ft)	Above the established airfield elevation.

Table 3-7. Airspace Imaginary Surfaces						
Item			Class A Runway Requirement		Class B Runway Requirement	
No.	Description	Legend	VFR	IFR	VFR and IFR	Remarks
17	Radius of inner horizontal surface	E	N/A	2,286.00 m (7,500 ft)		An imaginary surface constructed by scribing an arc with a radius of 2,286 m (7,500 ft) about the centerline at each end of each runway and inter-connecting these arcs with tangents.
18	Width between outer edges of inner horizontal surface	E	N/A	4,572.00 m (15,000 ft)		
19	Elevation of inner horizontal surface	E	N/A	45.72 m (150 ft)		Above the established airfield elevation. See Attachment 1 for the definitions of “airfield elevation” and “inner horizontal surface.” For Navy, also see UFC 2-000-05N.
20	Horizontal width of conical surface	F	N/A	2,133.60 m (7,000 ft)		Extends horizontally outward from the outer boundary of the inner horizontal surface.
21	Slope of conical surface	F	N/A	20:1		Slope ratio is horizontal:vertical. Example: 20:1 is 20 m (ft) horizontal to 1 m (ft) vertical
22	Elevation of conical surface at start of slope	F	N/A	45.72 m (150 ft)		Above the established airfield elevation.
23	Elevation of conical surface at end of slope	F	N/A	152.40 m (500 ft)		Above the established airfield elevation.
24	Distance to outer edge of conical surface	G	N/A	4,419.60 m (14,500 ft)		
25	Width of outer horizontal surface	G	N/A	9,144.00 m (30,000 ft)		Extending horizontally outward from the outer periphery of the conical surface.
26	Elevation of outer horizontal surface	G	N/A	152.40 m (500 ft)		Above the established airfield elevation.

Table 3-7. Airspace Imaginary Surfaces						
Item		Legend	Class A Runway Requirement		Class B Runway Requirement	Remarks
No.	Description		VFR	IFR	VFR and IFR	
27	Distance to outer edge of outer horizontal surface	G	N/A	13,563.60 m (44,500 ft)		An imaginary surface formed by scribing an arc with a radius of 13,563.6 m (44,500 ft) about the centerline at each end of each runway, and interconnecting the arcs with tangents.
28	Start of transitional surface	H	152.40 m (500 ft)		152.40 m (500 ft)	At Army airfields
			152.40 m (500 ft)		304.8 m (1,000 ft)	Air Force, Navy, and Marine Corps
29	End of transitional surface	H	See Remarks			The transitional surface ends at the inner horizontal surface, conical surface, outer horizontal surface, or at an elevation of 45.72 m (150 ft).
30	Slope of transitional surfaces	H	7:1			Slope ratio is horizontal:vertical. 7:1 is 7 m (ft) horizontal to 1 m (ft) vertical. Vertical height of vegetation and other fixed or mobile obstacles and/or structures will not penetrate the transitional surface. Taxiing aircraft are exempt from this requirement. For Navy and Marine Corps airfields, taxiway pavements are exempt from this requirement. For the USAF, the Air Traffic Control Tower is exempt from this requirement if the height will not affect TERPS criteria. See paragraph B16-2.7 and B16-4.3 of Appendix B, Section 16.

NOTES:

1. Approach-departure surfaces are based on instrument approach-departure procedures. Verify instrument approach-departure procedures with Army Aeronautical Service Agency, Air Force Flight Standard Agency, or Navy Flight Information Group (NAFIG), as appropriate, prior to using this table.
2. N/A = not applicable
3. Airfield and heliport imaginary surfaces and safe wingtip clearance dimensions are shown as a direct conversion from inch-pound to SI units.
4. Differences in elevation between the runway thresholds and the Established Airfield Elevation will have some effect on the extended length and width of the sloped portion of the ADCS and the start of the horizontal portion of the ADCS. Careful evaluation of these surfaces is required.

3-15 AIRSPACE FOR AIRFIELDS WITH TWO OR MORE RUNWAYS.

Typical airspace requirements for an airfield with multiple runways, such as a VFR and an IFR runway, are shown in Figure 3-19.

3-16 OBSTRUCTIONS TO AIR NAVIGATION.

An existing object (including a mobile object) is, and a future object would be, an obstruction to air navigation if it is higher than any of the heights or surfaces listed in FAR Part 77 and the surfaces described in this manual.

3-16.1 Aircraft Operating Area (AOA).

No part of the airfield (runway/taxiway aprons) where aircraft operate under their own power will be considered an obstruction if the applicable grading criteria are met. (See the glossary for the definition of "aircraft operating area," as used in this manual.)

3-16.2 Determining Obstructions.

For airfields located in the US and trust territories, an obstruction to air navigation is determined in accordance with this UFC and the standards contained in 14 Code of Federal Regulations (CFR) Part 77, Paragraph 77.23, "Standards for Determining Obstruction. For airfields located elsewhere, an obstruction is determined in accordance with either the host county's standards, or the individual Service's standards, whichever are more stringent.

3-16.3 Trees.

All trees within the runway, taxiway and apron lateral clearance distances and within the graded area of the clear zone need to be removed. Trees that project into the imaginary surfaces must be removed or lowered to a distance below the imaginary surface, as specified in Table 3-8. Trees are permitted near an airfield provided that they do not cause Bird Aircraft Strike Hazards (BASH), penetrate the imaginary surfaces, the taxiway clearance distance, the apron clearance distance, or instrument procedure obstacle identification surfaces (OIS) as described in TERPS regulations.

Table 3-8. Imaginary Surfaces Minimum Clearances over Highway, Railroad, Waterway, and Trees

Table 3-8. Imaginary Surfaces Minimum Clearances			
Item			**Class A and Class B Runways**
No.	**Description**	**Traverse Way/Objects**	**Dimensions**
1	Minimum vertical clearance between established imaginary surfaces and traverse ways/objects (measured from the highest and nearest elevation of the traverse ways/objects)	Interstate highway that is part of the National System of Military and Interstate Highways	5.18 m (17 ft)
2		Other public highways not covered in Item 1	4.57 m (15 ft)
3		Private or military road	3.05 m (10 ft) minimum or height of highest mobile object that would usually traverse them, whichever is greater
4		Railroad	7.01 m (23 ft)
5		Waterway or traverse way, not previously covered	A distance equal to the height of the highest mobile object that usually would traverse them
6		Trees*	3 m (10 ft)

* Trees must be removed or topped the distance shown below the applicable imaginary surface.

3-17 AIRCRAFT ARRESTING SYSTEMS.

Aircraft arresting systems consist of engaging devices and energy absorbers. Engaging devices are net barriers, disc-supported pendants (hook cables), and cable support systems that allow the pendant to be raised to the battery position or retracted below the runway surface. Energy-absorbing devices are ships' anchor chains, textile brake arresting systems, rotary friction brakes, such as the BAK-9 and BAK-12, or rotary hydraulic systems such as the BAK-13 and E-28. The systems designated "Barrier, Arresting Kit" (BAK) are numbered in the sequence of procurement of the system design. There is no connection between the Air Force designations of these systems and their function. The equipment is government-furnished equipment, as discussed in **\1** AFMAN 32-1040. **/1/** Other designations such as E-5, E-28, and M-31 are US Navy designations. These USAF systems are currently in use: MA-1A, E-5, BAK-12, BAK-14, 61QSII (BAK-15), mobile aircraft arresting system (MAAS), textile brake, and Type H hook cable retraction system.

3-17.1 Navy and Marine Corps Requirements.

Navy and Marine Corps unique requirements are identified where appropriate. In general, the Navy and Marine Corps use aircraft arresting gear design criteria consistent with requirements identified here.

3-17.2 Installation Design and Repair Considerations.

For the USAF, further information on planning, installing, and repairing an arresting system or arresting system complex is provided in **\1** AFMAN 32-1040 **/1/** and FC 3-260-18F. During the planning, installation, or repair process, consider the items in paragraphs 3-17.2.1 through 3-17.2.3.

3-17.2.1 Configuration and Location.

The configuration and location of arresting system installations will be determined in accordance with FC 3-260-18F. Design will conform to the criteria in section 3 of the appropriate 35E8 series technical order and the typical installation drawings. Both may be obtained from:

AFLCMC/WNZEC
ATTN: Aircraft Arresting Systems Engineer
235 Byron St
Robins AFB GA 31098-1813
or the AFLCMC/WNZ Workflow Box at:
642CBSG.Workflow@us.af.mil

3-17.2.2 Runway Pavement.

The 60 m (200 ft) of pavement on both the approach and departure sides of the arresting system pendant is a critical area. Protruding objects and undulating surfaces are detrimental to successful tailhook engagements and are not allowable. The maximum permissible longitudinal surface deviation in this area is plus or minus 3 mm (0.125 in) in 3.6 m (12 ft). Saw-cut grooves in runway pavement to improve surface drainage and surface friction characteristics in accordance with UFC 3-260-02 are not considered protruding objects or undulations; however, the pavement will not be grooved within the first 3 m (10 ft) on either side of the arresting system cables. For USAF facilities, changes in pavement type or an interface between rigid and flexible pavements are not permitted within the center 22.86 m (75 ft) of the runway for 60 m (200 ft) in either direction from the arresting system cables. Sacrificial panels installed beneath arresting system cables in accordance with **\1** AFMAN 32-1040 **/1/** are not considered a change in pavement type or an interface between rigid and flexible pavements. The prohibition on changes in surface pavement type is not applicable to emergency aircraft arresting systems located in overruns. Portland cement concrete (PCC) foundations designed in accordance with USAF Typical Installation Drawing 67F2013A are required for aircraft arresting system cable tie-downs and are also exempt from the prohibition on changes in surface pavement type. Navy aircraft arresting gear pavement protection will be designed in accordance with NAVFAC Standard Design Drawing numbers 4568319 through 4568322. The 2 m (6.56 ft) of pavement on both the approach and departure sides of the pendant are the critical areas for the Navy and Marine Corps. For Navy and Marine Corps runways, use a runway transverse slope of 0.75% for the center 2 slabs (for PCC) or twice the paving machine width (for asphalt concrete) but less than the center 6 m (20 feet), and 1% to 1.5% for the remainder of the runway section for at least 90 m (300 feet) in either longitudinal direction from the arresting gear cable.

3-17.2.3 Repair of Bituminous Pavements.

Rigid inlays will not be used as a surface repair material beneath the cable in a flexible runway system. This type of repair causes high hook skip potential when the flexible pavement consolidates, exposing the leading edge of the rigid pavement. Rigid pavement must be used, however, as a foundation for sacrificial pads installed beneath aircraft arresting system cables. No part of the foundation for the panels will be used as a surface pavement in a flexible runway pavement.

3-17.3 Joint-Use Airfields.

Arresting systems installed on joint-use civil/military airfields to support military aircraft are sited in accordance with FAA AC 150/5220-9 at https://www.faa.gov/airports/resources/advisory_circulars/.

3-17.3.1 Agreement to Install.

When planning the installation of an arresting system at a joint-use facility, the installation commander must first notify the airport manager/authority of the need. If the agreement is mutual, the installation commander submits the plan with sketches or drawings to the Air Force Liaison Officer in the appropriate FAA regional office. Disagreement between the responsible officials must be referred to the next higher level for resolution.

3-17.3.2 Disagreements.

If a lease agreement is involved and does not allow placement of additional structures on the leased premises, the issue will be elevated to the MAJCOM for resolution.

3-17.3.3 Operating Agency.

When an arresting system is installed at a joint-use civil airfield for the primary use of US military aircraft, the FAA acts for, and on behalf of, the DoD Service component in operating this equipment.

3-17.3.4 Third-Party Claims.

Third-party claims presented for damage, injury, or death resulting from the FAA operation of the system for military aircraft or from DoD maintenance of the system is the responsibility of the DoD and must be processed under the appropriate DoD component's regulatory guidance.

3-17.3.5 DoD and FAA Agreements.

Separate agreements between the DoD and the FAA are not required concerning liability for damage arising from the intentional operation of the system by FAA personnel for civil aircraft because such claims are the responsibility of the FAA.

3-17.3.6 Operational Agreement.

The MAJCOM is responsible for negotiating the operational agreement with the FAA for a joint-use civil airport; however, authority may be delegated to the installation commander. The agreement will describe FAA functions and responsibilities concerning the remote control operation of arresting systems by FAA air traffic controllers.

3-17.4 Military Rights Agreements for Non-CONUS Locations.

These systems are installed under the military rights agreement with the host government. If a separate agreement is specifically required for installation of a system, the installation commander coordinates with the local US diplomatic representative and negotiates the agreement with the host nation.

This Page Intentionally Blank

CHAPTER 4
ROTARY-WING RUNWAYS, HELIPADS, LANDING LANES, AND HOVERPOINTS

4-1 CONTENTS.

This chapter presents design standards and requirements for rotary-wing (helicopter) landing facilities: runways, helipads, helicopter landing lanes, and hoverpoints.

4-2 LANDING AND TAKEOFF LAYOUT REQUIREMENTS.

The landing design requirements for rotary-wing landing facilities, which include rotary-wing runways, helipads, landing lanes, slide areas (autorotation lanes), and hoverpoints, are similar to the requirements for fixed-wing runways as discussed in Chapter 3.

4-3 ROTARY-WING RUNWAY.

The rotary-wing runway allows for a helicopter to quickly land and roll to a stop, compared to the hovering stop used during a vertical helipad approach.

4-3.1 Orientation and Designation.

Consider the strength, direction, and frequency of the local winds when orienting a runway to minimize crosswinds. Follow the methods in Chapter 2 for rotary-wing runway orientation. Follow the guidance in Chapter 3, Paragraph 3-7 for determining rotary-wing runway designation. Runways are identified by the whole number, nearest one-tenth (1/10), of the magnetic azimuth of the runway centerline when viewed from the direction of approach.

4-3.2 Dimensions.

Table 4-1 presents dimensional criteria for the layout and design of rotary-wing runways.

4-3.3 Layout.

The layout for rotary-wing runways, including clear zones, are illustrated in Figure 4-1 for VFR runways and Figures 4-2 and 4-3 for IFR runways.

4-3.4 Special Tilt-Rotor Aircraft Considerations (V-22).

The V-22 is a tilt-rotor aircraft that can operate both as a fixed-wing aircraft or a rotary-wing aircraft. When the V-22 operates on rotary-wing facilities, this chapter applies with noted V-22 exceptions. See paragraph 1-2.2.4 for general V-22 planning considerations.

Table 4-1. Rotary-Wing Runways

Table 4-1. Rotary-Wing Runways			
Item			
No.	Description	Requirement	Remarks
1	Basic length	490 m (1,600 ft)	For Army and Air Force facilities, use basic length up to 1,220 m (4,000 ft) in elevation above mean sea level (AMSL). Increase basic length to 610 m (2,000 ft) when above 1,220 m (4,000 ft) in elevation above MSL. For Navy and Marine Corps facilities, basic length to be corrected for elevation and temperature. Increase 10% for each 300 m (1,000 ft) in elevation above 600 m (2,000 ft) MSL and add 4.0% for each 5 degrees C (10 degrees F), above 15 degrees C (59 degrees F) for the average daily maximum temperature for the hottest month. For a special mission or proficiency training such as autorotation operations, the length may be increased up to 300 m (1,000 ft); in that case, make no additive corrections.
		137.2 m (450 ft)	For facilities constructed prior to May 1999.
2	Width	23 m (75 ft)	For Navy and Marine Corps facilities, increase width to 30 m (100 ft) on runways which regularly accommodate H-53 and V-22.
3	Longitudinal grade	Max. 1.0%	Maximum longitudinal grade change is 0.167% per 30 linear meters (100 linear feet) of runway. Exceptions: 0.4% per 30 linear meters (100 linear feet) for edge of runways at runway intersections.
4	Transverse grade	Min. 1.0% Max. 1.5%	From centerline of runway. Runway may be crowned or cross-sloped.
5	Paved shoulders		See Table 4-4.
6	Runway lateral clearance zone (corresponds to half the width of primary surface area)	45.72 m (150 ft)	VFR operations
		114.30 m (375 ft)	IFR operations
		See Remarks	Measured perpendicularly from centerline of runway. This area is to be clear of fixed and mobile obstacles. In addition to the lateral clearance criterion, the vertical height restriction on structures and parked aircraft as a result of the transitional slope must be taken into account. (1) Fixed obstacles include man-made or natural features constituting possible hazards to moving aircraft. Navigational aids and meteorological equipment are possible exceptions. For Army and Air Force, siting exceptions for navigational aids and meteorological facilities are provided in Appendix B, Section 13, of this manual. For Navy and Marine Corps, siting exceptions for navigational aids and meteorological facilities are found in paragraph 2-11. (2) Mobile obstacles include parked aircraft, parked and moving vehicles, railroad cars and similar equipment. (3) Taxiing aircraft are exempt from this restriction. However, parallel taxiways (exclusive of shoulder width) must be located in excess of the lateral clearance distance.
7	Grades within the primary	Min. 2.0% Max. 5.0%	Exclusive of pavement and shoulders.

Table 4-1. Rotary-Wing Runways

Item No.	Item Description	Requirement	Remarks
	surface area in any direction		
8	Overrun		See Table 4-5.
9	Distance from the centerline of a fixed-wing runway to the centerline of a parallel rotary-wing runway, helipad, or landing lane	Min. 213.36 m (700 ft)	Simultaneous VFR operations for Class A runway and Army Class B runway
		Min. 304.80 m (1,000 ft)	Simultaneous VFR operations for Class B Runway for Air Force, Navy and Marine Corps.
		Min. 213.36 m (700 ft)	Non-simultaneous VFR and IFR operations. Distance may be reduced to 60.96 m (200 ft); however, waiver is required. Ensure waiver includes evaluation of effects of wake-turbulence and jet blast. In locating the helipad, the helipad must be sited beyond the runway hold line.
		Min. 762.00 m (2,500 ft)	IFR using simultaneous operations (depart-depart) (depart-approach).
		Min. 1,310.64 m (4,300 ft)	IFR using simultaneous approaches.
10	Distance between centerlines of: (a) parallel rotary-wing runways, helipads, or any combination thereof; (b) landing lane and parallel rotary-wing runway or helipad	Min. 213.36 m (700 ft)	VFR without intervening parallel taxiway between centerlines. For US Army, distance may be reduced to 60.96 m (200 ft) between parallel helipads for non-simultaneous operations. For V-22, may be reduced to 121.9 m (400 ft) offset, centerline to centerline, for non-simultaneous operations In locating the helipad, consideration must be given to hold position marking.
		Min. 762.00 m (2,500 ft)	IFR using simultaneous operations (depart-depart) (depart-approach).
		Min. 1,310.64 m (4,300 ft)	IFR using simultaneous approaches.

NOTES:
1. Metric units apply to new airfield construction and, where practical, modification to existing airfields and heliports, as discussed in paragraph 1-3.4.
2. The criteria in this manual are based on aircraft specific requirements and are not direct conversions from inch-pound (English) dimensions. Inch-pound units are included only as a reference to the previous standard.
3. Airfield and heliport imaginary surfaces and safe wingtip clearance dimensions are shown as a direct conversion from inch-pound to SI units.

NOTES

1. ADDITIONAL DIMENSIONS, LONGITUDINAL PROFILES AND TRANSVERSE SECTIONS FOR IFR HELICOPTER RUNWAY FACILITIES ARE SHOWN ON FIGURE 4-2. THE SAME INFORMATION FOR IFR HELIPAD FACILITIES IS SHOWN ON FIGURE 4-6.
2. THE CLEAR ZONE FOR HELICOPTER RUNWAYS AND HELIPADS CORRESPONDS TO THE CLEAR ZONE LAND USE CRITERIA FOR FIXED-WING AIRFIELDS AS DEFINED IN AICUZ STANDARDS.

4-4 HELIPADS.

Helipads allow for a helicopter hovering, landing, and takeoff. Except at facilities where helicopter runways are provided, helipads are the landing and takeoff locations for helicopters. The Army and Air Force provide for four types of helipads: standard VFR helipad, limited use helipad, IFR helipad and elevated helipad. The Navy and Marine Corps provide only one type of helipad: standard size helipad. Use High Temperature Concrete and neoprene joint sealants in locations where stationary V-22 nacelle exhaust exposure is ten minutes or greater. See Chapter 8 for additional materials information. The type of helipad depends on these operational requirements:

4-4.1 Standard VFR Helipad.

VFR design standards are used when no requirement exists or will exist in the future for an IFR helipad. Criteria for this type of helipad permit the accommodation of most helipad lighting systems.

4-4.2 Limited Use Helipad.

This is a VFR rotary-wing facility for use only by observation, attack, medical evacuation and utility (OH, AH, HH, and UH) helicopters. These type of helipads support only occasional operations at special locations such as hospitals, headquarters facilities, missile sites, and other similar locations. Limited use helipads may be located on airfields where one or more helipads are required to separate OH, AH, HH and UH traffic from other helicopter traffic or fixed-wing traffic.

4-4.3 IFR Helipad.

IFR design standards are used when an instrument approach capability is essential to the mission and no other instrument landing facilities, either fixed-wing or rotary-wing, are located within an acceptable commuting distance to the site.

4-4.4 Elevated Helipad.

This is a facility that has a helipad elevated above ground level on a building roof top or another structure built specifically for the pad (a ground level helipad with the pad on a mound is not an elevated helipad). For Army, elevated helipads require approval of USAASA. For Navy and Marine Corps facilities, contact the agency aviation office with safety waiver approval authority.

4-4.5 Helipad Location.

A helipad location should be selected with regard to mission requirements, overall facility development, approach-departure surfaces, and local wind conditions.

4-4.5.1 Near Runways.

When a helipad is to be located near fixed- and rotary-wing runways, its location should be based on the type of operations in accordance with the criteria in Table 4-1.

4-4.5.2 Standby Parking Pads.

Where it is necessary to have one or more helicopters on standby, an area adjacent to the helipad but clear of the landing approach and transitional surfaces should be designated for standby parking. This area will be designed as a parking apron in conformance with the criteria in Chapter 6.

4-4.6 Dimensional Criteria.

Table 4-2 presents dimensional criteria for the layout and design of helipads and hoverpoints.

Table 4-2. Rotary-Wing Helipads and Hoverpoints

Table 4-2. Rotary-Wing Helipads and Hoverpoints			
Item		Requirement	Remarks
No.	Description		
1	Size	30 m x 30 m (100 ft x 100 ft) min.	Standard VFR and IFR helipad – Army, Air Force and Navy including all V-22
		15 m x 15 m (50 ft x 50 ft) min.	Limited use VFR helipad – Army and Air Force
			Elevated Army and Air Force Helipads
		17 m x 17 m (55 ft x55 ft)	UH-60 or smaller helicopters
		30 m x 30 m (100 ft x 100 ft)	CH-47 and larger helicopters
		9 m (30 ft) diameter	Hoverpoints
2	Grade	Min. 1.0% Max. 1.5%	Grade helipad in one direction. Hoverpoints should be domed to a 150-mm (6-in) height at the center.
3	Paved shoulders		See Table 4-4.
4	Size of primary surface (center primary surface on helipad)	91.44 m x 91.44 m (300 ft x 300 ft)	Air Force and Army standard VFR helipad, including all V-22 IFR
		45.72 m x 45.72 (150 ft x 150 ft) min.	Air Force and Army limited use VFR helipad Navy and Marine Corps Standard VFR helipad Hoverpoints
		472.44 m x 228.60 m (1,550 ft x 750 ft)	Standard IFR. Long dimension in direction of helicopter approach.
		228.60 m x 228.60 m (750 ft x 750 ft)	Army and Air Force IFR same direction ingress/egress.

Table 4-2. Rotary-Wing Helipads and Hoverpoints			
Item No.	Item Description	Requirement	Remarks
			Elevated Army and Air Force Helipads
		59.44 m x 59.44 m (195 ft x195 ft)	UH-60 or smaller helicopters
		91.44 m x 91.44 m (300 ft x 300 ft)	CH-47 and larger helicopters
5	Grades within the primary surface area in any direction	Min. of 2.0% prior to channelization.* Max. 5.0%	Exclusive of pavement and shoulders. For IFR helipads, the grading requirements apply to a 91.44 m X 91.44 m (300 ft X 300 ft) area centered on the helipad. The balance of the area is to be clear of obstructions and rough graded to the extent necessary to reduce damage to aircraft in event of an emergency landing. For VFR helipads, the grade requirements apply to the entire primary surface. For elevated helipads, no obstacles may penetrate the elevation of the primary surface.
6	Length of clear zone**/protection zone	121.92 m (400 ft)	Hoverpoints, VFR, and standard IFR helipads. Begins at the end of the primary surface.
		251.46 m (825 ft)	Army and Air Force IFR same direction ingress/egress.
		335.28 m (1,100 ft)	V-22 IFR helipad.
7	Width of clear zone**/protection zone		Corresponds to the width of the primary surface. Center clear zone width on extended center of the pad.
		45.72 m (150 ft)	Air Force and Army VFR limited use helipads and hoverpoints. Navy and Marine Corps Standard VFR. See OPNAVINST 11010.16 (or latest version) for additional guidance.
		91.44 m (300 ft)	Air Force and Army standard VFR helipad and VFR helipad same direction ingress/egress.
		228.60 m (750 ft)	Standard IFR and V-22 IFR helipad

Table 4-2. Rotary-Wing Helipads and Hoverpoints			
Item		Requirement	Remarks
No.	Description		
			Elevated Army and Air Force Helipads
		59.44m (195 ft) at start of Protection Zone expanding to 89.92m (295 ft) at end of Protection Zone	UH-60 or smaller helicopters
		91.44m (300 ft) at start of Protection Zone expanding to 121.92m (400 ft) at end of Protection Zone	CH-47 and larger helicopters
8	Grades of clear zone** any direction	5.0% max	Area to be free of obstructions. Rough grade and turf when required.
9	APZ I length***	243.84 m (800 ft)	Elevated helipads, Hoverpoints, VFR, and standard IFR helipads, including V-22 IFR helipads
		121.92 m (400 ft)	Army and Air Force IFR same direction ingress/egress
10	APZ I width***	45.72 m (150 ft)	Army and Air Force VFR limited use and hoverpoints; Navy and Marine Corps standard VFR
		91.44 m (300 ft)	Army and Air Force standard VFR
		228.60 m (750 ft)	Standard IFR and V-22 IFR helipad
		 89.92 m (295 ft) 121.92 m (400 ft)	Elevated Army and Air Force Helipads UH-60 or smaller helicopters CH-47 or larger helicopters
11	Distance between centerline of helipad and fixed- or rotary-wing runways		See Table 4-1.

* Bed of channel may be flat.
** The clear zone area for helipads corresponds to the clear zone land use criteria for fixed-wing airfields as defined in DoD AICUZ standards. The remainder of the approach-departure zone corresponds to APZ I land use criteria similarly defined. APZ II criteria is not applicable for rotary-wing aircraft.
*** There are no grading requirements for APZ I.

NOTES:

1. Metric units apply to new airfield construction and, where practical, modification to existing airfields and heliports, as discussed in paragraph 1-3.4.
2. The criteria in this manual are based on aircraft specific requirements and are not direct conversions from inch-pound (English) dimensions. Inch-pound units are included only as a reference to the previous standard.
3. Airfield and heliport imaginary surfaces and safe wingtip clearance dimensions are shown as a direct conversion from inch-pound to SI units.

4-4.7 Layout Criteria.

Layouts for standard, limited use, and IFR helipads, including clear zones, are illustrated in Figures 4-8 through 4-10.

4-5 SAME DIRECTION INGRESS/EGRESS.

Helipads with same direction ingress/egress allow a helicopter pad to be located in a confined area where approach-departures are made from only one direction. The approach may be either VFR or IFR. For the USAF and Army, single direction ingress/egress VFR limited use helipads are configured as shown in Figure 4-12 using the criteria given in Tables 4-2 and 4-7.

4-5.1 Dimensions Criteria.

Table 4-2 presents dimensional criteria for VFR and IFR same direction ingress/egress helipads.

4-5.2 Layout Criteria.

Layout for VFR, VFR limited use, and IFR same direction ingress/egress helipads are illustrated in Figures 4-11, 4-12 and 4-13.

4-6 HOVERPOINTS.

4-6.1 General.

A hoverpoint is a prepared and marked surface used as a reference or control point for air traffic control purposes by arriving or departing helicopters.

4-6.2 Dimensions.

Table 4-2 presents dimensional criteria for the layout and design of hoverpoints. Layout. Hoverpoint design standards are illustrated in Figure 4-14.

4-7 ELEVATED HELIPADS – ARMY AND AIR FORCE ONLY.

4-7.1 General.

Elevating helipads 6 feet (1.8 m) or more above the level of the roof will generally minimize the turbulent effect of air flowing over the roof edge. While elevating the platform helps reduce or eliminate the air turbulence effects, a safety net may be required. Helipads should be constructed of metal or concrete. Surfaces should have a broomed pavement or other roughened finish that provides a skid-resistant surface for helicopters and non-slippery footing for people. The primary surface should be contained on the structure.

4-7.2 Rooftop and Other Elevated Helipads.

Elevated helipads and any supporting helipad structure should be capable of supporting the dynamic loads of the design helicopter in accordance with UFC 3-301-01, Structural Engineering. For UH-60 and smaller rotor diameter use 22,000 LB as the minimum aircraft weight for structural design. For CH-47, use 50,000 LB as the minimum aircraft weight for structural design. Use heavier design weight if mission aircraft is heavier than the minimum.

4-7.3 Dimensions.

Table 4-2 presents dimensional criteria for the layout and design of elevated helipads.

Figure 4-4. Elevated Helipad Layout Criteria for UH-60 or Smaller Rotor Diameter Helicopters (8H:1V)

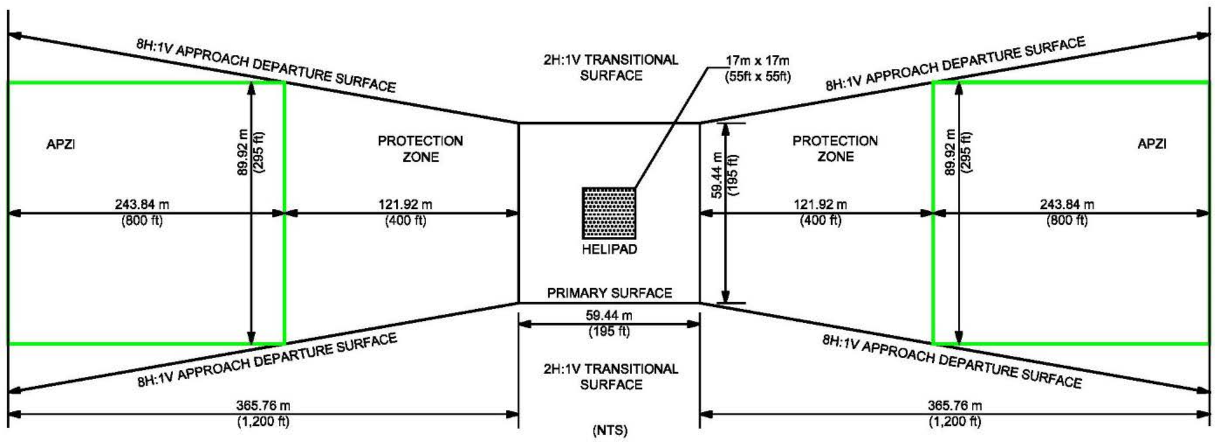

Figure 4-5. Elevated Helipad Layout Criteria for CH-47 and Larger Helicopters (8H:1V)

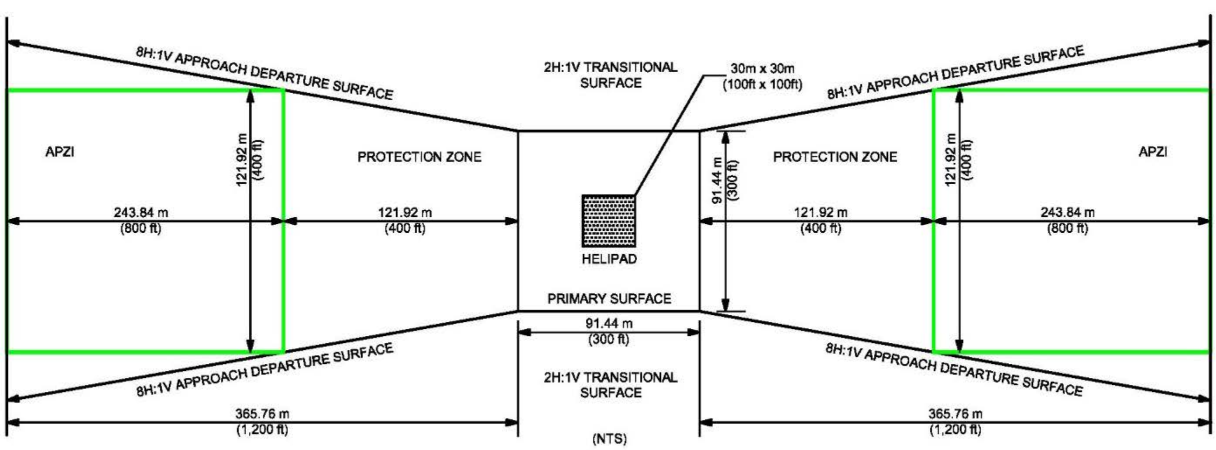

Figure 4-6. Elevated Hospital Helipad Layout Criteria for UH-60 or Smaller Rotor Diameter Helicopters (16.4H:1V)

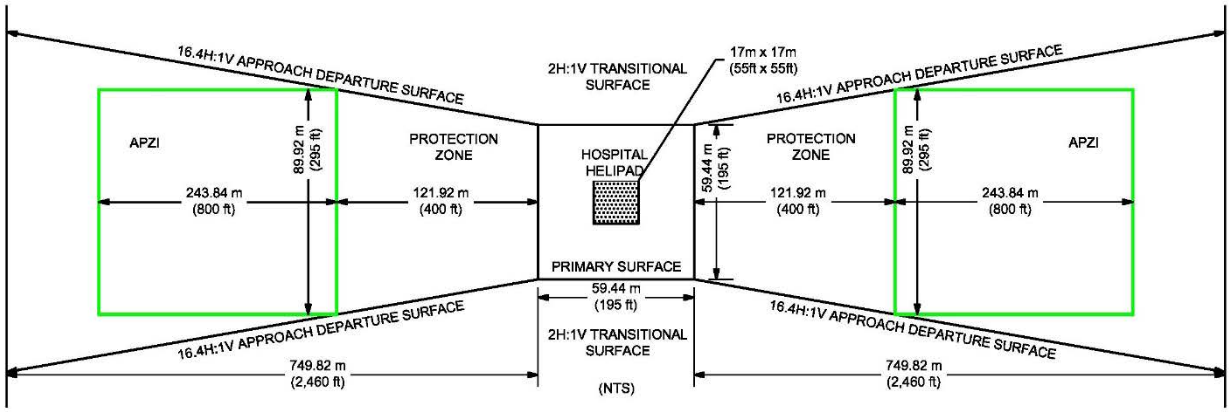

Figure 4-7. Elevated Hospital Helipad Layout Criteria for CH-47 and Larger Helicopters (16.4H:1V)

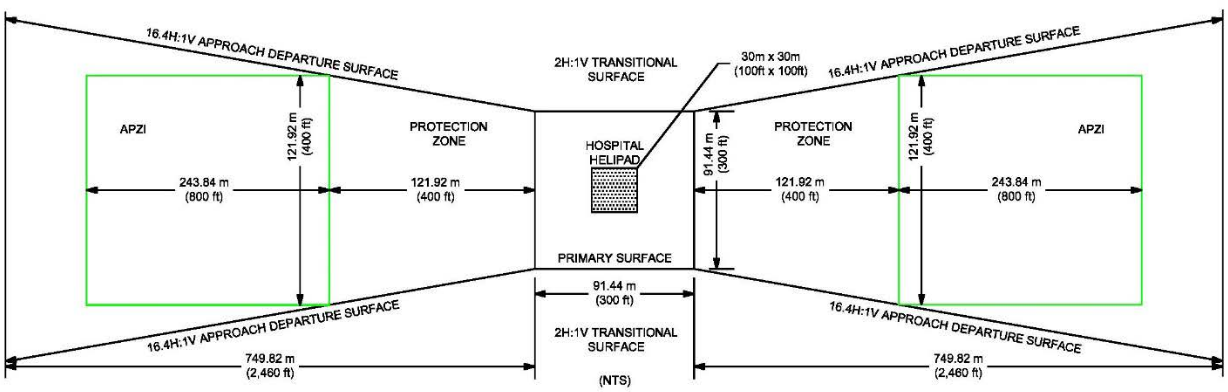

4-7.4 Safety Net.

When the helipad is on a platform elevated more than 30 inches (76 cm) above its surroundings, a safety net, not less than 5 feet (1.5 m) wide, should be provided. A railing or fence should not be used since it would be a safety hazard during helicopter operations. The safety net should have a load carrying capability of 25 lb/ft^2 (122 kg/m^2). The net should not project above the level of the helipad. Both the inside and outside edges of the safety net should be fastened to a solid structure.

4-7.5 Access to Elevated Helipads.

OSHA requires two separate access points for an elevated structure such as an elevated helipad. Hospital heliports should provide access to and from the helipad via a ramp in order to provide for quick and easy transportation of a patient on a gurney. Ramps should be built in accordance with state and local requirements. The width of the ramp, and any turns in the ramp, should be wide enough to accommodate a gurney with a person walking on each side. Straight segments of the ramp should be not less than 6 feet (1.8 m) wide. Additional width may be required in the turns. The ramp surface should provide a slip-resistant surface. The slope of the ramp should be no steeper than 12:1 (12 unit horizontal in 1 units vertical). Inside the primary surface any handrails should not extend above the elevation of the helipad. Where a handrail complying with Appendix A of 49 CFR 37, Section 4.8, is not provided, other means should be provided to protect personnel from fall hazards.

4-7.6 Fixed Objects within a Primary Surface.

No fixed object shall be permitted within a primary surface or protection zone, except for frangibly mounted objects that, due to their function, must be located there.

4-7.7 Obstructions.

Elevator penthouses, cooling towers, exhaust vents, fresh-air vents, and other raised features can impact helipad operations. Helicopter exhausts can impact building air quality if the helipad is too close to fresh-air vents. These issues shall be resolved during facility design. In addition, control mechanisms should be established to ensure that obstruction hazards are not installed after the helipad is operational. Those objects whose functions require them to be located within these areas should be less than a height of 8 inches (20 cm), be frangible, and must not penetrate the approach/departure surfaces or transitional surfaces.

4-7.8 Protection Zone.

The protection zone takes the place of a clear zone for elevated helipads. It is an imaginary planar surface that starts at the elevation of the helipad and extends out 400'. The area underlying the protection zone has to be owned or controlled by the installation. All incompatible objects or facilities should be removed from this area. Incompatible facilities include, occupied structures, main entrances, other areas where people congregate, and facilities that might create smoke or steam that would obscure visibility."

4-8 ROTARY-WING LANDING LANES.

Except when used as an autorotation lane, these lanes permit efficient simultaneous use by a number of helicopters in a designated traffic pattern.

4-8.1 Requirements for a Landing Lane.

Occasionally at airfields or heliports, helicopters are parked densely on mass aprons. When this occurs, there is usually a requirement to provide landing and takeoff facilities that permit more numerous rapid launch and recovery operations than otherwise could be provided by a single runway or helipad. Increased efficiency can be attained by providing one or more of, but not necessarily limited to, these options:

- Multiple helipads or hoverpoints
- A rotary-wing runway of length in excess of the criteria in Table 4-1
- Helicopter landing lanes

4-8.2 Landing Lane Location.

Landing lanes are typically located in front of the paved apron on which the helicopters park, as shown in Figure 4-15.

4-8.3 Touchdown Points.

The location at which the helicopters are to touchdown on the landing lane are designated with 1.2m (4') x 1.8m (6') rectangular panel markings placed at equal intervals on the landing lane centerline not less than 400 feet apart.

4-8.4 Dimensions.

Table 4-3 presents dimensional criteria for the layout and design of rotary-wing landing lanes.

4-8.5 Layout.

A layout for rotary-wing landing lanes is illustrated in Figure 4-15.

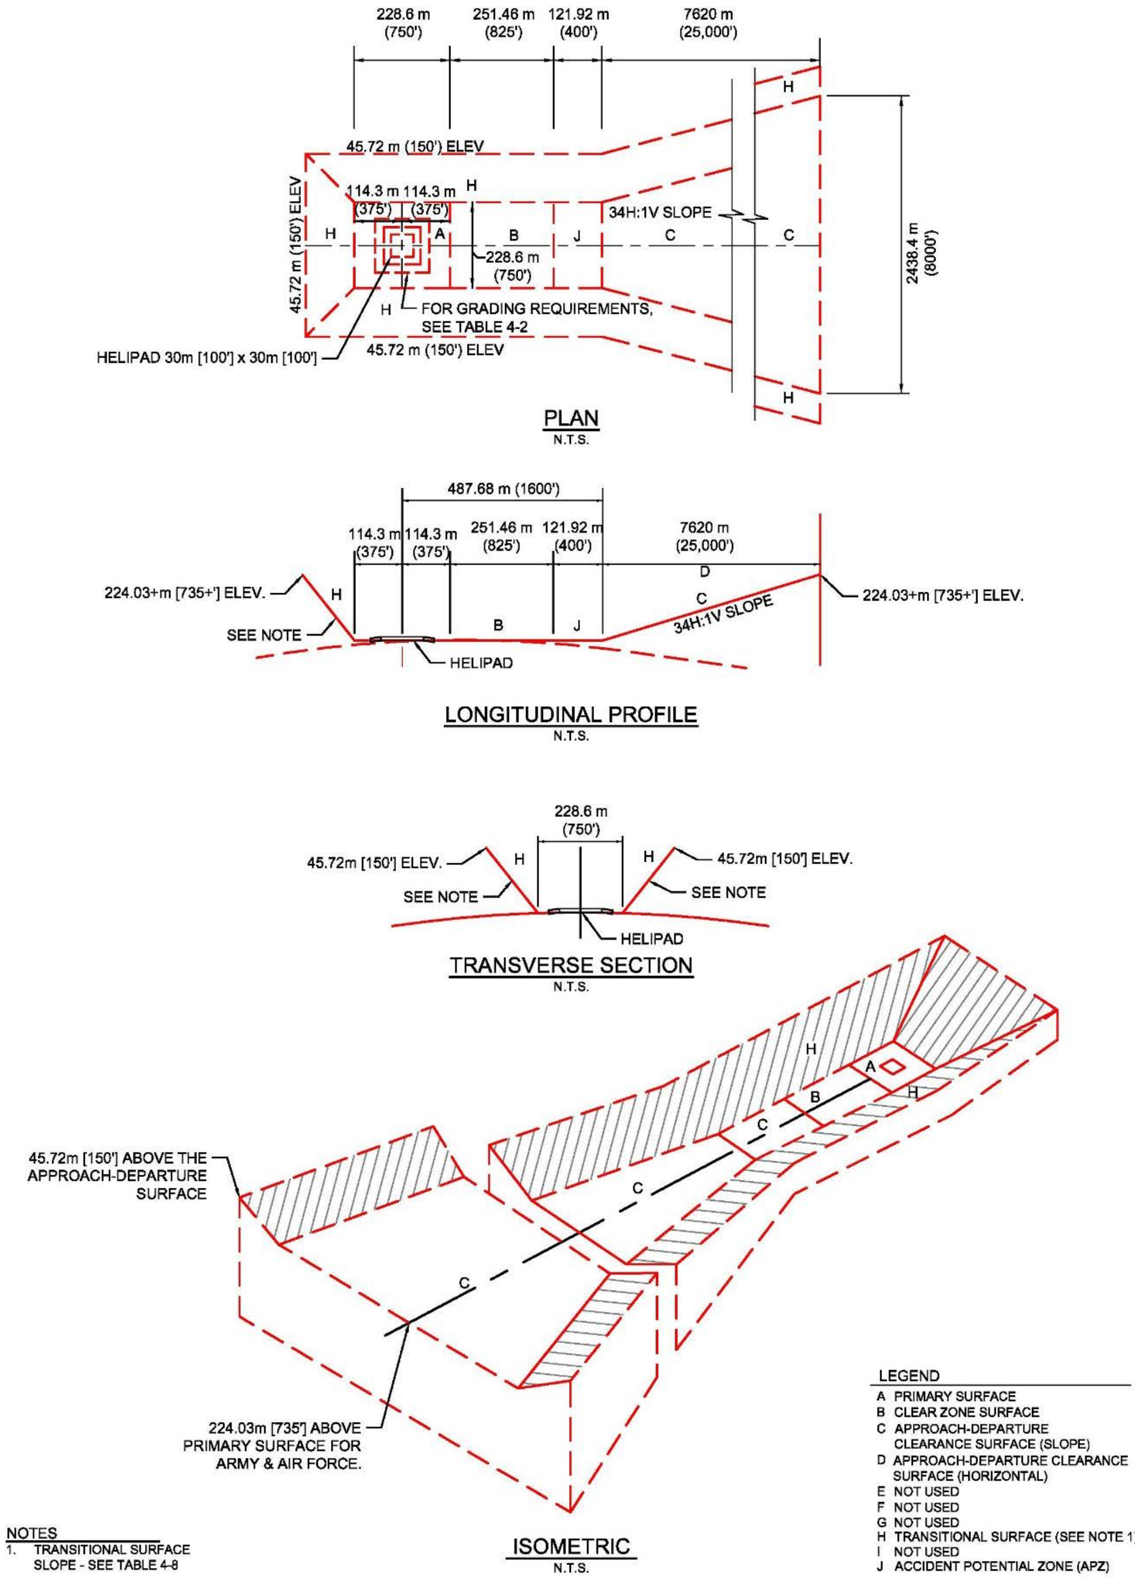

Figure 4-14. Helicopter Hoverpoint

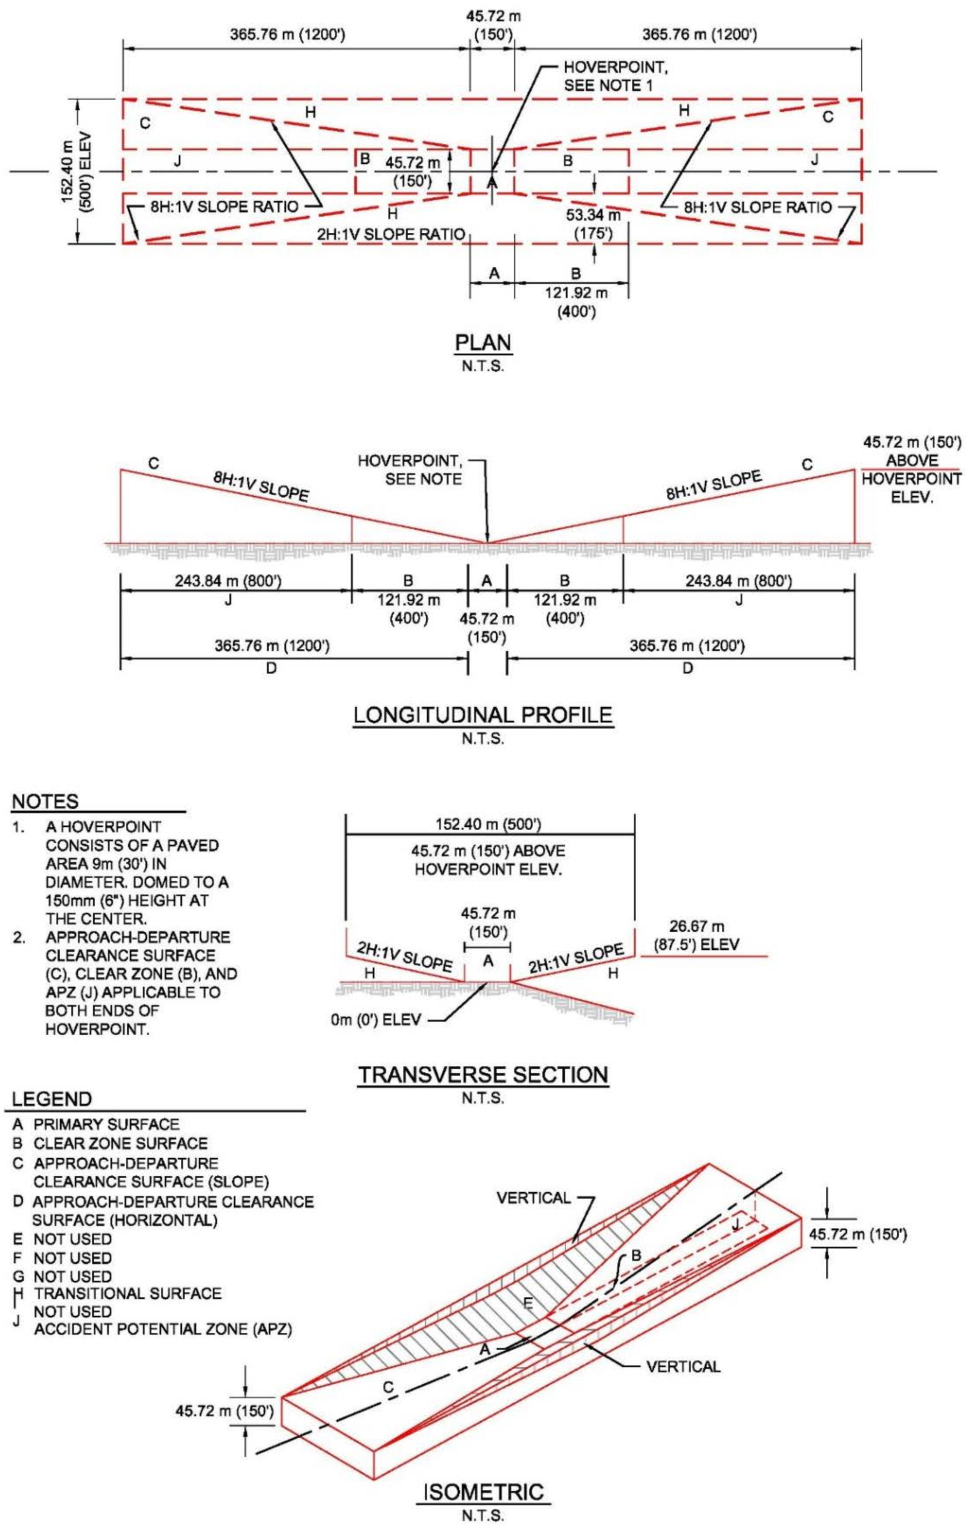

Table 4-3. Rotary-Wing Landing Lanes

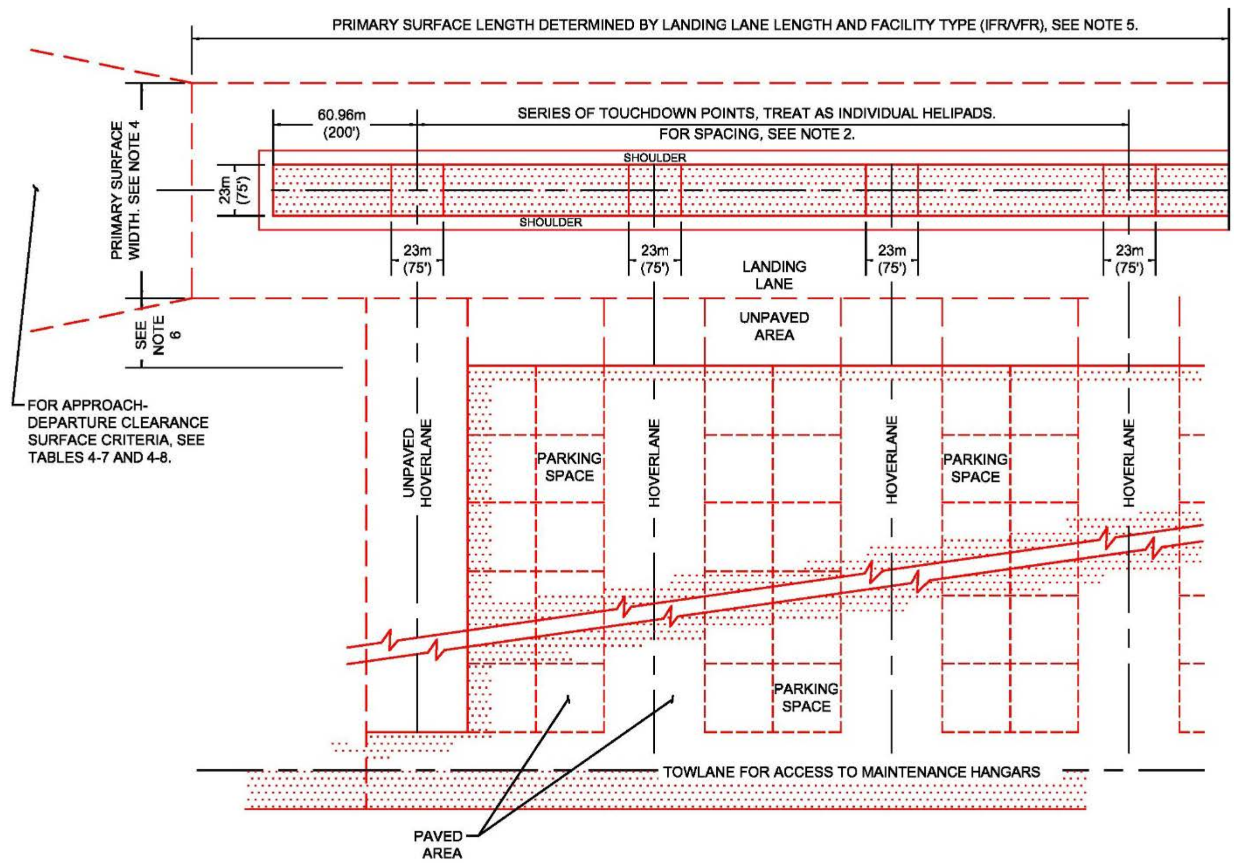
Table 4-3. Rotary-Wing Landing Lanes			
Item			
No.	Description	Requirement	Remarks
1	Length	480 m (1,600 ft) to 600 m (2,000 ft)	Landing lane length based on the number of touchdown points. Evenly space touchdown points along the landing lane. Minimum length is for four touchdown points spaced 120 m (400 ft) apart. The first and last pad centers are 60.96 m (200 feet) inward from the ends of the landing lanes.
2	Width	23 m (75 ft)	For Navy and Marine Corps facilities, increase width to 30 m (100 ft) on landing lanes that will regularly accommodate H-53 and V-22 aircraft
3	Distance between touchdown points on landing lane, center to center	120 m, min (400 ft, min)	Provide a number of equally spaced "touchdown" or holding points with adequate separation.
4	Longitudinal grade	Max. 1.0%	Maximum longitudinal grade change is 0.167% per 30 linear meters (100 linear feet). Exceptions: 0.4% per 30 linear meters (100 linear feet) is allowable for edge of landing lanes at intersections
5	Transverse grade	Min. 1.0% Max. 1.5%	From centerline of landing lane. Landing lanes may be crowned or uncrowned
6	Paved shoulders		See Table 4-4.
7	Distance between centerlines of rotary-wing landing lanes	60.96 m (200 ft)	For operations with an active operational air traffic control tower.
		91.44 m (300 ft)	For operations without an active operational air traffic control tower.
8	Landing lane lateral clearance zone (corresponds to half the width of primary surface area)	45.72 m (150 ft)	VFR facilities. Measured perpendicularly from centerline of runway to fixed or mobile obstacles. See Table 4-1, item 6, for obstacles definition.
		114.3 m (375 ft)	IFR facilities. Measured perpendicularly from centerline of runway to fixed or mobile obstacles. See Table 4-1, item 6, for obstacles definition.
9	Grades within the primary surface area in any direction	Min 2.0% Max 5.0%	Exclusive of pavement and shoulders.
10	Overrun	See Remarks	See Table 4-5
11	Clear zone*	See Remarks	See Table 4-6.
12	APZ I*	See Remarks	See Table 4-6.
13	Distance between centerlines of a fixed-wing runway and landing lane	See Table 4-1, item 9	
		213.36 m min (700 ft min)	

* The clear zone area for landing lanes corresponds to the clear zone land use criteria for fixed-wing airfields as defined in DoD AICUZ standards. The remainder of the approach-departure zone corresponds to APZ I land use criteria similarly defined. APZ II criteria are not applicable for rotary-wing aircraft.

NOTES:

1. Metric units apply to new airfield construction and, where practical, modification to existing airfields and heliports, as discussed in paragraph 1-3.4.
2. The criteria in this manual are based on aircraft specific requirements and are not direct conversions from inch-pound (English) dimensions. Inch-pound units are included only as a reference to the previous standard.
3. Airfield and heliport imaginary surfaces and safe wingtip clearance dimensions are shown as a direct conversion from inch-pound to SI units.

Figure 4-15. Rotary-Wing Landing Lane



NOTES

1. WIDTH OF HOVER LANES AND PARKING SPACES ARE DETERMINED BY THE TYPE OF HELICOPTER USED AND THE CLEARANCES REQUIRED.
2. THE DISTANCE BETWEEN THE TOUCHDOWN POINTS IS DETERMINED BY THE DISTANCE BETWEEN HOVERLANE CENTERLINES AND IS USUALLY NOT LESS THAN 120m (400') CENTER-TO-CENTER.
3. SIZE AND LAYOUT OF THE PARKING APRON VARIES WITH THE TYPE OF HELICOPTER USED AND THE MISSION REQUIREMENTS.
4. PRIMARY SURFACE WIDTH IS 91.44m (300') FOR VFR FACILITIES AND 228.60m (750') FOR IFR FACILITIES.
5. PRIMARY SURFACE LENGTH IS THE LANDING LANE LENGTH PLUS 45.72m (150') FOR ARMY AND AIR FORCE VFR LANDING LANES AND 60.96m (200') FOR NAVY AND MARINE CORPS VFR LANDING LANES. FOR ARMY, AIR FORCE, NAVY AND MARINE CORPS IFR LANDING LANES, THE PRIMARY SURFACE LENGTH IS THE LANDING LANE LENGTH PLUS 121.92m (400').
6. MINIMUM DISTANCE BETWEEN THE PRIMARY SURFACE AND THE APRON IS DETERMINED BY THE TRANSITIONAL SURFACE CLEARANCE TO PARKED AIRCRAFT. TRANSITIONAL SURFACE SLOPES ARE SHOWN IN TABLES 4-7 AND 4-8.

LEGEND

PAVEMENT

4-9 AIR FORCE HELICOPTER SLIDE AREAS (OR “SKID PADS”).

VFR helicopter runway criteria described in Table 4-1 and shown in Figures 4-1 and 4-8 (in terms of length, width, grade, and imaginary surfaces) are suitable for slide areas. The forces associated with helicopters landing at a small (but significant) rate of descent, and between 10 and 30 knots of forward velocity, require that slide area surfaces have both good drainage and some resistance to rutting; however, these landing surfaces need not be paved. Refer to UFC 3-260-02 for helicopter slide area structural criteria.

4-10 SHOULDERS FOR ROTARY-WING FACILITIES.

Unprotected areas adjacent to runways and overruns are susceptible to erosion caused by rotor wash. The shoulder width for rotary-wing runways, helipads, and landing lanes, shown in Table 4-4, includes both paved and unpaved shoulders. Paved shoulders are required adjacent to all helicopter operational surfaces, including runways, helipads, landing lanes, and hoverpoints. The unpaved shoulder must be graded to prevent water from ponding on the adjacent paved area. The drop-off next to the paved area prevents turf, which may build up over the years, from ponding water. Rotary-wing facility shoulders are illustrated in Figures 4-1 through 4-11. See paragraph 2-12 for requirements for designing buried utility structures in shoulders.

Table 4-4. Shoulders for Rotary-Wing Facilities

Table 4-4. Shoulders for Rotary-Wing Facilities			
Item		Requirement	Remarks
No.	Description		
1	Total width of shoulders (paved and unpaved) adjacent to all operational pavements	7.5 m (25 ft)	May be increased when necessary to accommodate dual operations with fixed-wing aircraft
2	Paved shoulder width	7.5 m (25 ft)	Air Force, Army, Navy and Marine Corps Exception: For Navy and Marine Corps helipads, use 3.75 m (12.5 ft) paved shoulders. Note: For V-22 and CH-53 taxiways, increase paved shoulder width to ensure 30 m (100 ft) total width (taxiway and shoulder) of paved surface.
3	Longitudinal grade	Variable	Conform to the longitudinal grade of the abutting primary pavement
4	Transverse grade	2.0% min 4.0% max	Slope downward from edge of pavement
5	Grade (adjacent to paved shoulder)	(a) 40-mm (1.5-in) drop-off at edge of paved shoulder +/- 13 mm (0.5 in) (b) minimum 2%, maximum 5% within the primary surface	Primary surface and clear zone criteria apply beyond this point.

NOTES:
1. Metric units apply to new airfield construction and, where practical, modification to existing airfields and heliports, as discussed in paragraph 1-3.4.
2. The criteria in this manual are based on aircraft specific requirements and are not direct conversions from inch-pound (English) dimensions. Inch-pound units are included only as a reference to the previous standard.
3. Airfield and heliport imaginary surfaces and safe wingtip clearance dimensions are shown as a direct conversion from inch-pound to SI units.

4-11 OVERRUNS FOR ROTARY-WING RUNWAYS AND LANDING LANES.

Overruns are required at the end of all rotary-wing runways and landing lanes. Table 4-5 shows the dimensional requirements for overruns for rotary-wing runways and landing lanes. The pavement in the overrun is considered a paved shoulder. Rotary-wing overruns for runways and landing lanes are illustrated in Figures 4-1, 4-2, and 4-15. See paragraph 2-12 for requirements for designing buried utility structures in overruns.

Table 4-5. Overruns for Rotary-Wing Runways and Landing Lanes

Table 4-5. Overruns for Rotary-Wing Runways and Landing Lanes			
Item			
No.	**Description**	**Requirement**	**Remarks**
1	Total length (paved and unpaved)	23 m (75 ft)	
2	Paved length of overrun	7.5 m (25 ft) 0 m (0 ft)	Air Force and Army only Navy
3	Width	38 m (125 ft)	Width of runway plus shoulders A minimum width of 45 m (150 ft) for airfields that regularly accommodate H-53 and V-22 aircraft (30-m (100-ft) runway and 7.5-m (25-ft) shoulders)
4	Longitudinal centerline grade	Same as last 150 m (500 ft) of runway. Remainder Max. 1.0%	To avoid abrupt changes in longitudinal grade between the runway and overrun, the maximum change of grade is 2.0% per 30 linear m (100 linear ft)
5	Transverse grade (paved and unpaved)	Min. 2.0% Max. 3.0%	Warp to meet runway and shoulder grades.

NOTES:

1. Metric units apply to new airfield construction and, where practical, modification to existing airfields and heliports, as discussed in paragraph 1-3.4.
2. The criteria in this manual are based on aircraft specific requirements and are not direct conversions from inch-pound (English) dimensions. Inch-pound units are included only as a reference to the previous standard.
3. Airfield and heliport imaginary surfaces and safe wingtip clearance dimensions are shown as a direct conversion from inch-pound to SI units.

4-12 CLEAR ZONE AND ACCIDENT POTENTIAL ZONE (APZ).

The clear zone and APZ are areas on the ground, located under the rotary-wing approach-departure surface. The clear zone and APZ are required for rotary-wing runways, helipads, landing lanes, and hoverpoints.

4-12.1 Clear Zone Land Use.

The clear zone for rotary-wing facilities must be free of obstructions, both natural and man-made, and rough-graded to minimize damage to an aircraft that runs off or lands short of the end of the landing surface. In addition, the clear zone permits recovery of aircraft that are aborted during takeoff. The clear zone should be either owned or protected under a long-term lease. Land use for the clear zone area for rotary-wing facilities corresponds to the clear zone land use criteria for fixed-wing airfields as defined for DoD AICUZ and Service-specific standards and as discussed in Chapter 3.

4-12.2 Accident Potential Zone (APZ).

Land use for the APZ area at rotary-wing facilities corresponds to the APZ land use criteria for fixed-wing airfields as defined in DoD AICUZ and Service-specific standards and as discussed in Chapter 3. Ownership of the APZ is desirable but not required. If ownership is not possible, land use should be controlled through long-term lease agreements or local zoning ordinances.

4-12.3 Dimensions.

Table 4-6 shows the dimensional requirements for the clear zone and APZ. These dimensions apply to rotary-wing runways, helipads, landing lanes, and hoverpoints, depending on whether they support VFR or IFR operations. Layout of the clear zone and APZ are shown in Figures 4-1, 4-2, and 4-8 through 4-15.

4-13 IMAGINARY SURFACES FOR ROTARY-WING RUNWAYS, HELIPADS, LANDING LANES, AND HOVERPOINTS.

Rotary-wing runways, helipads, landing lanes, and hoverpoints have imaginary surfaces similar to the imaginary surfaces for fixed-wing facilities. The imaginary surfaces are defined planes in space that establish clearance requirements for helicopter operations. An object, either man-made or natural, that projects through an imaginary surface plane is an obstruction to air navigation. Layout of the rotary-wing airspace imaginary surfaces is provided in Tables 4-7 and 4-8 and Figures 4-1 through 4-15. Rotary-wing airspace imaginary surfaces are defined in the glossary and listed here:
Primary surface

- Approach-departure clearance surface (VFR)
- Approach-departure clearance surface (VFR limited use helipads)
- Approach-departure clearance surface (IFR)
- Horizontal surface (IFR)
- Transitional surfaces

Table 4-6. Rotary-Wing Runway and Landing Lane Clear Zone and APZ

Table 4-6. Rotary-Wing Runway and Landing Lane Clear Zone and APZ1,2			
Item			
No.	**Description**	**Requirement**	**Remarks**
1	Clear zone length	121.92 m (400 ft)	Clear zone begins at the end of the primary surface.
2	Clear zone width (center width on extended runway/landing lane centerline) (corresponds to the width of the primary surface)	91.44 m (300 ft)	VFR rotary-wing runways and landing lanes See note 2.
		228.60 m (750 ft)	IFR rotary-wing runways and landing lanes See note 2.
3	Grades in clear zone in any direction	2.0% Min. 5.0% Max.	Clear zone only Area to be free of obstructions. Rough-grade and turf when required.
4	APZ I length	243.84 m (800 ft)	See notes 2 and 3.
5	APZ I width	91.44 m (300 ft)	VFR rotary-wing runways and landing lanes See notes 2 and 3.
		228.60 m (750 ft)	IFR rotary-wing runways and landing lanes See notes 2 and 3.

NOTES:

1. The clear zone area for rotary-wing runways and landing lanes corresponds to the clear zone land use criteria for fixed-wing airfields as defined in DoD and Service-specific AICUZ standards and as discussed in Chapter 3 . The remainder of the approach-departure zone corresponds to APZ I land use criteria similarly defined. APZ II criteria is not applicable for rotary-wing aircraft.
2. No grading requirements for APZ I.
3. Metric units apply to new airfield construction and, where practical, modification to existing airfields and heliports, as discussed in paragraph 1-3.4.
4. The criteria in this manual are based on aircraft specific requirements and are not direct conversions from inch-pound (English) dimensions. Inch-pound units are included only as a reference to the previous standard.
5. Airfield and heliport imaginary surfaces and safe wingtip clearance dimensions are shown as a direct conversion from inch-pound to SI units.

Table 4-7. Rotary-Wing Imaginary Surface for VFR Approaches

Item		Legend in Figures	Helicopter Runway and Landing Lane	Helipad		Elevated Helipad	Remarks
No.	Description			Air Force and Army VFR Standard	Air Force and Army VFR Limited Use; Navy and Marine Corps Standard Helipad and Hoverpoints[1,2]	Air Force and Army

Item		Legend in Figures	Helicopter Runway and Landing Lanes	Helipad		Remarks
No.	Description			Standard	Same Direction Ingress/Egress	
						scribing an arc about the end of each runway or landing lane, and interconnecting these arcs with tangents
			1,554.48 m (5,100 ft) for 34:1 approach-departure surfaces	N/A	N/A	Navy and Marine Corps airfields only
			N/A	1,402.08 m (4,600 ft)	1,402.08 m (4,600 ft)	Navy and Marine Corps airfields only. Circular in shape, located 45.72 m (150 ft) above the established heliport or helipad elevation, defined by scribing an arc with a 1,402.08 m (4,600 ft) radius about the center point of the helipad
14	Elevation of horizontal surface	H	45.72 m (150 ft)	45.72 m (150 ft)	45.72 m (150 ft)	Navy and Marine Corps airfields only

NOTES:
1. Metric units apply to new airfield construction and, where practical, modification to existing airfields and heliports, as discussed in paragraph 1-3.4.
2. The criteria in this manual are based on aircraft specific requirements and are not direct conversions from inch-pound (English) dimensions. Inch-pound units are included only as a reference to the previous standard.
3. Airfield and heliport imaginary surfaces and safe wingtip clearance dimensions are shown as a direct conversion from inch-pound to SI units.
4. N/A = not applicable

4-14 OBSTRUCTIONS AND AIRFIELD AIRSPACE CRITERIA.

If the imaginary surface around a rotary-wing runway, helipad, elevated helipad, landing lane, or hoverpoint is penetrated by man-made or natural objects as defined in 14 CFR Part 77, Paragraph 77.23 “Standards for Determining Obstruction”, the penetrating object is an obstruction.

THIS PAGE INTENTIONALLY BLANK

CHAPTER 5
TAXIWAYS

5-1 CONTENTS.

This chapter presents design standards and considerations for fixed- and rotary-wing taxiways.

5-2 TAXIWAY REQUIREMENTS.

Taxiways provide for ground movement of fixed- and rotary-wing aircraft. Taxiways connect the runways, helipads and other landing/takeoff surfaces of the airfield with the parking and maintenance areas and provide access to hangars, docks, and various parking aprons and pads.

5-3 TAXIWAY SYSTEMS.

5-3.1 Basic.

The basic airfield layout consists of a taxiway connecting the center of the runway, helipads and other landing/takeoff surfaces with the parking apron. This system limits the number of aircraft operations at an airfield. Departing aircraft must taxi on the runway to reach the runway threshold. When aircraft are taxiing on the runway, no other aircraft is allowed to use the runway. If runway operations are minimal or capacity is low, the basic airfield layout with one taxiway may be an acceptable layout.

5-3.2 Parallel Taxiway.

A taxiway parallel for the length of the runway, with connectors to the end of the runway and parking apron, is the most efficient taxiway system. Aircraft movement is not hindered by taxiing operations on the runway, and the connectors permit rapid entrance and exit of traffic.

5-3.3 High-Speed Taxiway Turnoff.

High-speed taxiway turnoffs are located intermediate of the ends of the runway to increase the capacity of the runway. The high-speed taxiway turnoff enhances airport capacity by allowing aircraft to exit the runways at a faster speed than turnoff taxiways allow.

5-3.4 Additional Types of Taxiways.

Besides the types of taxiways already discussed in this section, there are other taxiways at an airfield. Taxiways are often referred to based on their function. Common airfield taxiways and their designations are shown in Figure 5-1.

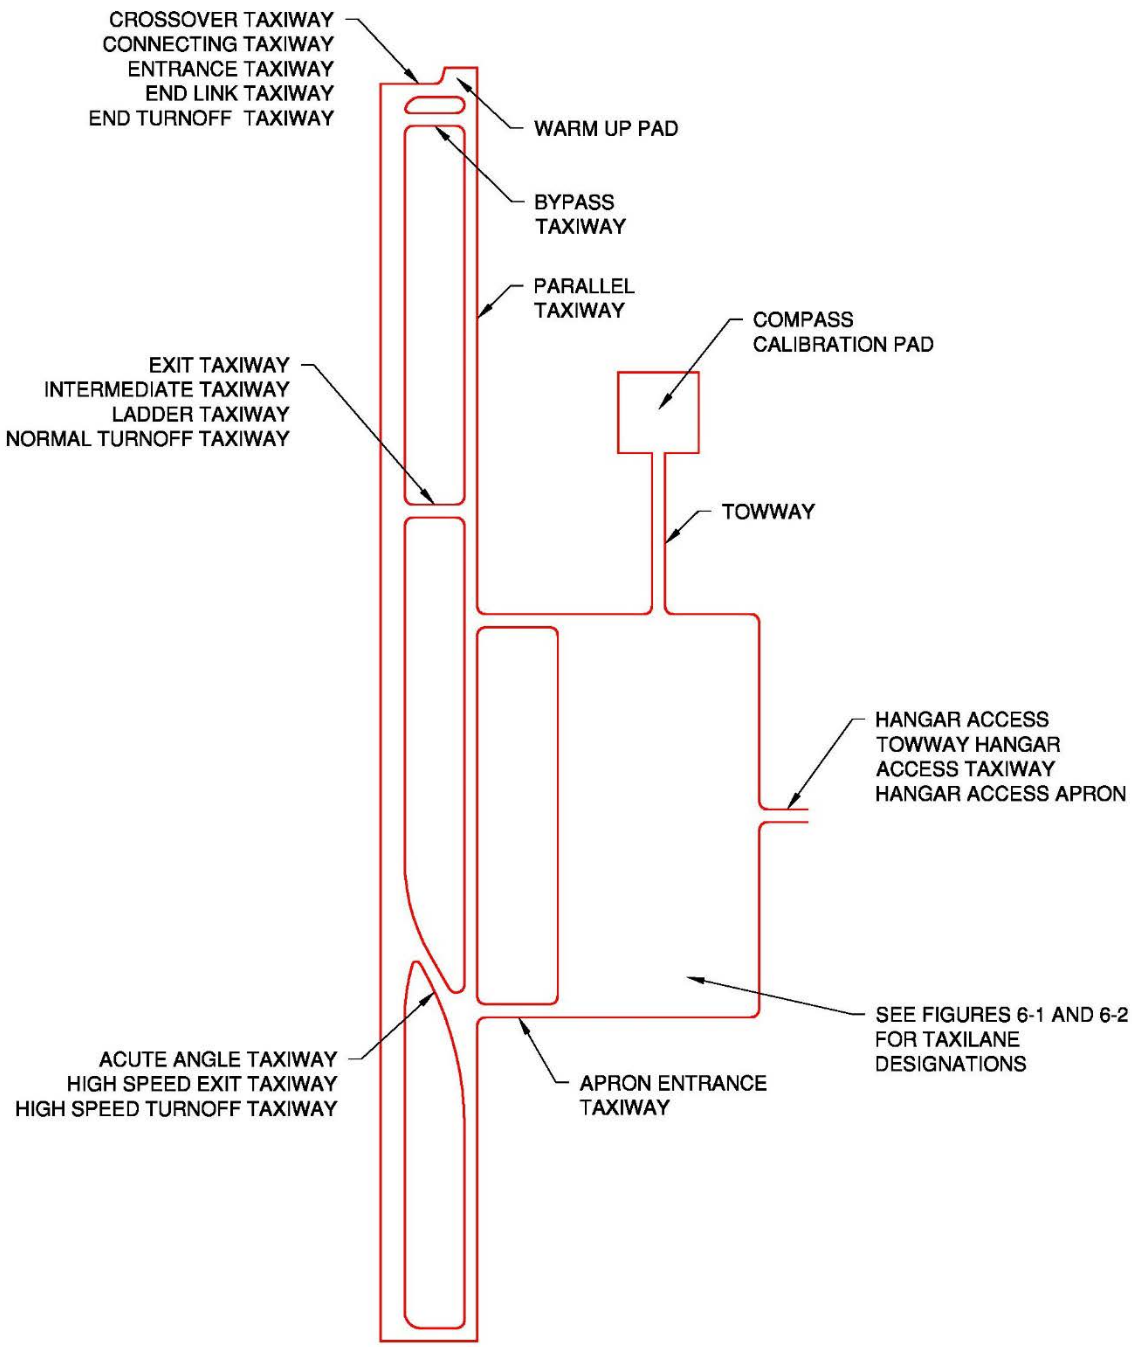
5-3.5 Taxilanes.

A taxi route through an apron is referred to as a “taxilane.” Taxilanes are discussed further in Chapter 6 for the Army and Air Force and UFC 2-000-05N for the Navy and Marine Corps.

5-3.6 USAF Taxitraks.

A taxi route connecting a dispersed parking platform (e.g., a fighter loop) to a taxiway or runway is referred to as a “taxitrak.” Dispersed parking platform and taxitrak use are limited to fighter aircraft only. Use of taxitraks by tactical transport aircraft is permitted provided minimum clearances as set by MAJCOM guidance are met. Table 5-7 presents the criteria for taxitraks.

Figure 5-1. Common Taxiway Designations



PLAN
N.T.S.

NOTES

1. TAXIWAY LAYOUT IS FOR GUIDANCE ONLY.

5-4 TAXIWAY LAYOUT.

These considerations should be addressed when planning and locating taxiways at an airfield:

5-4.1 Efficiency.

Runway efficiency is enhanced by planning for a parallel taxiway.

5-4.2 Direct Access.

Taxiways should provide as direct an access as possible from the runway, helipads and other landing/takeoff surfaces to the apron. Connecting taxiways should be provided to join the runway, helipads and other landing/takeoff surfaces exit points to the apron.

5-4.3 Simple Taxiing Routes.

A sufficient number of taxiways should be provided to prevent complicated taxiing routes. Turning from one taxiway onto another often creates confusion and may require additional airfield signs and communication with the air traffic control tower.

5-4.4 Delay Prevention.

A sufficient number of taxiways should be provided to prevent capacity delays that may result when one taxiway must service more than one runway.

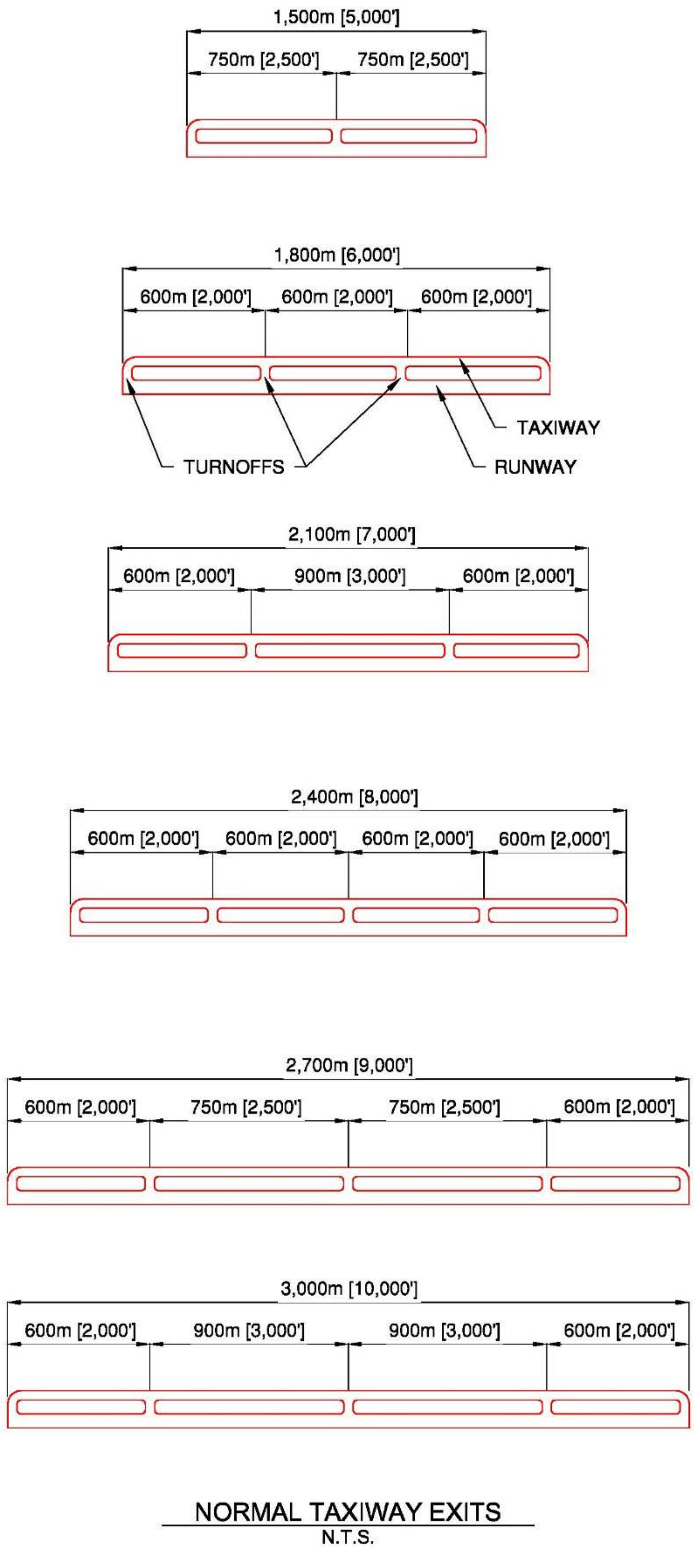
5-4.5 Runway Exit Criteria.

The number, type, and location of exits is a function of runway length, as shown in Figure 5-2 and as discussed in Chapter 2.

5-4.6 Taxiway Designation.

Use letters of the alphabet for designating taxiways. Optimally, designation of the taxiways should start at one end of the airport and continue to the opposite end, e.g., east to west or north to south (see UFC 3-535-01). Designate all separate, distinct taxiway segments. Do not use the letters I, O, or X for taxiway designations.

Figure 5-2. Spacing Requirements: Normal Taxiway Exits



5-5 FIXED-WING TAXIWAY DIMENSIONS.

The dimensions of a taxiway are based on the class of runway that the taxiway serves.

5-5.1 Criteria.

Table 5-1 presents the criteria for fixed-wing taxiway design, including clearances, slopes, and grading dimensions.

5-5.2 Transverse Cross-Section.

A typical transverse cross-section of a taxiway is shown in Figure 5-3.

Table 5-1. Fixed-Wing Taxiways

Table 5-1. Fixed-Wing Taxiways				
Item		**Class A Runway**	**Class B Runway**	
No.	**Description**	**Requirement**		**Remarks**
1	Width	15 m (50 ft)	23 m (75 ft)	Army and Air Force airfields
		12 m (40 ft)	23 m (75 ft)	Navy and Marine Corps airfields
		See Remarks		May be modified for particular mission requirements (special taxiways such as high-speed and end turn-off)
2	Total width of shoulders (paved and unpaved)	7.5 m (25 ft)	15 m (50 ft)	
3	Paved shoulder width	7.5 m (25 ft)	7.5 m (25 ft)	Army and Air Force airfields except as noted below
		N/A	3 m (10 ft)	Air Force taxiways devoted exclusively for fighter and trainer aircraft A paved shoulder up to 7.5 m (25 ft) is allowed on the outside of taxiway turns of 90 degrees or more.
		N/A	15 m (50 ft)	Airfields for B-52 aircraft. Also see note 3.
		As Required	As Required	Navy and Marine Corps airfields – where V-22 operations occur, provide total paved width (taxiway and shoulder) of 30 m (100 ft). Where rotary operations occur on fixed wing taxiways, follow paragraph 5-7.2. Air Force airfields devoted exclusively to trainer aircraft operations. Local Commanders must complete a risk

Table 5-1. Fixed-Wing Taxiways				
Item		Class A Runway	Class B Runway	
No.	Description	Requirement		Remarks
				assessment if not opting to install shoulders.
4	Longitudinal grade of taxiway and shoulders	Max 3.0%		Army, Navy, and Marine Corps airfields. For Navy and Marine Corps airfields, a maximum of 2.0% is recommended when jet aircraft are required to accelerate from a standing position.
		Max 1.5%		Air Force airfields. A gradient exception of 5.0% is permitted for a distance of not more than 120 m (400 ft) unless within 180 m (600 ft) of a runway entrance. There, a 3.0% maximum applies.
		See Remarks		Grades may be positive or negative but must not exceed the limits specified.
5	Rate of longitudinal taxiway grade change	Max 1.0% per 30 m (100 ft)		The minimum distance between two successive points of intersection (PI) is 150 m (500 ft). Changes are to be accomplished by means of vertical curves. For the Air Force and Army, up to a 0.4% change in grade is allowed without a vertical curve. A vertical curve is not necessary where a taxiway crosses a runway or taxiway crown.
6	Longitudinal sight distance	Min 600 m (2,000 ft) between eye level at 2.14 m (7 ft) and an object 3.05 m (10 ft) above taxiway pavement		Army, Navy, and Marine Corps airfield taxiways
		Min 300 m (1,000 ft). Any two points 3 m (10 ft) above the pavement must be mutually visible for the distance indicated.		Air Force airfield taxiways
7	Transverse grade of taxiway	Min 1.0% Max 1.5%		New taxiway pavements will be centerline crowned. Slope pavement downward from the centerline of the taxiway. When existing taxiway pavements have insufficient transverse gradients for rapid drainage, provide for increased gradients when the pavements are overlaid or reconstructed.

Table 5-1. Fixed-Wing Taxiways				
Item		Class A Runway	Class B Runway	Remarks
No.	Description	Requirement		
				The transverse gradients requirements are not applicable at or adjacent to intersections where pavements must be warped to match abutting pavements.
8	Transverse grade of paved shoulders	Min 2.0% Max 4.0%		Army, Navy, Marine Corps, and Air Force airfields not otherwise specified
		N/A	Min 1.5% Max 2.0%	Air Force taxiways designed for B-52 aircraft
9	Transverse grade of unpaved shoulders	(a) 40 mm (1.5 in) drop-off at edge of pavement +/- 13 mm (0.5 in) (b) 2.0% min, 4.0% max		For additional information, see Figure 5-3. Unpaved shoulders shall be graded to provide positive surface drainage away from paved surfaces.
10	Clearance from taxiway centerline to fixed or mobile obstacles (taxiway clearance line)	Min 45.72 m (150 ft)		Army, Navy, and Marine Corps airfields
		Min 45.72 m (150 ft)	Min 60.96 m (200 ft)	Air Force airfields
		See Remarks		See Table 3-2, item 12, for obstacle definition.
11	Distance between taxiway centerline and parallel taxiway/taxilane centerline	53 m (175 ft)	57 m (187.5 ft) or wingspan + 15.3 m (wingspan + 50 ft), whichever is greater	Army airfields
		53 m (175 ft)	72.4 m (237.5 ft) or wingspan + 15.3 m (wingspan + 50 ft), whichever is greater	Air Force and Navy airfields
12	Grade of area between taxiway shoulder and taxiway clearance line	Min of 2.0% prior to channelization Max 10.0%[2]		Army, Air Force, Navy, and Marine Corps airfields, except as noted below. For additional information, see Figure 5-3. Unpaved areas shall be graded to provide positive surface drainage away from paved surfaces. For cases where the entire shoulder is paved (Class A airfields and taxiways designed for B-52 aircraft), provide a 40 mm (1.5-in) drop-off at pavement edge, +/- 13 mm (0.5 in).

NOTES:

1. N/A = not applicable
2. Bed of channel may be flat. When drainage channels are required, the channel bottom cross section may be flat but the channel must be sloped to drain.
3. A 15-m (50-ft) paved shoulder is allowed for C-5, E-4, and 747 aircraft where vegetation cannot be established. Transverse grade of paved shoulder is 2% minimum to 4% maximum.
4. Metric units apply to new airfield construction and, where practical, modification to existing airfields and heliports, as discussed in paragraph 1-3.4.
5. The criteria in this manual are based on aircraft specific requirements and are not direct conversions from inch-pound (English) dimensions. Inch-pound units are included only as a reference to the previous standard.
6. Airfield and heliport imaginary surfaces and safe wingtip clearance dimensions are shown as a direct conversion from inch-pound to SI units.

Figure 5-3. Taxiway and Primary Surface Transverse Sections

N.T.S.

EDGE OF TAXIWAY FOR CLASS A RUNWAYS AND CLASS B RUNWAYS FOR B-52 AIRCRAFT
N.T.S.

5-6 ROTARY-WING TAXIWAY DIMENSIONS.

Rotary-wing taxiways are either paved or unpaved. Wheel-gear configured rotary-wing aircraft require a paved surface on which to taxi. Skid-gear configured rotary-wing aircraft taxi by hovering along a paved or unpaved taxiway. Table 5-2 presents the criteria for rotary-wing taxiway design, including taxiway widths, clearances, slopes, and grading dimensions.

Table 5-2. Rotary-Wing Taxiways

Table 5-2. Rotary-Wing Taxiways			
Item			
No.	Description	Requirement	Remarks
1	Width	15 m (50 ft)	Army and Air Force facilities
		12 m (40 ft)	Navy and Marine Corps facilities
		See Remarks	Basic width applicable to taxiways that support helicopter operations only. When dual use taxiways support fixed-wing aircraft operations, use the appropriate fixed-wing criteria.
2	Longitudinal grade	Max 2.0%	
3	Rate of longitudinal grade change	Max 2.0% per 30 m (100 ft)	Longitudinal grade changes are to be accomplished using vertical curves. For the Air Force and Army, up to a 0.4% change in grade is allowed without a vertical curve. A vertical curve is not necessary where a taxiway crosses a runway or taxiway crown.
3	Transverse grade	Min 1.0% Max 1.5%	New taxiways are to be centerline crowned.
4	Paved shoulders		See Table 5-3.
5	Clearance from centerline to fixed and mobile obstacles (taxiway clearance line)	Min 30.48 m (100 ft)	Basic helicopters clearance. Increase as appropriate for dual use taxiways. See Table 3-2, item 12, for definitions of fixed and mobile obstacles.
6	Grades within the clear area	Max 5.0%	The clear area is the area between the taxiway shoulder and the taxiway clearance line.
7	Intersection fillet radius	See Table 5-4 and Table 5-5	Use the appropriate fillet depending on the width of the rotary-wing taxiway.

NOTES:
1. Metric units apply to new airfield construction and, where practical, modification to existing airfields and heliports, as discussed in paragraph 1-3.4.
2. The criteria in this manual are based on aircraft specific requirements and are not direct conversions from inch-pound (English) dimensions. Inch-pound units are included only as a reference to the previous standard.
3. Airfield and heliport imaginary surfaces and safe wingtip clearance dimensions are shown as a direct conversion from inch-pound to SI units.

5-7 TAXIWAYS AT DUAL USE (FIXED- AND ROTARY-WING) AIRFIELDS.

5-7.1 Criteria.

For taxiways at airfields supporting both fixed- and rotary-wing aircraft operations, the appropriate fixed-wing criteria will be applied, except as noted for shoulders or for STOVL aircraft requirements.

5-7.2 Taxiway Shoulders.

A paved shoulder will be provided at dual use airfields. Shoulder widths may be increased beyond the requirement in Table 5-3 when necessary to accommodate dual operations with fixed-wing aircraft.

Table 5-3. Rotary-Wing Taxiway Shoulders

Table 5-3. Rotary-Wing Taxiway Shoulders			
Item			
No.	Description	Requirement	Remarks
1	Total width of shoulder (paved and unpaved)	7.5 m (25 ft)	May be increased when necessary to accommodate dual operations with fixed-wing aircraft
2	Paved shoulder width adjacent to all rotary-wing taxiways	7.5 m (25 ft)	May be increased when necessary to accommodate dual operations with fixed-wing aircraft. See Note 4 where fire hydrants are installed along apron shoulders. Navy and Marine Corps CH-53 & V-22: Increase shoulder width to provide minimum 30 m (100 ft) total paved width (taxiways and shoulders.
3	Longitudinal grade	Variable	Conform to the longitudinal grade of the abutting primary pavement.
4	Transverse grade	2.0% min 4.0% max	Slope downward from the edge of the pavement.
5	Grades within clear area (adjacent to paved shoulder)	(a) 40 mm (1.5 in) drop-off at edge of paved shoulder. (b) 2% min 5% max	Slope downward from the edge of the shoulder. For additional grading criteria in primary surface and clear areas, see Chapter 3 for fixed-wing facilities and Chapter 4 for rotary-wing facilities.

NOTES:

1. Metric units apply to new airfield construction and, where practical, modification to existing airfields and heliports, as discussed in paragraph 1-3.4.

2. The criteria in this manual are based on aircraft specific requirements and are not direct conversions from inch-pound (English) dimensions. Inch-pound units are included only as a reference to the previous standard.
3. Airfield and heliport imaginary surfaces and safe wingtip clearance dimensions are shown as a direct conversion from inch-pound to SI units.
4. Hydrants are to be “30-35 ft” outside the “Apron” edge. Provide paved access lane to fire hydrants where needed.

5-8 TAXIWAY INTERSECTION CRITERIA.

To prevent the main gear of an aircraft from coming dangerously close to the outside edge of the taxiway during a turn, fillets and lead-ins to fillets are provided at taxiway intersections. When an aircraft turns at an intersection, the nose gear of the aircraft usually follows the painted centerline marking. The main gears, located to the rear of the nose gear, do not remain a constant distance from the centerline stripe during the turn due to the physical design of the aircraft. The main gears pivot on a shorter radius than does the nose gear during a turn. Intersections should be designed to ensure that the main gear wheels stay a minimum of 3 m (10 ft) from the pavement edge. Intersection geometry can be determined using wheel-tracking simulation tools, or using the criteria described in paragraphs 5-8.1 and 5-8.2.

For rotary-wing taxiway intersections, use Table 5-4 and Table 5-5 with the appropriate taxiway width to determine the fillet dimensions.

For additional support see CE Dash Airfield geometrics page for report "Developing Aircraft Turning Templates" at https://cs2.eis.af.mil/sites/10159/SitePages/Service%20Page.aspx?Service=Airfield Geometry .

5-8.1 Fillet-Only Dimensions.

Fillets are required at runway-taxiway and taxiway-taxiway intersections. Fillets at runway-taxiway intersections are arcs installed in accordance with Table 5-4 and Figure 5-4. Fillets at taxiway-taxiway intersections are installed in accordance with Table 5-5 and Figure 5-5. Centerline and fillet radii used for these figures and tables are based on a 45.72-m (150-ft) centerline turning radius for runway/taxiway intersections and a 38.1-m (125-ft) centerline turning radius for taxiway/taxiway intersections using the geometry of the C-5 aircraft and a taxiway width of 22.86 m (75 ft). Larger centerline turning radii, other aircraft (e.g. Boeing 747-800 or Airbus A380), or narrower taxiways may require larger fillets; therefore, the designer must consider the most demanding situation and ensure the 3 m (10 ft) edge safety margin is provided. Use of these specific criteria are not mandatory.

Table 5-4. Runway/Taxiway Intersection Fillet Radii

Table 5-4. Runway/Taxiway Intersection Fillet Radii				
Runway Width	**Taxiway Width**	**Fillet Radius**	**Fillet Radius**	**Fillet Radius**
W	**T**	**R1**	**R2**	**R3**
More than 22.86 m (75 ft) but less than 45.72 m (150 ft)	22.86 m (75 ft)	45.72 m (150 ft)	38.1 m (125 ft)	76.2 m (250 ft)
45.72 m (150 ft) or more	22.86 m (75 ft)	38.1 m (125 ft)	38.1 m (125 ft)	76.2 m (250 ft)
More than 22.86 m (75 ft) but less than 45.72 m (150 ft)	15.24 m (50 ft)	18.29 m (60 ft)	18.29 m (60 ft)	18.29 m (60 ft)
45.72 m (150 ft) or more	15.24 m (50 ft)	15.24 m (50 ft)	15.24 m (50 ft)	15.24 m (50 ft)
More than 22.86 m (75 ft) but less than 45.72 m (150 ft)	12.19 m (40 ft)	15.24 m (50 ft)	15.24 m (50 ft)	15.24 m (50 ft)
45.72 m (150 ft) or more	12.19 m (40 ft)	15.24 m (50 ft)	15.24 m (50 ft)	15.24 m (50 ft)

Table 5-5. Taxiway/Taxiway Intersection and Taxiway Turns Fillet Radii

Table 5-5. Taxiway/Taxiway Intersection and Taxiway Turns Fillet Radii			
Taxiway Width	**Fillet Radius**	**Fillet Radius**	**Fillet Radius**
W	**R4**	**R5**	**R6**
22.86 m (75 ft)	45.72 m (150 ft)	38.1 m (125 ft)	76.2 m (250 ft)
15.24 m (50 ft)	18.29 m (60 ft)	12.19 m (40 ft)	27.43 m (90 ft)
12.19 m (40 ft)	18.29 m (60 ft)	12.19 m (40 ft)	27.43 m (90 ft)

Figure 5-4. Runway/Taxiway Intersection Fillets

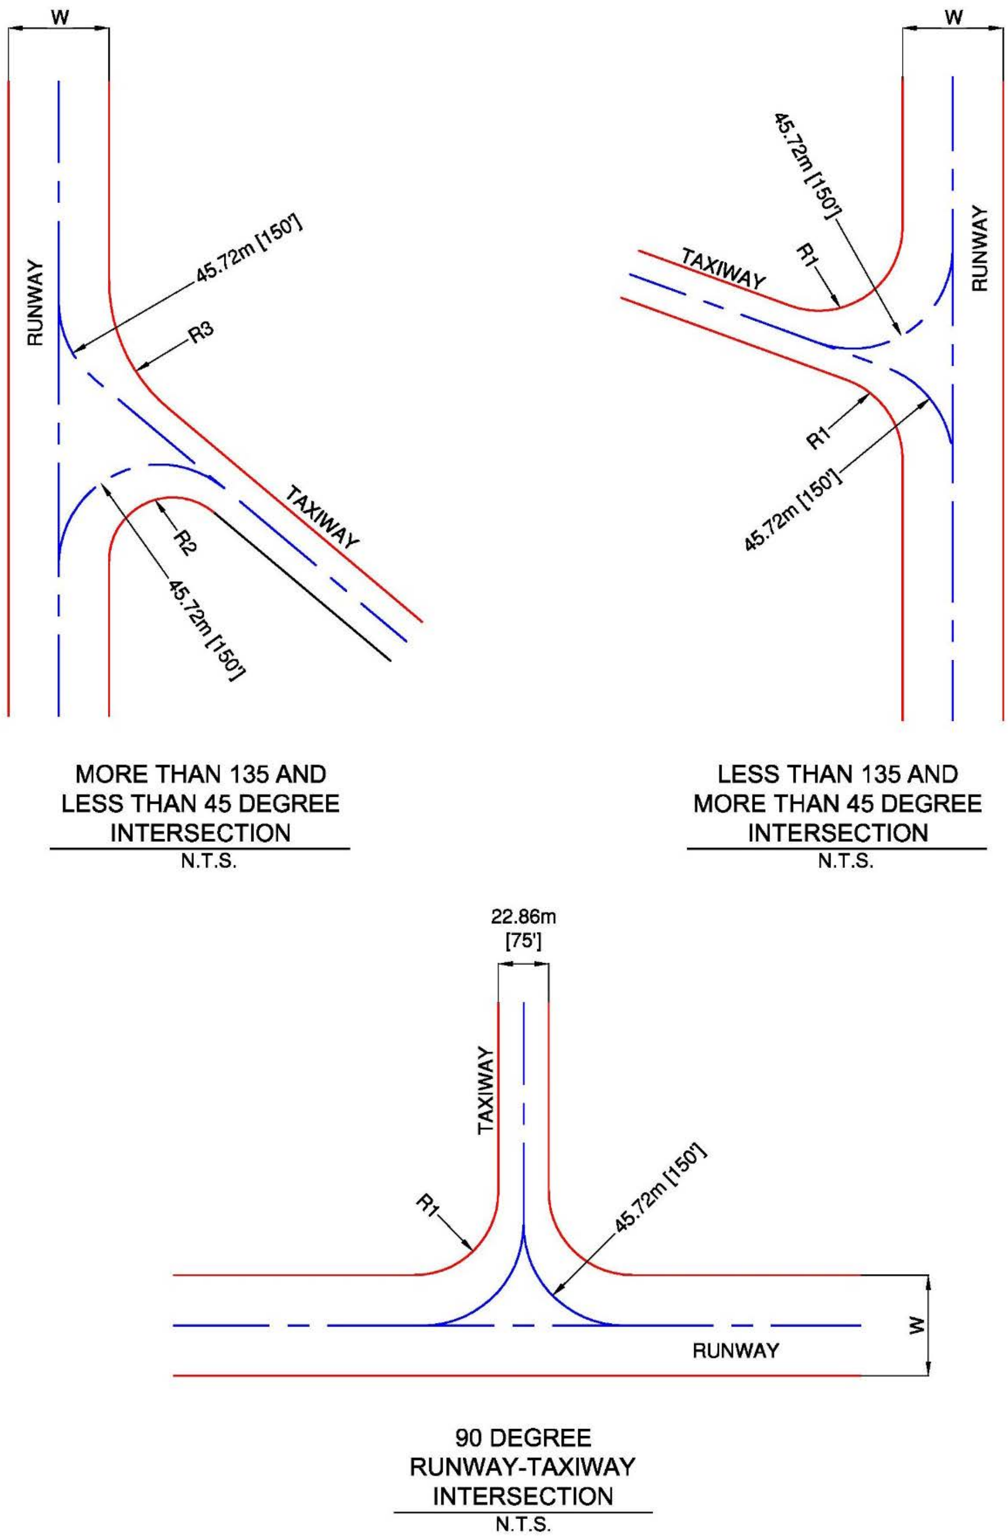

Figure 5-5. Taxiway/Taxiway Intersection Fillets

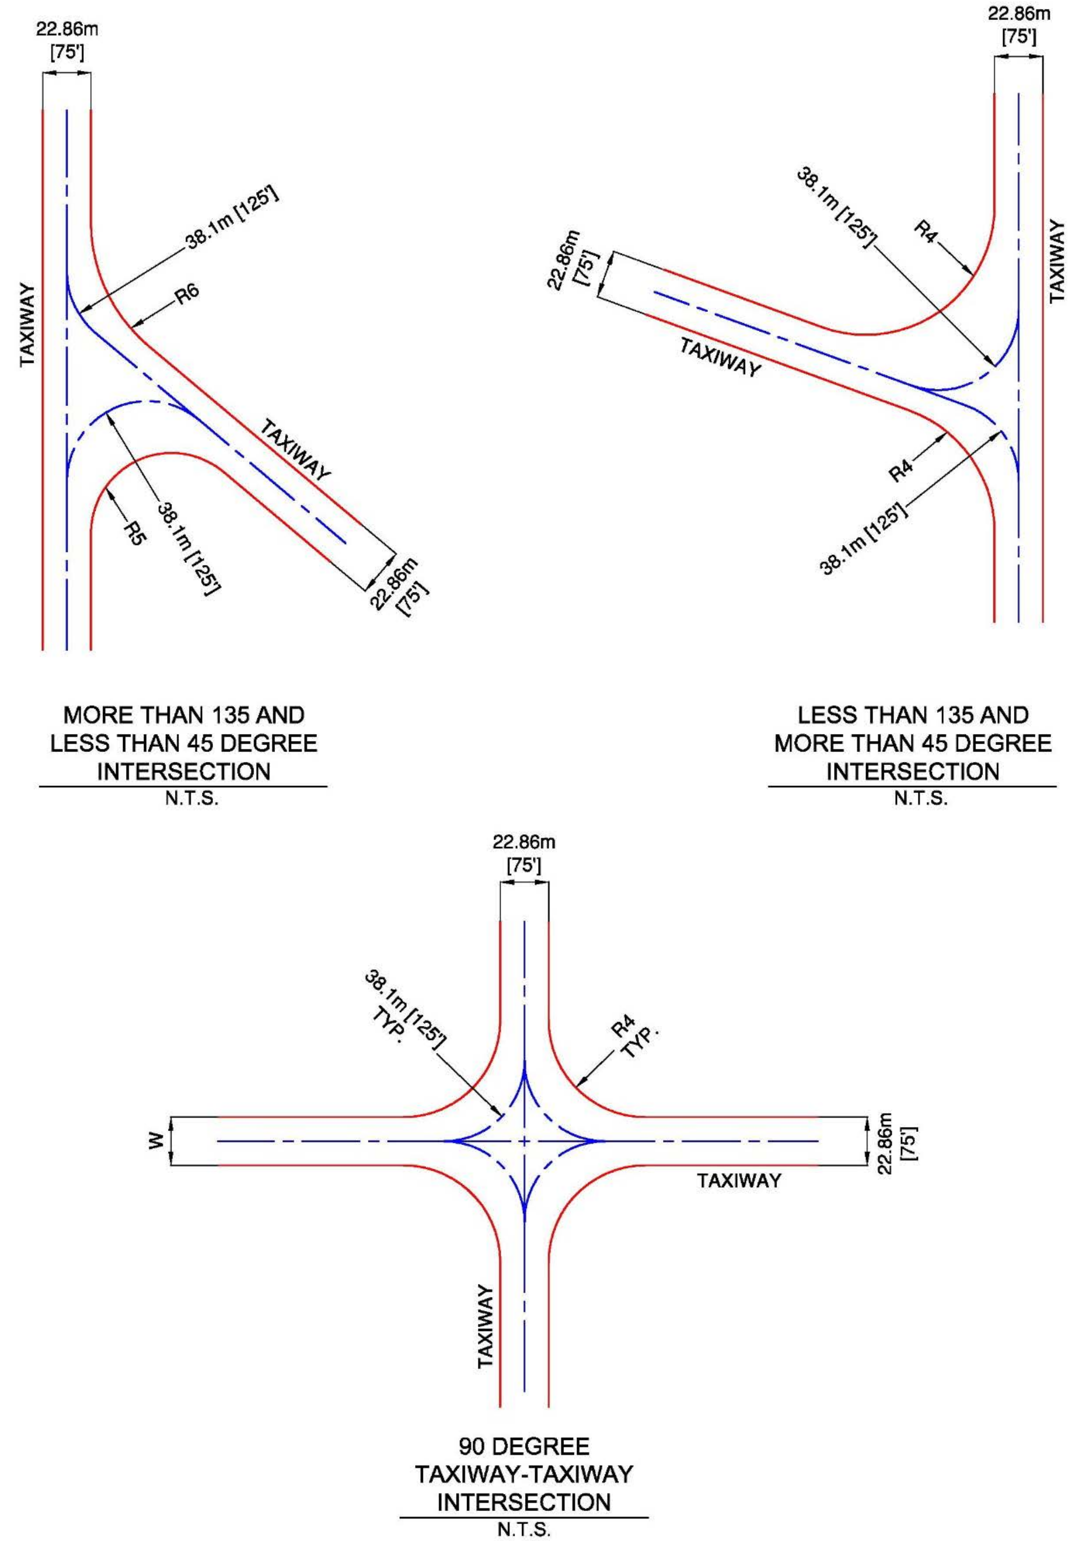

5-9 HIGH-SPEED RUNWAY EXITS.

If peak operations are expected to exceed 30 takeoffs and landings per hour, aircraft may be required to exit runways at greater than normal taxi speeds to maintain airfield capacity. In these cases, an acute-angle exit taxiway may be required. Air Force designers should contact their MAJCOM pavements engineer or Headquarters Air Force Civil Engineer Center for assistance. Army designers should contact the U.S. Army Corps of Engineers Transportation Systems Center (USACE-TSC). Navy and Marine Corps designers may use the criteria for transport aircraft provided in FAA AC 150/5300-13.

5-10 APRON ACCESS TAXIWAYS.

Apron access taxiways are provided for aircraft access onto an apron. The number of apron access taxiways should allow sufficient capacity for departing aircraft. The apron access taxiways should be located to enhance the aircraft's departing sequence and route.

5-10.1 Parking Aprons.

The minimum number of apron access taxiways for any parking apron will be two. For the USAF, the minimum may be one if a single access taxiway will not inhibit planned operations.

5-10.2 Fighter Aircraft Aprons.

Three apron access taxiways should be provided for aprons with over 24 parked fighter aircraft. Four entrance taxiways should be provided for aprons with over 48 parked fighter aircraft.

5-11 SHOULDERS.

Shoulders are provided along a taxiway to allow aircraft to recover if they leave the paved taxiway. Paved shoulders prevent erosion caused by jet blast, support an occasional aircraft that wanders off the taxiway, support vehicular traffic, and reduce maintenance of unpaved shoulder areas.

5-11.1 Fixed-Wing Taxiways.

The shoulder for fixed-wing taxiways may be either paved or unpaved, depending on the agency, class of runway, and type of aircraft. Criteria for fixed-wing taxiway shoulders, including widths and grading requirements to prevent the ponding of storm water, are presented in Table 5-1. See Paragraph 2-12 for requirements for designing buried utility structures in shoulders.

5-11.2 Rotary-Wing Taxiways.

Paved shoulders are required adjacent to rotary-wing taxiways to prevent blowing dust and debris due to rotor-wash. The criteria for a rotary-wing taxiway shoulder layout, including shoulder width, cross slopes, and grading requirements, are presented in Table 5-3.

5-12 TOWWAYS.

A towway is used to tow aircraft from one location to another or from an apron to a hangar.

5-12.1 Dimensions.

Table 5-6 presents the criteria for towway layout and design, including clearances, slopes, and grading dimensions. When designing for access to a hangar, flare the pavement to the width of the hangar door from a distance beyond the hangar sufficient to allow maintenance personnel to turn the aircraft around.

5-12.2 Layout.

A typical transverse cross-section of a towway is shown in Figure 5-6.

5-12.3 Existing Roadway.

When existing roads or other pavements are modified for use as towways, provide for necessary safety clearances, pavement strengthening (if required), and all other specific requirements set forth in Table 5-6 and Figure 5-6.

5-13 HANGAR ACCESS.

The pavement that allows access from the apron to the hangar is referred to as a “hangar access apron” and is discussed in more detail in Chapter 6.

Table 5-6. Towways

Table 5-6. Towways				
Item		Class A Runway	Class B Runway	
No.	Description	Requirement		Remarks
1	Width	(outside gear width of towed mission aircraft) +3 m (10 ft)		Army and Air Force facilities 1.5 m (5 ft) on each side of gear
		11 m (36 ft)		Navy and Marine Corps facilities for carrier aircraft
		12 m (40 ft)		Navy and Marine Corps facilities for patrol and transport aircraft

Table 5-6. Towways				
Item		Class A Runway	Class B Runway	
No.	Description	Requirement		Remarks
		10.7 m (35 ft)		Navy and Marine Corps facilities for rotary-wing aircraft
2	Total width of shoulders (paved and unpaved)	7.5 m (25 ft)		
3	Paved shoulder width	Not Required		If provided: 2.0% min. and 4.0% max.
4	Longitudinal grade of towway	Max 3.0%		Grades may be both positive and negative but must not exceed the limit specified.
5	Rate of longitudinal grade change per 30 m (100 ft)	Max 1.0%		The minimum distance between two successive PI is 150 m (500 ft). Changes are to be accomplished by means of vertical curves. For the Air Force and Army, up to a 0.4% change in grade is allowed without a vertical curve. A vertical curve is not necessary where a taxiway crosses a runway or taxiway crown.
6	Longitudinal sight distance	N/A (See note 1.)		
7	Transverse grade	Min 2.0% Max 3.0%		Pavement crowned at towway centerline Slope pavement downward from centerline of towway.
8	Towway turning radius	46 m (150 ft) radius		Criteria presented here are for straight sections of towway. Pavement width and horizontal clearance lines may need to be increased at horizontal curve locations, based on aircraft alignment on the horizontal curve.
9	Fillet radius at intersections	30 m (100 ft) radius		
10	Transverse grade of unpaved shoulder	(a) 40 mm (1.5 in) drop-off at edge of pavement, +/- 13 mm (0.5 in). (b) 2.0% min, 4.0% max.		
11	Horizontal clearance from towway centerline to fixed or mobile obstacles	The greater of: (½ the wing span width of the towed mission aircraft + 7.6 m [25 ft]); or the minimum of 18.25 m (60 ft)		Army and Air Force facilities for fixed-wing aircraft
		15 m (50 ft)		Navy and Marine Corps facilities for carrier aircraft

Table 5-6. Towways

Item		Class A Runway	Class B Runway	Remarks
No.	**Description**	**Requirement**		
		23 m (75 ft)		Navy and Marine Corps facilities for patrol and transport aircraft
		14 m (45 ft)		Army, Navy, and Marine Corps facilities for rotary-wing aircraft
12	Vertical clearance from towway pavement surface to fixed or mobile obstacles	(Height of towed mission aircraft) + 3 m (10 ft)		Army and Air Force facilities
		7.5 m (25 ft)		Navy and Marine Corps facilities for carrier aircraft
		14 m (45 ft)		Navy and Marine Corps facilities for patrol and transport aircraft
		9 m (30 ft)		Navy and Marine Corps facilities for rotary-wing aircraft
13	Grade (area between towway shoulder and towway clearance line)	Min of 2.0% prior to channelization Max 10%. (See note 2.)		

NOTES:

1. N/A = not applicable
2. Bed of channel may be flat.
3. Metric units apply to new airfield construction and, where practical, modification to existing airfields and heliports, as discussed in paragraph 1-3.4.
4. The criteria in this manual are based on aircraft specific requirements and are not direct conversions from inch-pound (English) dimensions. Inch-pound units are included only as a reference to the previous standard.
5. Airfield and heliport imaginary surfaces and safe wingtip clearance dimensions are shown as a direct conversion from inch-pound to SI units.

1. Metric units apply to new airfield construction and, where practical, modification to existing airfields and heliports, as discussed in paragraph 1-3.4.
2. The criteria in this manual are based on aircraft specific requirements and are not direct conversions from inch-pound (English) dimensions. Inch-pound units are included only as a reference to the previous standard.

CHAPTER 6
APRONS AND OTHER PAVEMENTS

6-1 CONTENTS.

This chapter presents design standards for fixed- and rotary-wing aircraft parking aprons, access aprons, maintenance pads, and wash racks. It provides minimum wingtip clearance requirements, grades, and lateral clearance standards, as well as typical aircraft parking arrangements. The general principles of this chapter apply to the Navy and Marine Corps. Specific data for Navy and Marine Corps aprons is contained in the referenced publications. See Figures 6-43 and 6-44 and Tables 6-7 through 6-10 for Navy and Marine Corps aircraft parking apron criteria (taken from UFC 2-000-5N).

6-2 APRON REQUIREMENTS.

Aprons must provide sufficient space for parking fixed- and rotary-wing aircraft. They should be sized to allow safe movement of aircraft under their own power. During design, consider the effects of jet blast turbulence and temperature. Programming requirements for Air Force aviation facilities are provided in AFMAN 32-1084. Requirements for Navy and Marine Corps aviation facilities are contained in UFC 2-000-05N and UFC 3-260-02. The general principles of this chapter apply to the Navy and the Marine Corps. Specific data on Navy/Marine Corps aprons is contained in the referenced publications. Use High Temperature Concrete and neoprene joint sealants in locations where stationary V-22 nacelle exhaust exposure is ten minutes or greater. This will likely include but is not limited to fuel pits, warm-up areas, and aprons. Rinse facilities supporting V-22s must also include High Temperature Concrete due to heat and vapor flux.

6-3 TYPES OF APRONS AND OTHER PAVEMENTS.

Listed here are types of aprons and other aviation facilities:

- Aircraft parking apron
- Transient parking apron
- Mobilization apron
- Aircraft maintenance apron
- Hangar access apron
- Warm-up pad (holding apron)
- Unsuppressed power check pads
- Arm/dearm pad
- Compass calibration pad
- Hazardous cargo pad

- Alert pad
- Aircraft wash rack

6-4 AIRCRAFT CHARACTERISTICS.

Dimensional characteristics of various military, civil, and commercial fixed- and rotary-wing aircraft are available in TSC Report 13-2 (Aircraft Characteristics for Military Aircraft) and in TSC Report 13-3 (Aircraft Characteristics for Selective Commercial Aircraft).

6-5 PARKING APRON FOR FIXED-WING AIRCRAFT.

Fixed-wing parking at an aviation facility may consist of separate aprons for parking operational aircraft, transient aircraft, and transport aircraft, or an apron for consolidated parking.

6-5.1 Location.

Parking aprons should be located near and contiguous to maintenance and hangar facilities. Do not locate them within runway and taxiway lateral clearance distances. A typical parking apron is illustrated in Figure 6-1.

6-5.2 Size.

As a general rule, there are no standard sizes for aircraft aprons. Aprons are individually designed to support aircraft and missions at specific facilities. The actual dimensions of an apron are based on the number of authorized aircraft, the maneuvering space, and the type of activity that the apron serves. Air Force allowances are provided in AFMAN 32-1084. Army facility authorizations are discussed in RPLANS and applicable programming directives. The ideal apron size affords the maximum parking capacity with a minimum amount of paving. Generally, this is achieved by reducing the area dedicated for use as taxilanes by parking aircraft perpendicular to the long axis of the apron.

6-5.3 Army Parking Apron Layout.

6-5.3.1 Variety of Aircraft.

Where there are a large variety of fixed-wing aircraft types, fixed-wing aircraft mass parking apron dimensions will be based on the C-12J (Huron). The C-12J parking space width is 17 m (55 ft), and the parking space length is 18.25 m (60 ft).

6-5.3.2 Specific Aircraft.

If the assigned aircraft are predominantly one type, the mass parking apron will be based on the specific dimensions of that aircraft.

6-5.3.3 Layout.

Figure 6-2 illustrates a parking apron. These dimensions can be tailored for specific aircraft, including the C-12J.

6-5.4 Air Force Parking Apron Layout.

Parking apron dimensions for Air Force facilities will be based on the specific aircraft assigned to the facility and the criteria presented in AFMAN 32-1084. A typical mass parking apron should be arranged in rows as shown in Figure 6-2.

6-5.5 Layout for Combined Army and Air Force Parking Aprons.

Parking apron dimensions for combined Army and Air Force facilities will be based on the largest aircraft assigned to the facility.

6-5.6 Tactical/Fighter Parking Apron Layout.

The recommended tactical/fighter aircraft parking arrangement is to park aircraft at a 45-degree angle as discussed in AFMAN 32-1084. Arranging these aircraft at a 45-degree angle may be the most economical method for achieving the clearance needed to dissipate jet blast temperatures and velocities to levels that will not endanger aircraft or personnel (Figure 6-3). Jet blast relationships for tactical and fighter aircraft are discussed in TSC Report 13-2.

Figure 6-1. Apron Nomenclature and Criteria

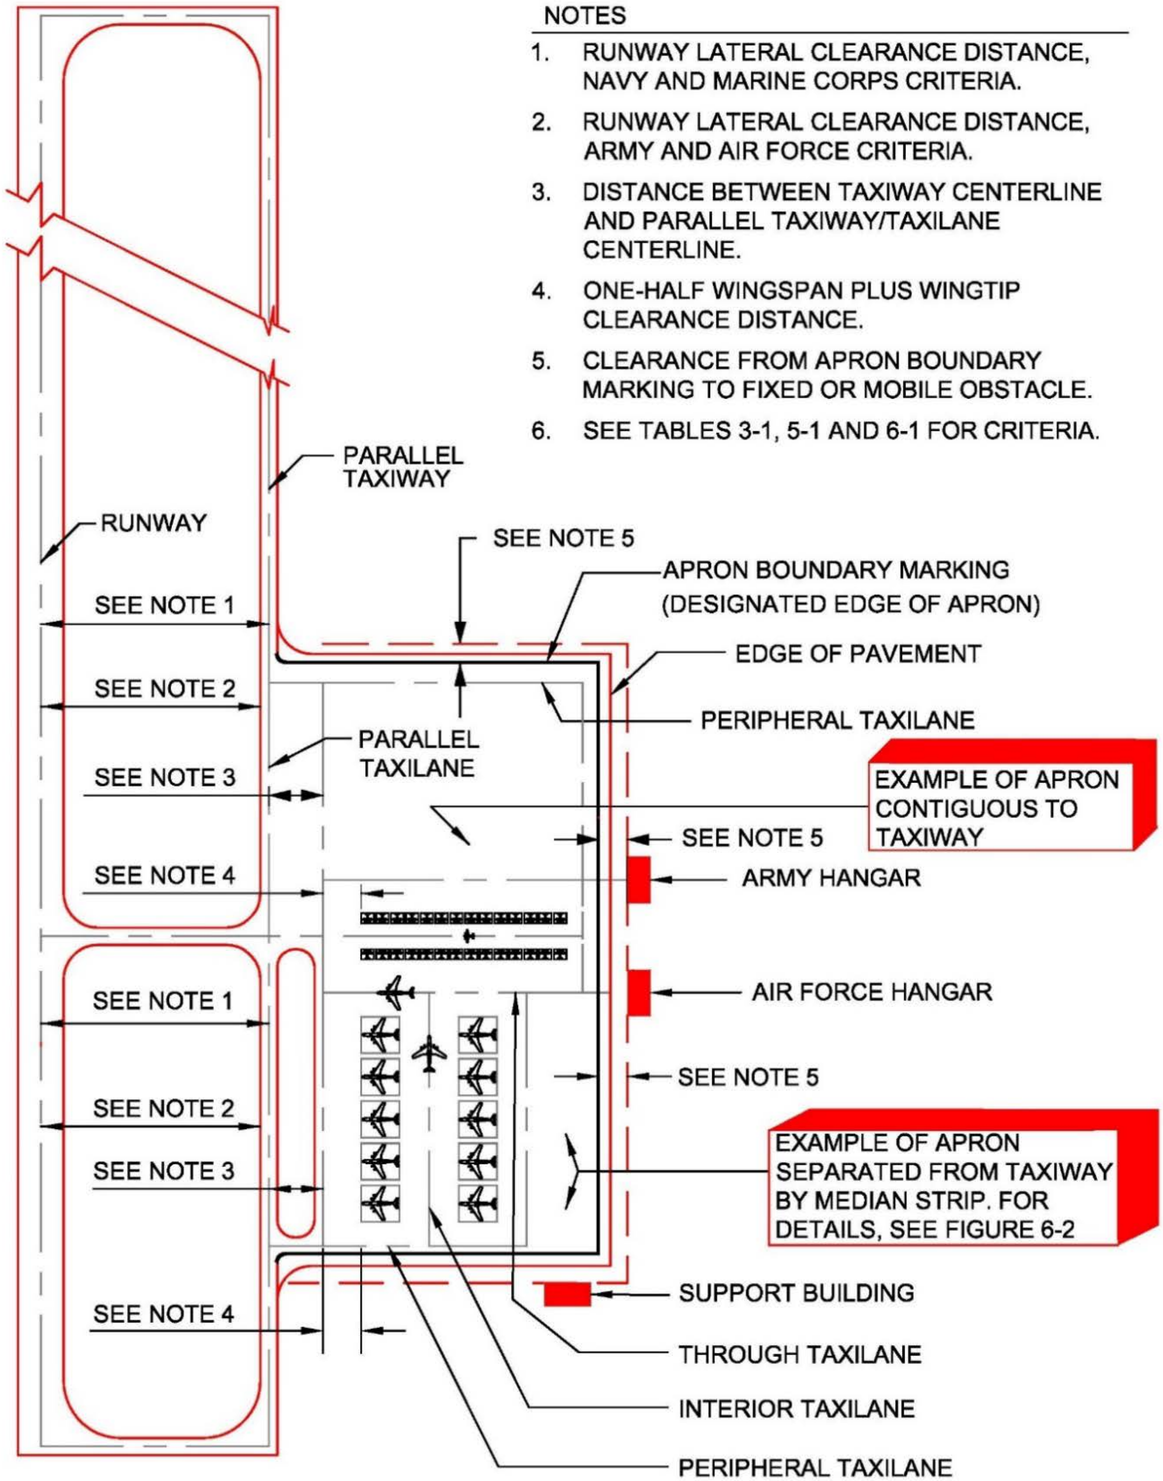

Figure 6-2. Army and Air Force Parking Plan

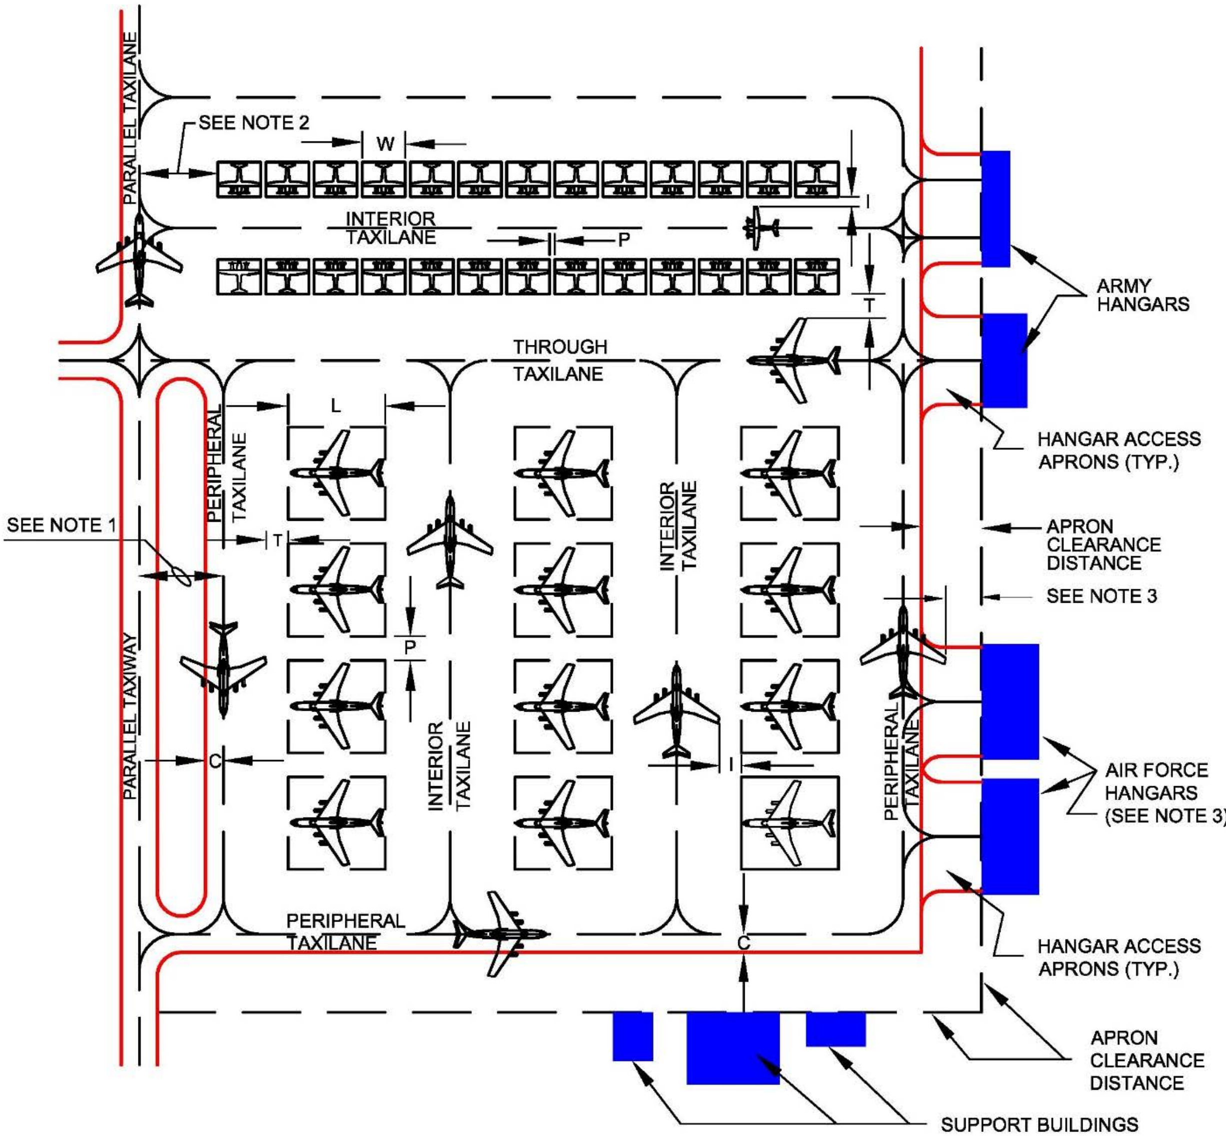

LEGEND

W -- AIRCRAFT WIDTH
L --AIRCRAFT LENGTH

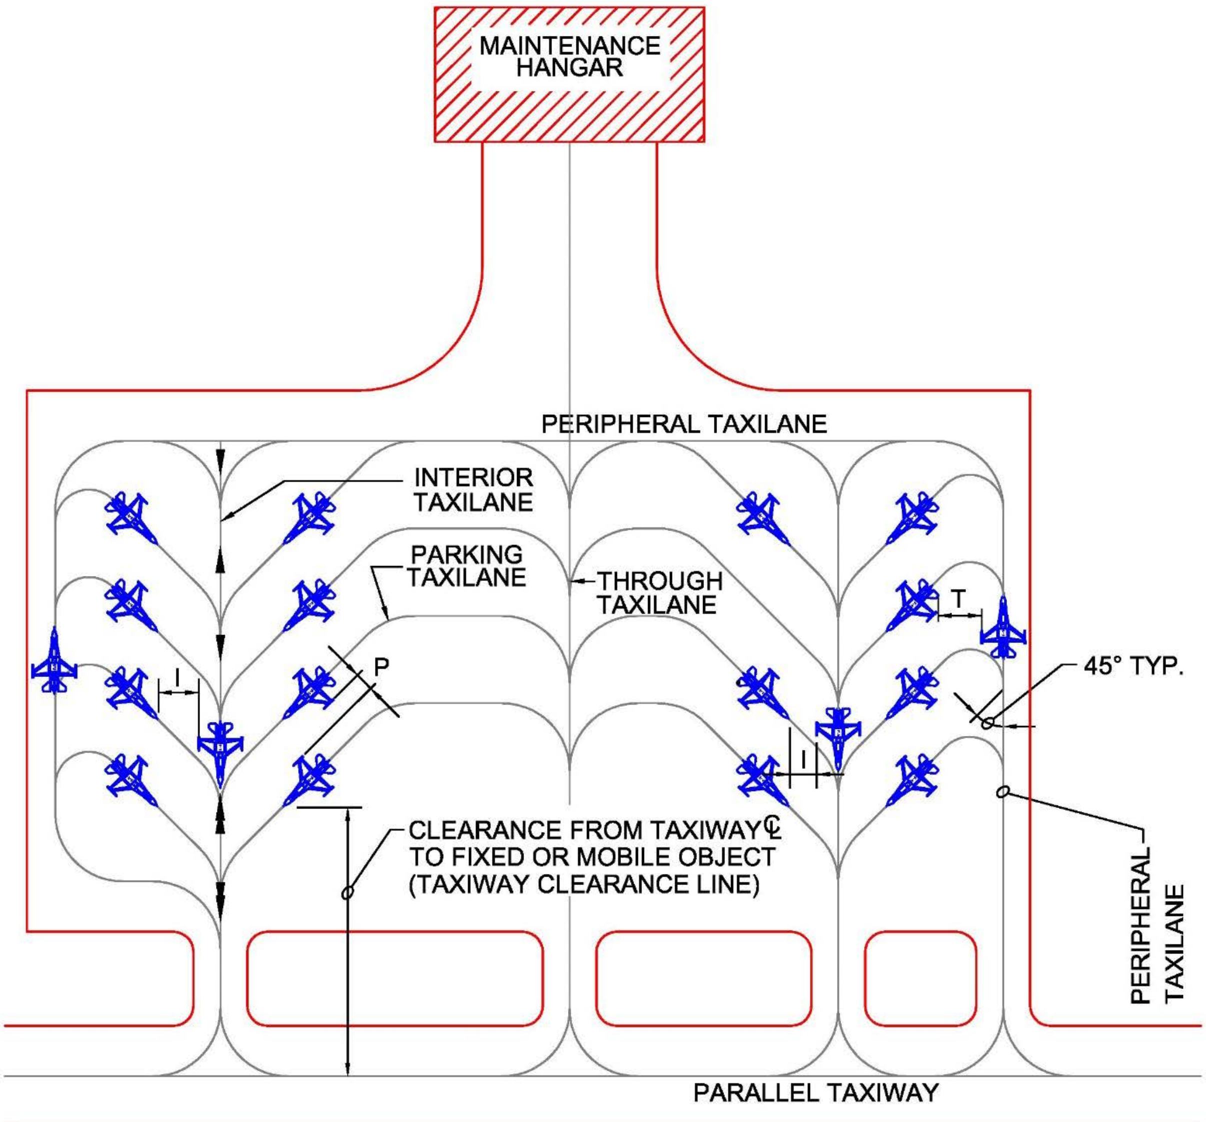
NOTES:

1. TAXIWAY CLEARANCE DISTANCE AT FACILITIES WITH PARALLEL TAXIWAYS; SEE TABLE 5-1, ITEM 11.
2. SEE TABLE 6-1 FOR DIMENSIONAL DEFINITIONS.
3. FOR AIR FORCE: INSURE MINIMUM WINGTIP CLEARANCE IS PROVIDED TO HANGARS OR OTHER PERMISSIBLE DEVIATIONS (SEE TABLE 6-1 ITEMS 5, 6 AND 15, AND APPENDIX B, SECTION 13).

Figure 6-3. Apron with Diagonal Parking



NOTES

1. SEE TABLE 6-1 FOR DIMENSIONAL CRITERIA.
2. THIS PARKING ARRANGEMENT IS SHOWN FOR INFORMATION ONLY AND NOT NECESSARILY AN IDEAL PARKING ARRANGEMENT.

6-5.7 Refueling Considerations.

\1 Layout of aircraft parking locations and taxilanes should consider aircraft taxiing routes when an aircraft is refueled. Refueling operations should not prevent an aircraft from leaving the parking apron. Two routes in and out of the apron may be required. During refueling, active ignition sources such as sparks from ground support equipment or jet engines (aircraft) are prohibited from a zone around the aircraft. The Army and Air Force refer to this zone as the fuel servicing safety zone (FSSZ). The Navy and Marine Corps refer to this zone as the refueling safety zone (RSZ). An example of the RSZ around a fixed-wing aircraft is shown in Figure 6-4. The safety zone is the area within 15 m (50 ft) of a pressurized fuel carrying servicing component (e.g., servicing hose, fuel nozzle, single-point receptacle (SPR), hydrant hose car, ramp hydrant connection point) and 7.6 m (25 ft) around aircraft fuel vent outlets. The FSSZ is established and maintained during pressurization and movement of fuel. For additional information, see Air Force technical order (T.O.) 00-25-172*.* For additional Navy information, see MIL-HDBK-274. **/1/**

6-5.8 Parking Dimensions.

Table 6-1 presents the minimum geometric criteria for fixed-wing apron design. When designing new aprons for AMC bases hosting C-5 and C-17 aircraft, provide 15.3 m (50 ft) of wingtip separation. EXCEPTION: When you are rehabilitating an existing apron, provide the maximum wingtip separation the existing apron size will allow up to 15.3 m (50 ft), but not less than 7.7 m (25 ft). This additional separation is both desirable and permitted. At non-AMC bases, the maximum separation that can reasonably be provided for these aircraft is desirable.

6-5.8.1 Jet Blast Considerations.

The clearances listed in Table 6-1 do not consider the effects of temperature and velocity due to jet blast. The effects of jet blast and the minimum standoff distance to the edge of the pavement are described in Appendix B, Section 7.

6-5.8.2 Cargo Loading Considerations.

Consider the effects of jet blast on aircraft loading operations and cargo storage locations when you design a layout for parking cargo aircraft.

6-5.9 Tie-downs and Mooring Points.

Tie-downs or mooring points are required. See Appendix B, Section 11, for grounding requirements.

Figure 6-4. Truck Refueling Safety Zone Example

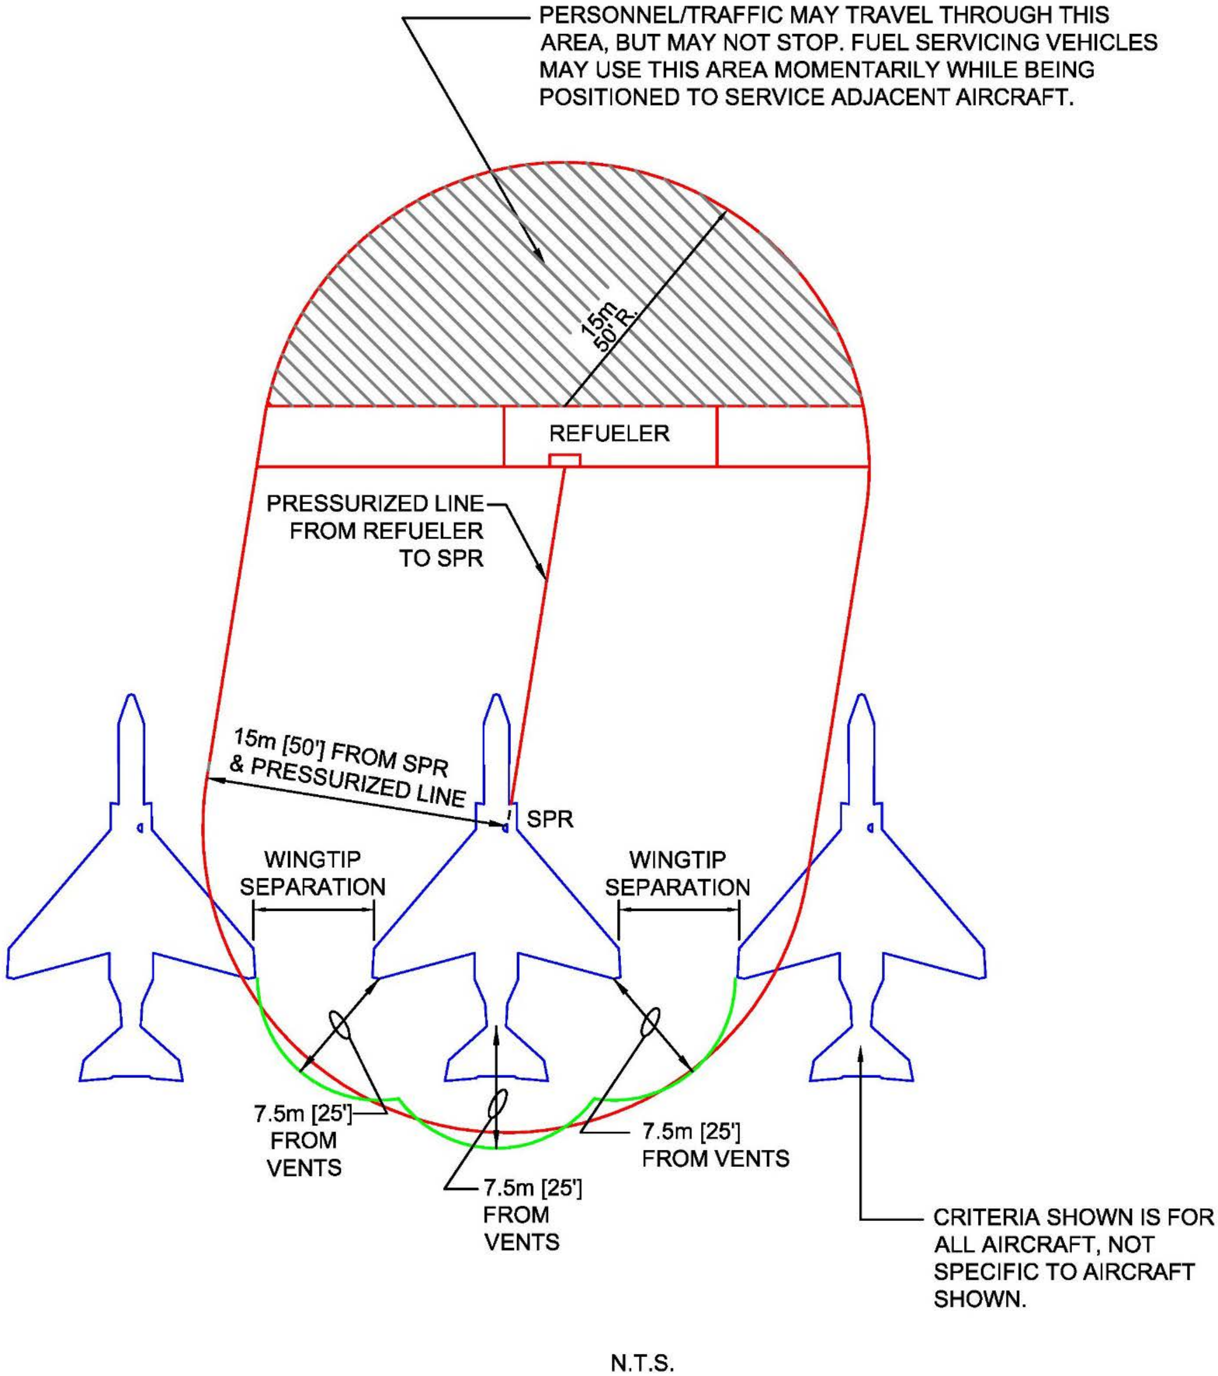


Table 6-1. Fixed-Wing Aprons

Table 6-1. Fixed-Wing Aprons				
Item		Class A Runway	Class B Runway	Remarks
No.	Description	Requirement		
1	Size and configuration	Variable For Army and Air Force requirements, see the criteria listed below and AFMAN 32-1084. For Navy and Marine Corps requirements, see UFC 2-000-05N .		As a general rule there are no standard sizes for aprons. They are individually designed to support specific aircraft uses. The dimensions are determined by the number and type of aircraft involved, the function of the apron, the maneuvering characteristics of the aircraft, the jet blast of the aircraft, and the degree of unit integrity to be maintained. Other determinants are the physical characteristics of the site, the relationship of the apron area to other airfield facilities, and the objective of the comprehensive plan.
2	Parking space width ("W")	Design aircraft wingspan		Army and Air Force airfields. For V-22 parking dimensions, see Figure 6-44.
3	Parking space length ("L")	Design aircraft length		Army and Air Force airfields. For V-22 parking dimensions, see Figure 6-44.
4	Wingtip clearance of parked aircraft ("P")	3.1 m (10 ft)		Army and Air Force airfields, aircraft with wingspans up to 33.5 m (110 ft) For V-22 wingtip clearances, see Figure 6-44.
		6.1 m (20 ft)		Army and Air Force airfields, aircraft with wingspans of 33.5 m (110 ft) or more except as noted below See note 1 for USAF.
		7.7 m (25 ft)		Army and Air Force airfields, transient aprons, C-5 and C-17 aircraft (also see paragraph 6-5.8) See note 1 for USAF.
		15.3 m (50 ft)		Army and Air Force airfields, KC-10, KC-46 and KC-135 aircraft to accommodate refueling and defueling operations. See note 1 for USAF.

Table 6-1. Fixed-Wing Aprons				
Item		Class A Runway	Class B Runway	Remarks
No.	Description	Requirement		
5	Wingtip clearance of aircraft on interior or secondary peripheral taxilanes ("I")	6.1 m (20 ft)		Army and Air Force airfields, aircraft with wingspans up to 33.5 m (110 ft), except transient aprons. For V-22 wingtip clearances, see Figure 6-44. Taxilanes that provide access to individual parking spots or hangars are considered secondary taxi routes. See note 1 for USAF.
		7.7 m (25 ft)		Army and Air Force airfields, transient aprons. Taxilanes that serve multiple types of aircraft or serve to provide circulation beyond access to individual parking spots or hangars are considered primary facilities. See note 1 for USAF. For V-22 wingtip clearances, see Figure 6-44.
		9.2 m (30 ft)		Army and Air Force airfields, aircraft with wingspans of 33.5 m (110 ft) or more, except transient aprons Taxilanes that serve multiple types of aircraft or serve to provide circulation beyond access to individual parking spots or hangars are considered primary facilities. See note 1 for USAF.
6	Wingtip clearance of aircraft on through or primary peripheral taxilanes ("T")	9.2 m (30 ft)		Army and Air Force airfields, aircraft with wingspans up to 33.5 m (110 ft). For V-22 wingtip clearances, see Figure 6-44. Taxilanes that serve multiple types of aircraft or serve to provide circulation beyond access to individual parking spots or hangars are considered primary facilities. See note 1 for USAF.
		Min 15.3 m (50 ft)		Army and Air Force airfields, aircraft with wingspans of 33.5 m (110 ft) or more Taxilanes that serve multiple types of aircraft or serve to provide circulation beyond access to individual parking spots or hangars are considered primary facilities. See note 1 for USAF.

Table 6-1. Fixed-Wing Aprons

Item No.	Item Description	Class A Runway Requirement	Class B Runway Requirement	Remarks
7	Distance from peripheral taxilane centerline to the outside edge of the apron boundary marking ("C")	7.7 m (25 ft)		Army and Air Force airfields Designed for aircraft with wingspan up to 33.5 m (110 ft). For V-22 wingtip clearances, see Figure 6-44.
		11.5 m (37.5 ft)		Army and Air Force airfields Designed for aircraft with wingspan of 33.5 m (110 ft) and greater
8	Clear distance around aircraft during fueling (see paragraph 6-5.7.)	7.7 m (25 ft)		Around aircraft fuel vent outlets (see T.O. 00-25-172).
		15.3 m (50 ft)		From a pressurized fuel carrying servicing component (see T.O. 00-25-172).
		See Remarks		Consider refueling operations when locating taxilanes.
9	Grades in the direction of drainage	Min 0.5% Max 1.5%		Avoid surface drainage patterns with numerous or abrupt grade changes that can produce excessive flexing of aircraft and structural damage. Lateral and transverse slopes must be combined to derive maximum slope in the direction of drainage. (i.e., the square root of the transverse slope squared plus longitudinal slope squared is equal to the slope in the direction of drainage.) For the Air Force, no grade changes are allowed for individual parking positions within the aircraft block dimensions (not including clearance distances) of the design aircraft. Exceptions are allowed for fuel hydrant pits.
10	Width of shoulders (total width including paved and unpaved)	7.5 m (25 ft)	15 m (50 ft)	Army and Air Force airfields
11	Paved width of shoulders	7.5 m (25 ft)	7.5 m (25 ft)	Army and Air Force airfields not otherwise specified. For apron shoulders where fire hydrants must be installed, see Note 5 and Appendix B, Section 13, for the minimum set back from the taxilane centerline.

Table 6-1. Fixed-Wing Aprons				
Item		Class A Runway	Class B Runway	Remarks
No.	Description	Requirement		
		N/A	15 m (50 ft)	Army and Air Force airfields that accommodate B-52, C-5, E-4, and 747 aircraft. For apron shoulders where fire hydrants must be installed, see Note 5 and Appendix B, Section 13, for the minimum set back from the taxilane centerline.
12	Longitudinal grade of shoulders	Variable		Conform to longitudinal grade of the abutting primary pavement.
13	Transverse grade of paved shoulder	Min 2.0% Max 4.0%		Army airfields and Air Force airfields not otherwise specified
		N/A	Min 1.5% Max 2.0%	Air Force airfields that accommodate B-52 aircraft
14	Transverse grade of unpaved shoulders	N/A	(a) 40 mm (1.5 in) drop-off at edge of paved shoulder, +/- 13 mm (0.5 in). (b) 2.0% min, 4.0% max.	Unpaved shoulders shall be graded to provide positive surface drainage away from paved surfaces.
15	Clearance from apron boundary marking to fixed or mobile obstacles	Variable		Compute this distance by multiplying 0.5 x the wingspan of the most demanding aircraft that will use the apron and add the appropriate wingtip clearance required by item 5 or 6. Then subtract the distance from the taxilane centerline to the outside edge of the apron boundary marking (item 7) to find the required clear distance. This distance is to be clear of all fixed and mobile obstacles except as specifically noted in Appendix B, Section 13, even if there is no peripheral taxilane along the edge of apron. This clear distance is required for safety purposes. **NOTES:** 1. Light poles are not allowed within this distance without waiver. 2. Implement operational controls to ensure that aircraft larger than the design aircraft do not use the apron without wing-walkers. Publish this information in the airfield operating instruction.

Table 6-1. Fixed-Wing Aprons				
Item		Class A Runway	Class B Runway	Remarks
No.	Description	Requirement		
				3. Submit a revised summary of airfield restrictions to allow update to the AMC Airfield Suitability and Restrictions Report. Mail the revision to: HQ AMC/A3AS 402 Scott Drive Unit 3A1 Scott AFB IL 62225-5302
16	Grades in cleared area beyond shoulders to fixed or mobile obstacles	(a) 40 mm (1.5 in) drop-off at edge of paved shoulder, +/- 13 mm (0.5 in). (b) Min 2% Max 10% .	Min 2% Max 10.0%	40 mm (1.5–in) drop-off (+/- 13 mm (0.5 in)) at edge of pavement when the entire shoulder is paved. When a slope reversal is required within this area, a flat bottom ditch that is graded to drain adequately shall be provided.

NOTES:
1. Air Force wingtip clearances may be reduced to those allowed by AFI 11-218 with a waiver. A waiver will be granted only if no other viable options exist.
2. Metric units apply to new airfield construction and, where practical, to modifications to existing airfields and heliports, as discussed in paragraph 1-3.4.
3. The criteria in this manual are based on aircraft specific requirements and are not direct conversions from inch-pound (English) dimensions. Inch-pound units are included only as a reference to the previous standard.
4. Airfield and heliport imaginary surfaces and safe wingtip clearance dimensions are shown as a direct conversion from inch-pound to SI units.
5. For apron edges where fire hydrants must be installed, widen paved shoulders to within 3 m (10 ft) of the hydrants to allow paved access for firefighting vehicles.
6. N/A = not applicable

6-6 TAXIING CHARACTERISTICS ON APRONS FOR FIXED-WING AIRCRAFT.

6-6.1 Apron Taxilanes.

Taxi routes across parking aprons, referred to as taxilanes, are marked on the apron for safe passage of the aircraft. Typical taxilane locations are illustrated in Figures 6-1, 6-2 and 6-3. Minimum wingtip clearances between parked and taxiing aircraft are shown in Table 6-1 (see Figure 6-2). AFI 11-218 provides authorization for operating aircraft at reduced clearances under certain circumstances. If a decision is made to reduce clearances based on this authorization, a waiver must be obtained in accordance with Appendix B, Section 1. Waivers should be pursued only when all avenues for compliance have been exhausted.

6-6.2 Turning Capabilities (Aircraft Turning and Maneuvering Characteristics).

TSC Report 13-2 (Aircraft Characteristics for Airfield Pavement Design and Evaluation Air Force and Army Aircraft) and TSC Report 13-3 (Aircraft Characteristics for Airfield Pavement Design and Evaluation Selective Commercial Aircraft) provide sources for obtaining various turning diagrams for US Army, Air Force, and numerous civil and commercial fixed-wing aircraft.

6-6.3 Departure Sequencing.

Egress patterns from aircraft parking positions to taxiways should be established to prevent congestion at the apron exits. For parking apron access taxiway requirements, see Chapter 5, section 5-10.

6-6.4 Minimum Standoff Distances from Edge Pavements.

See Appendix B, Section 7, for information on minimum standoff distances from edge pavements.

6-7 PARKING APRON FOR ROTARY-WING AIRCRAFT.

Mass parking of rotary-wing aircraft will require an apron designated for rotary-wing aircraft. Parking for transient rotary-wing aircraft and at aviation facilities where only a few rotary-wing aircraft are assigned, may be located on aprons for fixed-wing aircraft. At aviation facilities with assigned rotary-wing aircraft, a transport apron for fixed-wing aircraft is desirable.

6-7.1 Location.

Parking aprons for rotary-wing aircraft should be located similar to parking aprons for fixed-wing aircraft. Rotary-wing aprons must not be located within the lateral clearance distances discussed in Chapters 3 and 4 of this UFC. Generally, company and/or squadron units should be parked together in rows for organizational integrity in locations adjacent to their assigned hangars. Parking aprons for small helicopters (OH, UH, and AH) should be separate from parking areas used by cargo helicopters due to the critical operating characteristics of the larger aircraft.

6-7.2 Apron Size.

As with fixed-wing aircraft aprons, there is no standard size for rotary-wing aircraft aprons. The actual dimensions are based on the number of authorized aircraft, the maneuvering space, and the type of activity that the apron serves.

6-7.3 Maneuverability.

The layout of the rotary-wing parking spacing should allow aircraft access to these locations.

6-7.3.1 Approach.

Rotary-wing aircraft approach the parking spaces with either a front approach or a sideways (except USN/USMC) approach.

6-7.3.2 Undercarriage.

Rotary-wing aircraft are equipped with either a skid gear or wheel gear. Once on the ground, skid gear-equipped helicopters cannot be easily moved. Wheeled rotary-wing aircraft can be moved after they are on the ground.

6-7.4 Army Parking Apron Layout.

Rotary-wing aircraft are parked in one of two configurations, referred to as Type 1 or Type 2.

6-7.4.1 Type 1.

In this configuration, rotary-wing aircraft are parked in a single lane, which is perpendicular to the taxilane. In this configuration, the parking arrangement resembles that of fixed-wing aircraft. This parking arrangement is preferred for wheeled aircraft.

6-7.4.1.1 Parking Space, All Aircraft Except CH-47 and CH-53.

In the Type 1 configuration, the parking space dimensions for all rotary-wing aircraft except the CH-47 and CH-53 is a width of 25 m (80 ft) and a length of 30 m (100 ft). This is illustrated in Figure 6-5.

6-7.4.1.2 Parking Space, CH-47.

In the Type 1 configuration, the parking space dimensions for the CH-47 rotary-wing aircraft is a width of 30 m (100 ft) and a length of 46 m (150 ft). This is illustrated in Figure 6-6.

6-7.4.1.3 Parking Space, CH-53.

In the Type 1 configuration, the parking space dimensions for the CH-53 rotary-wing aircraft are a width of 37 m (120’) and a length of 50 m (165 ft). This is illustrated in Figure 6-7.

6-7.4.2 Type 2.

In this configuration, rotary-wing aircraft are parked in a double lane, which is parallel to the taxilane. This parking arrangement is preferred for skid-gear aircraft.

6-7.4.2.1 Parking Space, Skid-Gear Aircraft.

The parking space dimensions for all skid-gear rotary-wing aircraft in the Type 2 configuration is a width of 25 m (80 ft) and a length of 30 m (100 ft). This is illustrated in Figure 6-9.

6-7.4.2.2 Parking Space, Wheeled.

The parking space dimensions for all wheeled rotary-wing aircraft in the Type 2 configuration is a width of 30 m (100 ft) and a length of 50 m (160 ft). This is illustrated in Figure 6-10.

6-7.4.3 Barricades and Shelters.

Where barricades are provided between parking spaces or pull-through shelters are used, include an additional 8 m (26 ft) gap between parking spaces. This is illustrated in Figure 6-8.

6-7.5 Air Force Parking Apron Layout.

Rotary-wing aircraft at Air Force facilities are parked in a layout similar to that of fixed-wing aircraft. Parking space, taxilane, and clearance dimensions for Air Force facilities will be based on the rotor diameter of the specific aircraft assigned to the facility. For the Air Force, the wingtip clearance criteria provided in AFMAN 32-1084, Table 2.7, is preferred. However, USAF activities may use the Army criteria presented in this UFC for all rotary-wing aircraft except CH-53 and CH-54.

6-7.6 Refueling Considerations.

As discussed in paragraph 6-5.7, layout of aircraft parking locations and taxilanes should consider aircraft taxiing routes when an aircraft is refueled. There are two primary aircraft fueling systems used:

- Aircraft Direct-Refueling System
- Mobile Aircraft Refuelers

6-7.6.1 Aircraft Direct-Refueling System.

Aircraft direct fueling stations provide outlets located in the apron where aircraft can be fueled from closed circuit fuel system utilizing multi-arm pantographs or hydrant servicing vehicles (HSV). For design criteria, see UFC 3-460-01. Aircraft direct-refueling systems are designed primarily for “hot” refueling of aircraft.

6-7.6.1.1 Hot Refueling Criteria and Requirements.

Hot refueling is performed with engines running, it provides minimum aircraft turnaround times and reduces fueling personnel and equipment support requirements. However, it presents hazards not normally encountered during normal fueling operations. Hot refueling is performed while the fuel lines are under pressure. For the Air Force, hot refueling requires the approval of MAJCOM and will not be permitted unless individual aircraft technical order guidance, appropriate checklists and individual fueling systems are available. For additional information, see Air Force T.O. 00-25-172.

6-7.6.2 Mobile Aircraft Refuelers.

Mobile Aircraft Refuelers are tanker trucks of various capacities and configurations and are used primarily for normal (cold) fueling operations with occasional hot-refueling operations at stations where installation of a direct refueling system is not justified. If continuous or extensive hot fueling is being performed with mobile refuelers, the use of an anchored pantograph should be considered.

6-7.6.3 Safety Zone.

The safety zone for rotary-wing aircraft is the area 3 m (10 ft) greater than the area bounded by the blades and tail of the aircraft as shown on Figure 6-11 and Figure 6-12 for mobile aircraft refuelers and for aircraft direct-refueling system (pit). As shown for direct-refueling systems, the pit should be located outside of the aircraft safety zone, at a minimum, for safe operation. For additional information, see Air Force T.O. 00-25-172 and Navy UFC 2-000-05N.

6-7.6.4 Tie-downs and Mooring Points.

Tie-downs or mooring points are required. See Appendix B, Section 11, for grounding requirements.

6-7.7 Parking Dimensions.

Table 6-2 presents the criteria for rotary-wing apron design for Army airfields. Included in this table are parking space widths, grade requirements, and clearances. Criteria for rotary-wing apron design for the Air Force are presented in AFMAN 32-1084; for the Navy, they are in UFC 2-000-5N .

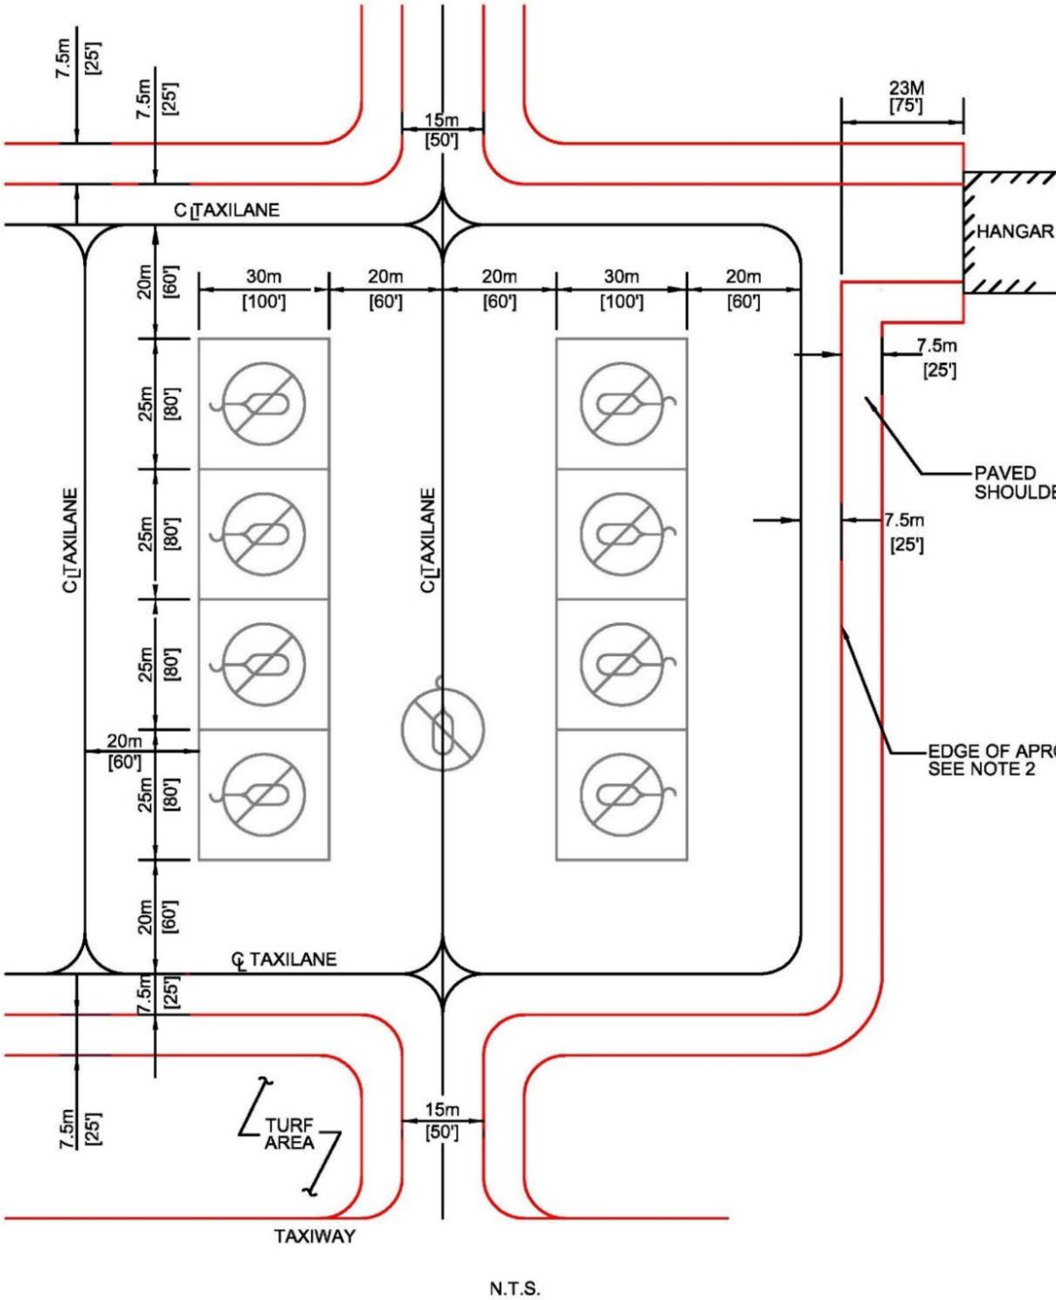
6-7.7.1 Distances between Parking Spaces.

The parking space dimensions, discussed in Table 6-2, include separation distances between parked aircraft. When laying out the rotary-wing parking spaces, the spaces should abut next to each other. Separation between rotors and the aircraft bodies is also included in the parking space dimensions.

6-7.7.2 Rotor Blade Clearances.

The taxilane and hoverlane dimensions in Table 6-2 provide adequate rotor blade clearances for the size of helicopter noted.

Figure 6-5. Type 1 Parking for All Rotary-Wing Aircraft Except CH-47



NOTES:

1. THE DASHED LINES FORMING BOXES AROUND THE PARKING POSITIONS SHOW THE LIMITS OF THE SAFETY ZONE AROUND THE PARKED AIRCRAFT. AIRCRAFT ARE TO BE PARKED IN THE CENTER OF THE BOX TO PROVIDE THE PROPER TAXILANE CLEARANCES.
2. EDGE OF APRON IS DEFINED AS EDGE OF A PARKED AIRCRAFT BLOCK OR EDGE OF A PERIMETER TAXIWAY.

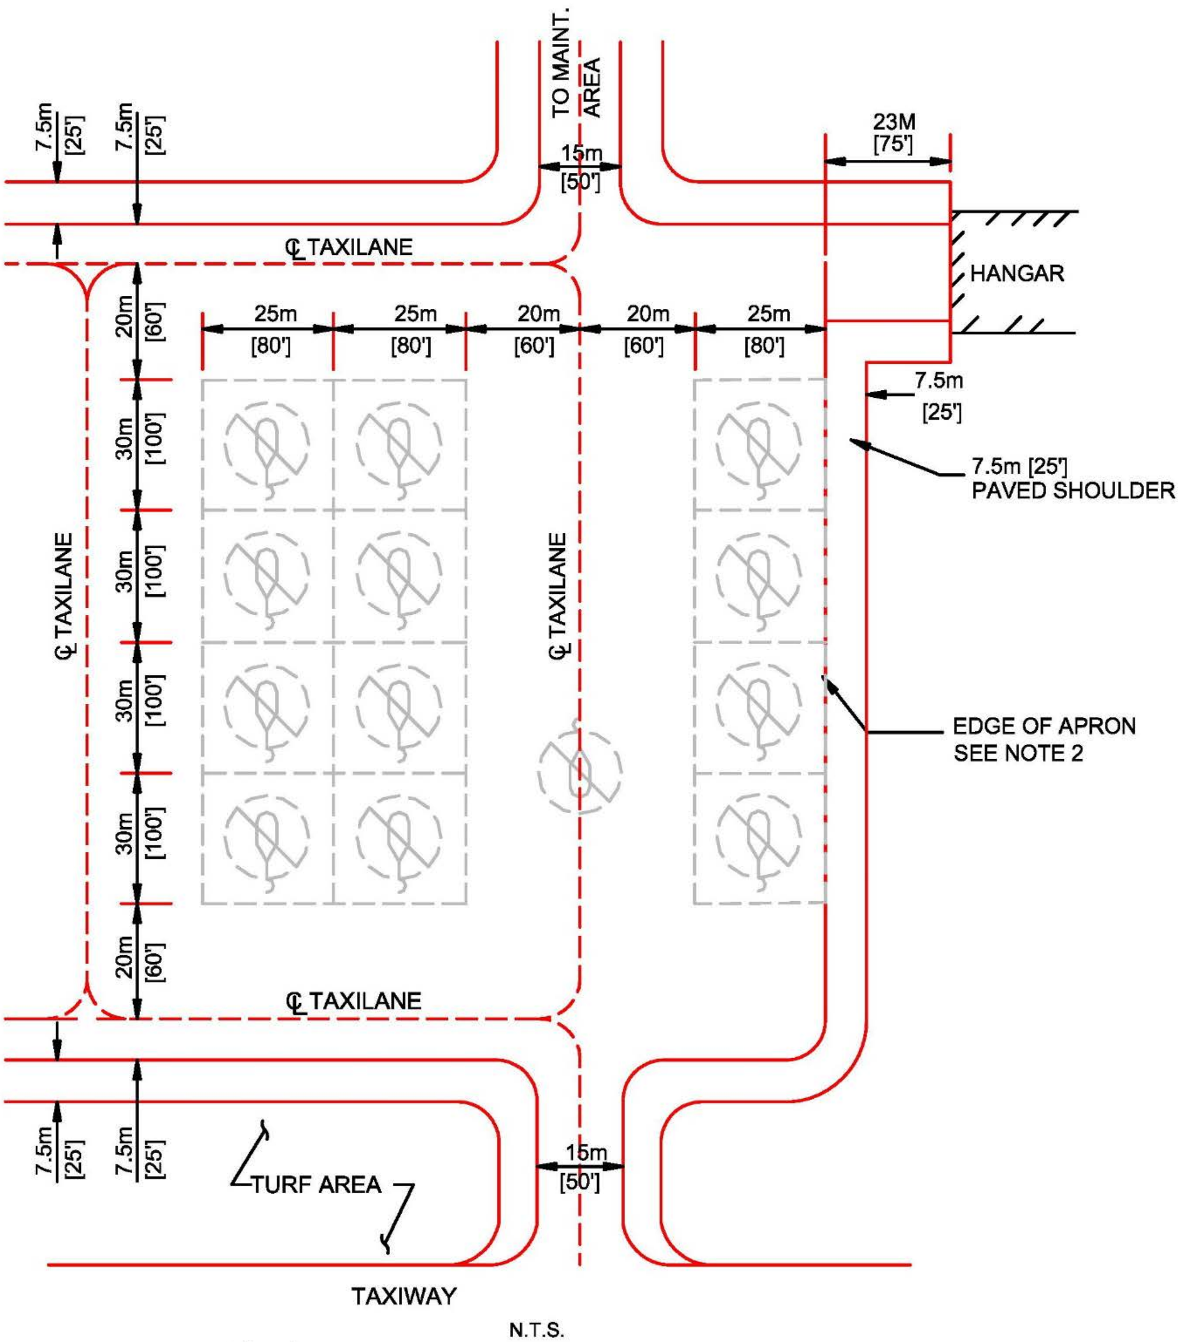
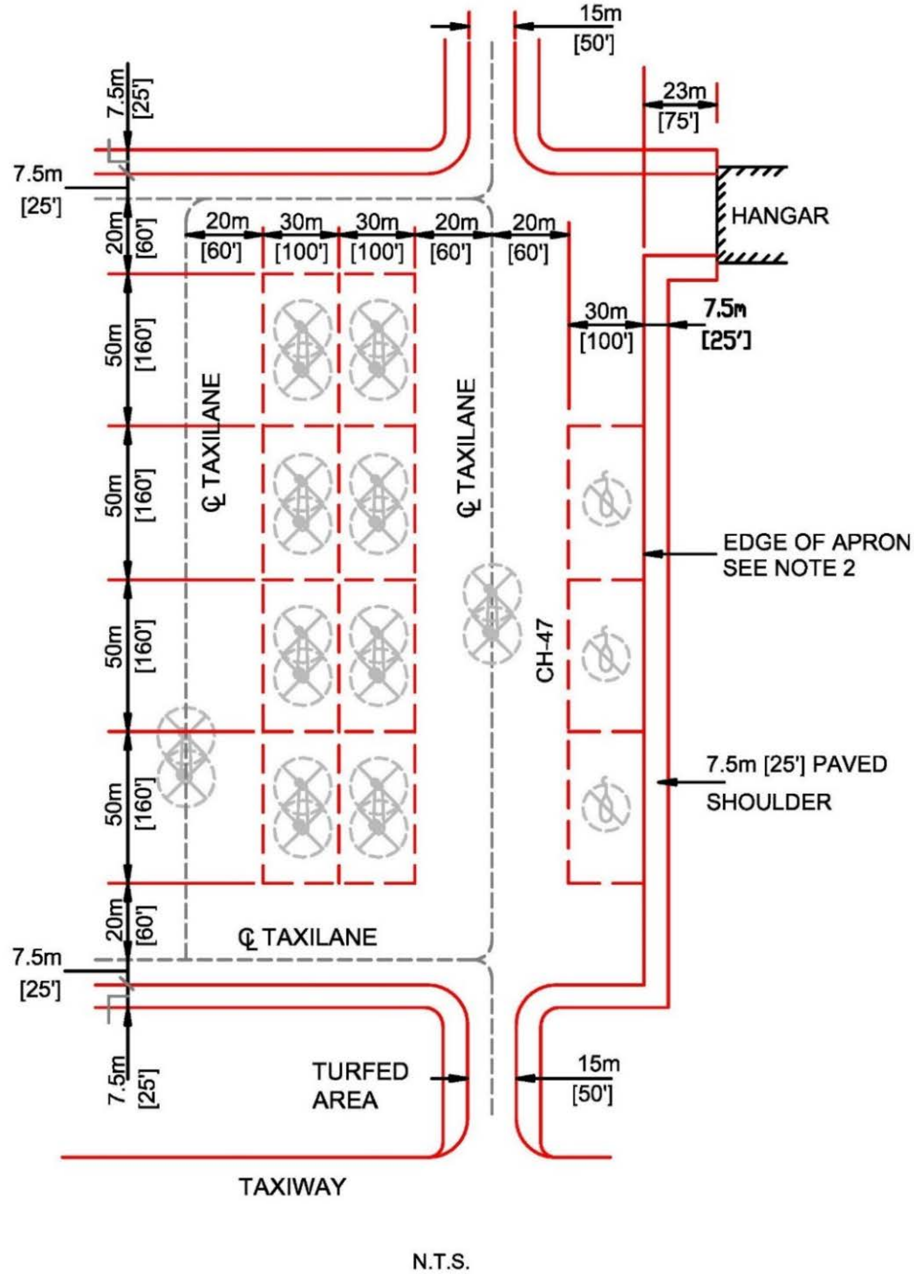
Figure 6-9. Type 2 Parking for Skid Rotary-Wing Aircraft



NOTES

1. THE DASHED LINES FORMING BOXES AROUND THE PARKING POSITIONS SHOW THE LIMITS OF THE SAFETY ZONE AROUND THE PARKED AIRCRAFT. AIRCRAFT ARE TO BE PARKED IN THE CENTER OF THE BOX TO PROVIDE PROPER TAXILANE CLEARANCES.
2. EDGE OF APRON IS DEFINED AS EDGE OF A PARKED AIRCRAFT BLOCK OR EDGE OF A PERIMETER TAXIWAY.

Figure 6-10. Type 2 Parking for Wheeled Rotary-Wing Aircraft



NOTES

1. THE DASHED LINES FORMING BOXES AROUND THE PARKING POSITIONS SHOW THE LIMITS OF THE SAFETY ZONE AROUND THE PARKED AIRCRAFT. AIRCRAFT ARE TO BE PARKED IN THE CENTER OF THE BOX TO PROVIDE PROPER TAXILANE CLEARANCES.
2. EDGE OF APRON IS DEFINED AS EDGE OF A PARKED AIRCRAFT BLOCK OR EDGE OF A PERIMETER TAXIWAY.
3. PARKING AREAS FOR CH-47 AIRCRAFT AND AH-64/UH-60 SHOULD BE SEPARATED BY A TAXILANE.

Figure 6-11. Refueling Safety Zone Example for Rotary-Wing Aircraft for Normal (Cold) Refueling Operations

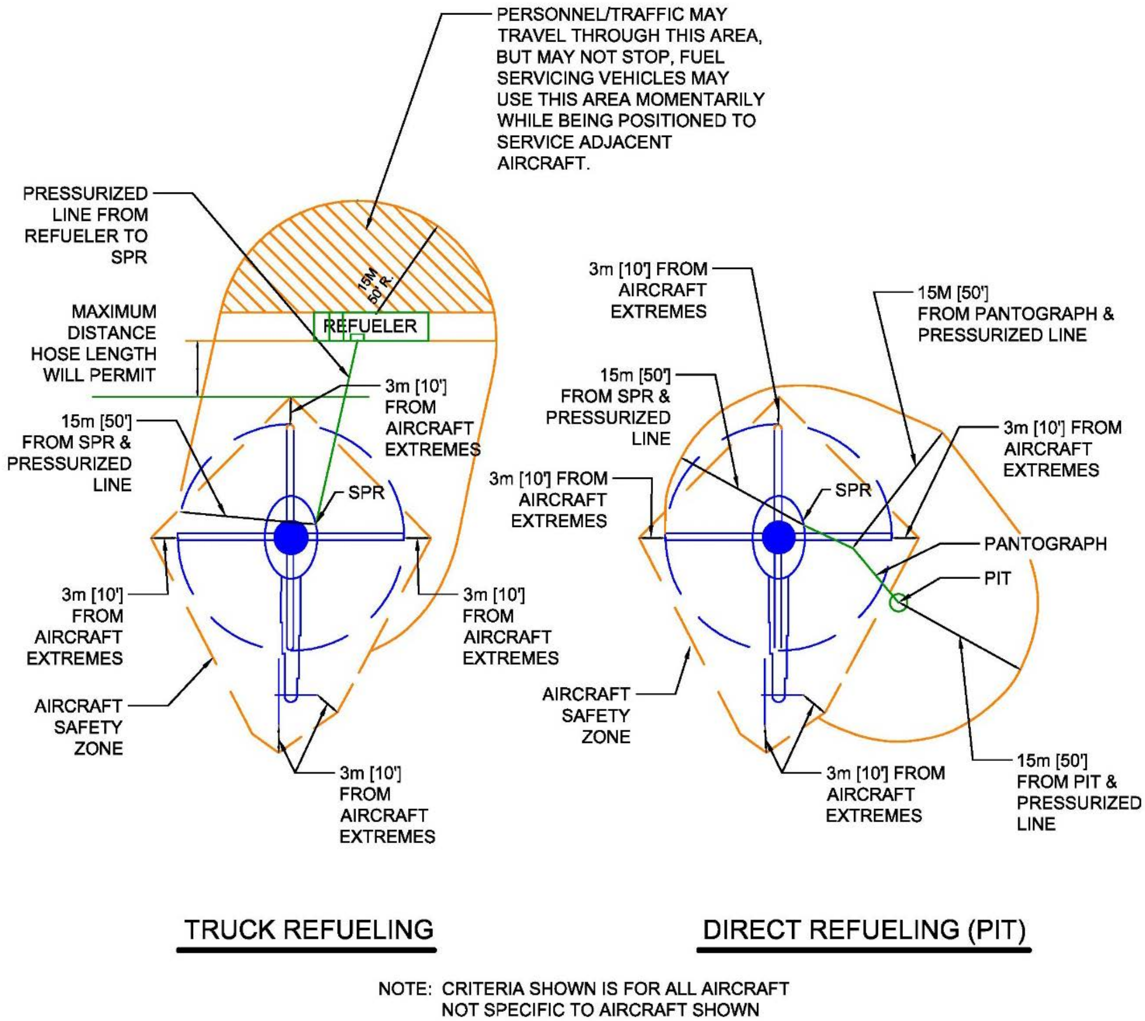


Figure 6-12. Refueling Safety Zone Example for Rotary-Wing Aircraft for Hot Refueling

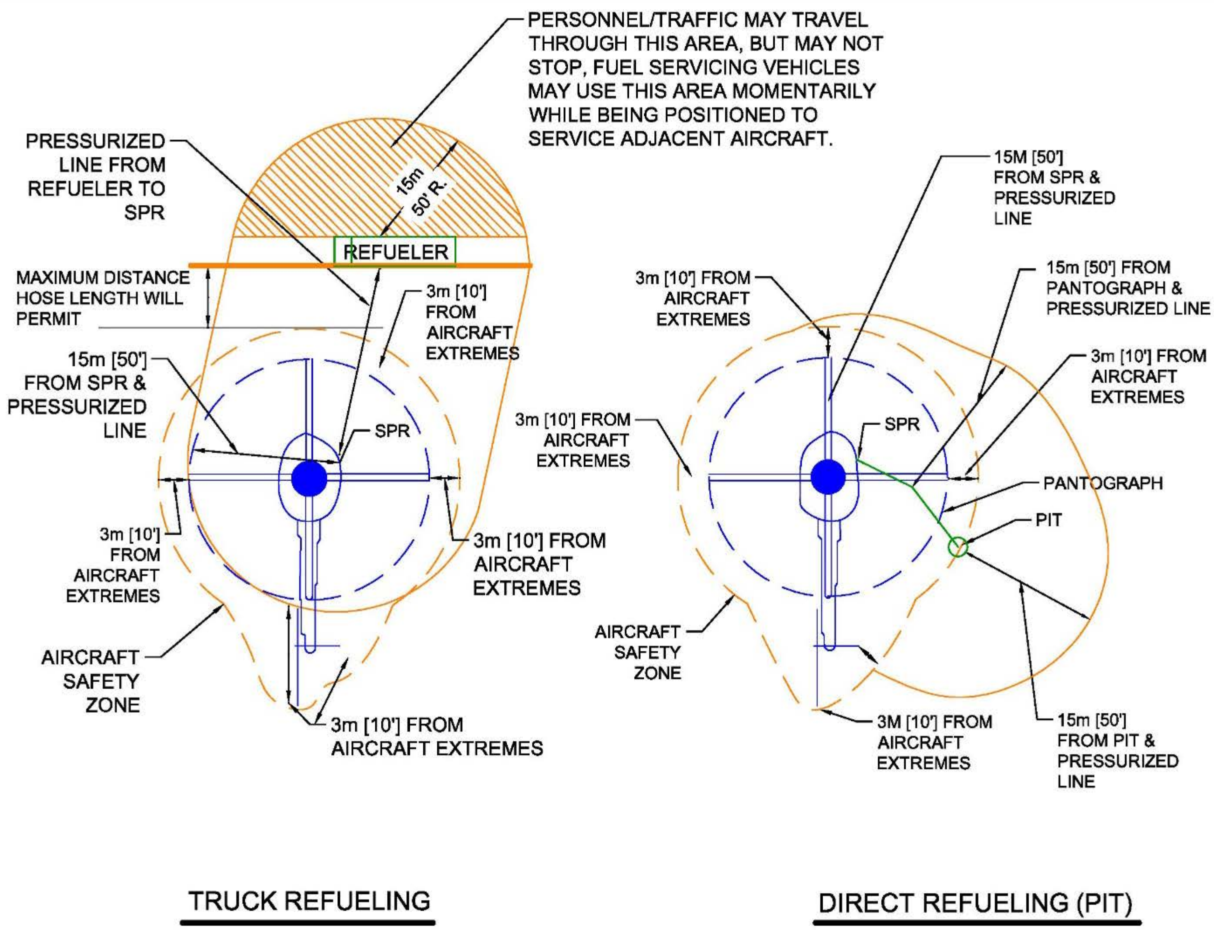

NOTE: CRITERIA SHOWN IS FOR ALL AIRCRAFT. NOT SPECIFIC TO AIRCRAFT SHOWN.

Table 6-2. Rotary-Wing Aprons for Army Airfields

Table 6-2. Rotary-Wing Aprons for Army Airfields			
Item			
No.	Description	Requirement	Remarks
1	Size and configuration	Variable For Air Force space requirements, see AFMAN 32-1084. For Navy and Marine Corps space requirements, see UFC 2-000-05N.	Aprons are determined by the types and quantities of helicopters to be accommodated. Other determinants are the physical characteristics of the site and the objective of the master plan.
2	Type 1 parking space width	25 m (80 ft)	Army helicopters not otherwise specified
		30 m (100 ft)	Army CH-47 helicopters
		37 m (120 ft)	Army CH-53 helicopters
			Helicopters parked in single lanes and perpendicular to the taxilane Park helicopter in center of parking space.
3	Type 1 parking space length	30 m (100 ft)	Army helicopters not otherwise specified
		46 m (150 ft)	Army CH-47 helicopters
		50 m (165 ft)	Army CH-53 helicopters
			Helicopters parked in a single lane and perpendicular to the taxilane Park helicopter in center of parking space.
4	Type 2 parking space width	25 m (80 ft)	Army helicopters, skid configuration
		30 m (100 ft)	Army helicopters, wheeled configuration
			Helicopter parked in double lanes and parallel to the taxilane Park helicopter in center of parking space.
5	Type 2 parking space length	30 m (100 ft)	Army helicopters with skid configuration
		50 m (160 ft)	Army helicopters with wheeled configuration

Table 6-2. Rotary-Wing Aprons for Army Airfields

Item No.	Item Description	Requirement	Remarks
			Helicopter parked in double lanes and parallel to the taxilane Park helicopter in center of parking space.
6	Distance between the edge of the parking space and the taxilane centerline	20 m (60 ft)	All Army helicopters
7	Grades in the direction of drainage	Min 0.5% Max 1.5%	Engineering analysis occasionally may indicate a need to vary these limits; however, arbitrary deviation is not intended. Avoid surface drainage with numerous or abrupt grade changes that can cause adverse flexing in the rotor blades.
8	Interior taxilane/hoverlane width (between rows of aircraft)	40 m (120 ft)	From edge of parking space to edge of parking space
9	Peripheral taxilane/hoverlane width	26 m (85 ft)	From edge of parking space to edge of apron
10	Distance between the peripheral taxilane centerline and the edge of apron	7.5 m (25 ft)	From taxilane centerline to edge of apron
11	Clear distance around refueling aircraft	3 m (10 ft)	Outside of an area formed by lines connecting the tips of the blades and tail
12	Shoulders		See Table 5-3.
13	Clearance from the edge of the apron to fixed and mobile obstacles (clear area)	23 m (75 ft)	Measured from rear and side of apron. Distance to other aircraft operational pavements may require a greater clearance except as noted in Appendix B, Section 13.
		30m (100 ft)	For aprons regularly servicing H-53 helicopters
		23 m (75 ft)	When aircraft are towed on and off washracks the rotor clearance can be reduced to 25’.

NOTES:

1. Metric units apply to new airfield construction and, where practical, modification to existing airfields and heliports, as discussed in paragraph 1-3.4.
2. The criteria in this manual are based on aircraft specific requirements and are not direct conversions from inch-pound (English) dimensions. Inch-pound units are included only as a reference to the previous standard.
3. Airfield and heliport imaginary surfaces and safe wingtip clearance dimensions are shown as a direct conversion from inch-pound to SI units.

6-8 WARM-UP PADS.

A warm-up pad, also referred to as a holding apron, is a paved area adjacent to a taxiway at or near the end of a runway. The intent of a warm-up pad is to provide a holding location, off the taxiway, for aircraft that must hold due to indeterminate delays. A warm-up pad allows other departing aircraft unencumbered access to the runway. Pads must be sized to provide a minimum of 7.62 m (25 ft) of blast-resistant pavement behind the tail of an aircraft to prevent damage from jet blast.

6-8.1 Navy and Marine Corps.

Warm-up pads are not usually required at Navy facilities. Typically, the end crossover taxiway is widened to 46 m (150 ft), which provides room to accommodate aircraft warming up or waiting for other reasons.

6-8.2 Location.

6-8.2.1 At End Turnoff Taxiway.

The most advantageous position for a warm-up pad is adjacent to the end turnoff taxiway, between the runway and parallel taxiway, as shown in Figure 6-13; however, other design considerations such as NAVAIDS may make this location undesirable. Do not site new warm-up pads, other aprons, hot cargo spots, or taxiways to these facilities in a way that will allow penetration of the approach-departure clearance surface.

6-8.2.2 Along Parallel Taxiway.

If airspace and NAVAIDS prevent locating the warm-up pad adjacent to the end turnoff taxiway, the warm-up pad should be located at the end of and adjacent to the parallel taxiway, as shown in Figure 6-14.

6-8.3 Siting Considerations.

6-8.3.1 End of Runway.

Locate a warm-up pad as close to the runway as possible.

6-8.3.2 Approach-Departure Clearance Surface.

As discussed in Chapter 3, an obstruction to air navigation occurs when the imaginary surfaces are penetrated. Do not site new warm-up pads, other aprons, hot cargo spots, or taxiways to these facilities in a way that will allow penetration of the approach-departure clearance surface. Such aircraft penetrations may require revisions to TERPS procedures. Properly sited warm-up positions are illustrated in Figures 6-15 and 6-16.

6-8.3.3 Navigational Aids (NAVAIDS).

Warm-up pads must be located so that they do not interfere with the operation of NAVAIDS, including instrument landing system (ILS) equipment and precision approach radar (PAR) facilities. To eliminate interference of the ILS signal by holding aircraft, holding aircraft on or off a warm-up pad must be outside the critical areas. The critical area for ILS equipment is illustrated in Figures 6-17, 6-18, and 6-19. Additional discussion of ILS critical areas is provided in TM 5-823-4, AFI 13-203, and UFC 3-260-04.

6-8.4 Warm-Up Pad Size.

The size of the warm-up pad will be such to allow accommodating two of the largest aircraft assigned to the facility simultaneously, wingtip clearances required by the clear distance information presented in Table 6-1, and to provide a minimum of 7.62 m (25 ft) of blast-resistant pavement behind the tail of an aircraft to prevent damage from jet blast.

6-8.5 Taxi-In/Taxi-Out Capabilities.

The parking locations will have taxi-in/taxi-out capabilities to allow aircraft to taxi to their warm-up position under their own power as shown in Figure 6-20.

Figure 6-13. Warm-Up Pad at End of Parallel Taxiway

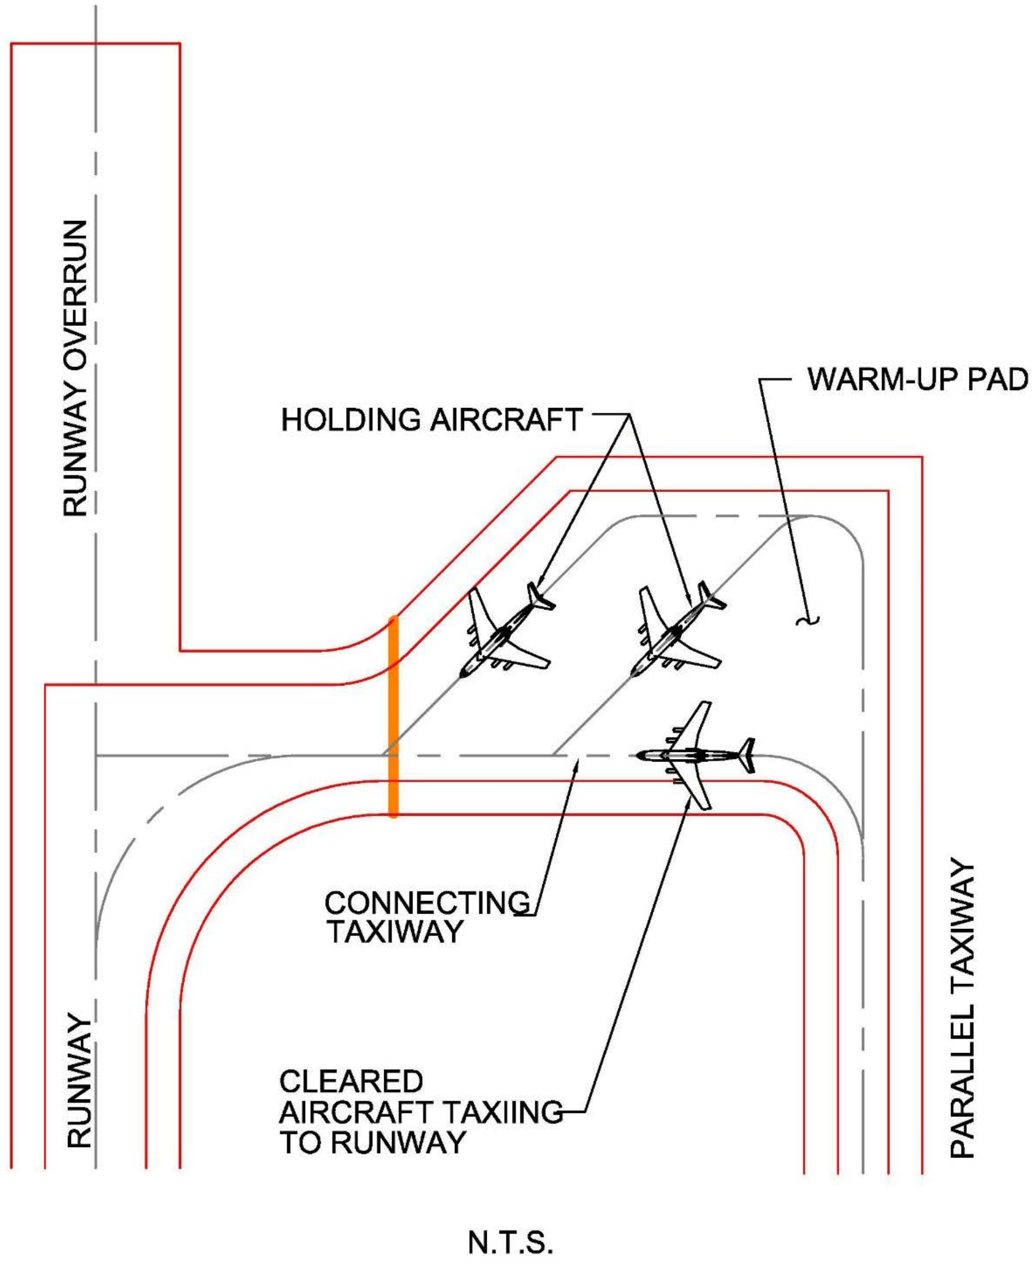

Figure 6-14. Warm-Up Pad Next to Parallel Taxiway

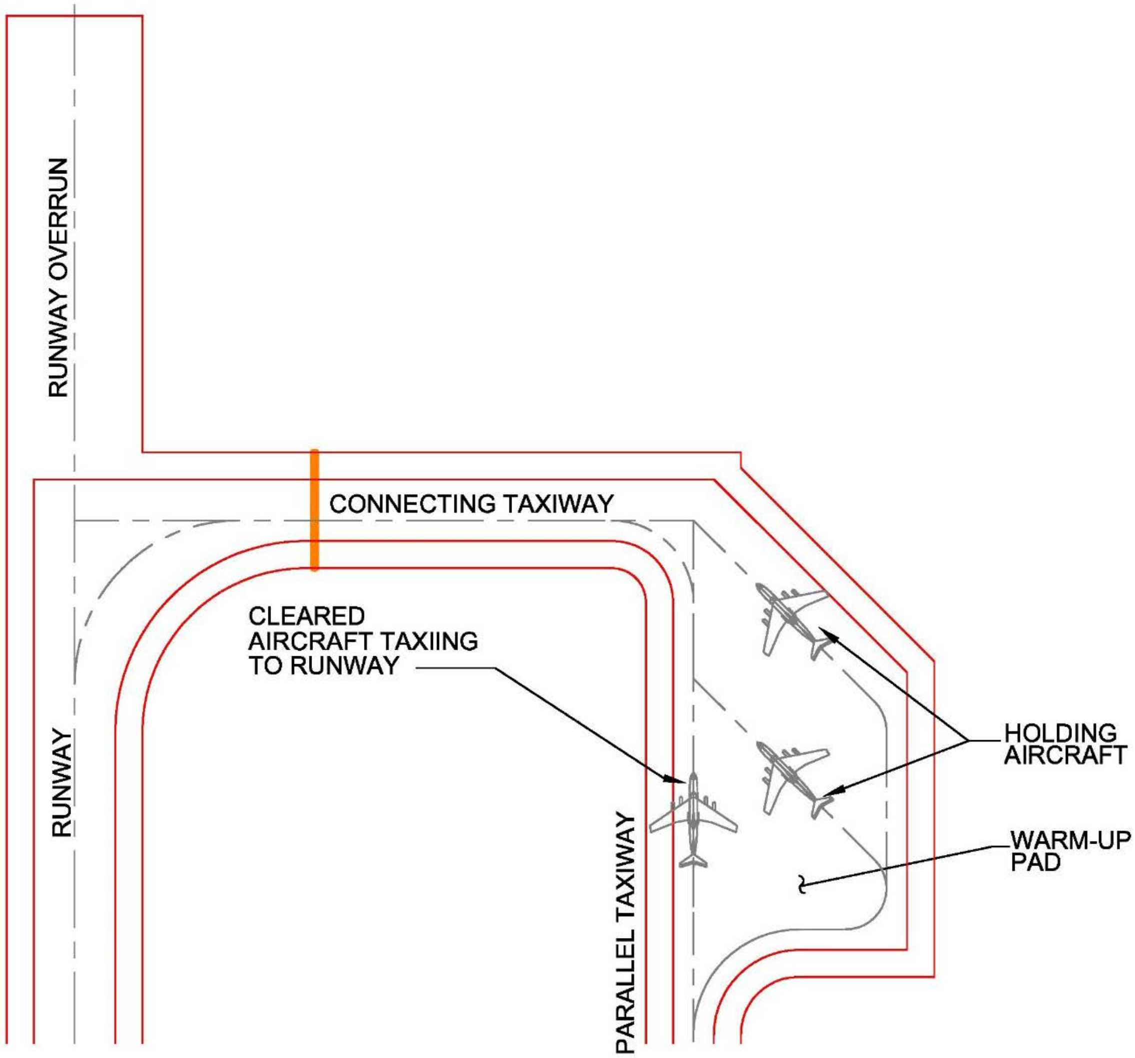

N.T.S.

Figure 6-15. Warm-Up Pad Located in Clear Zone

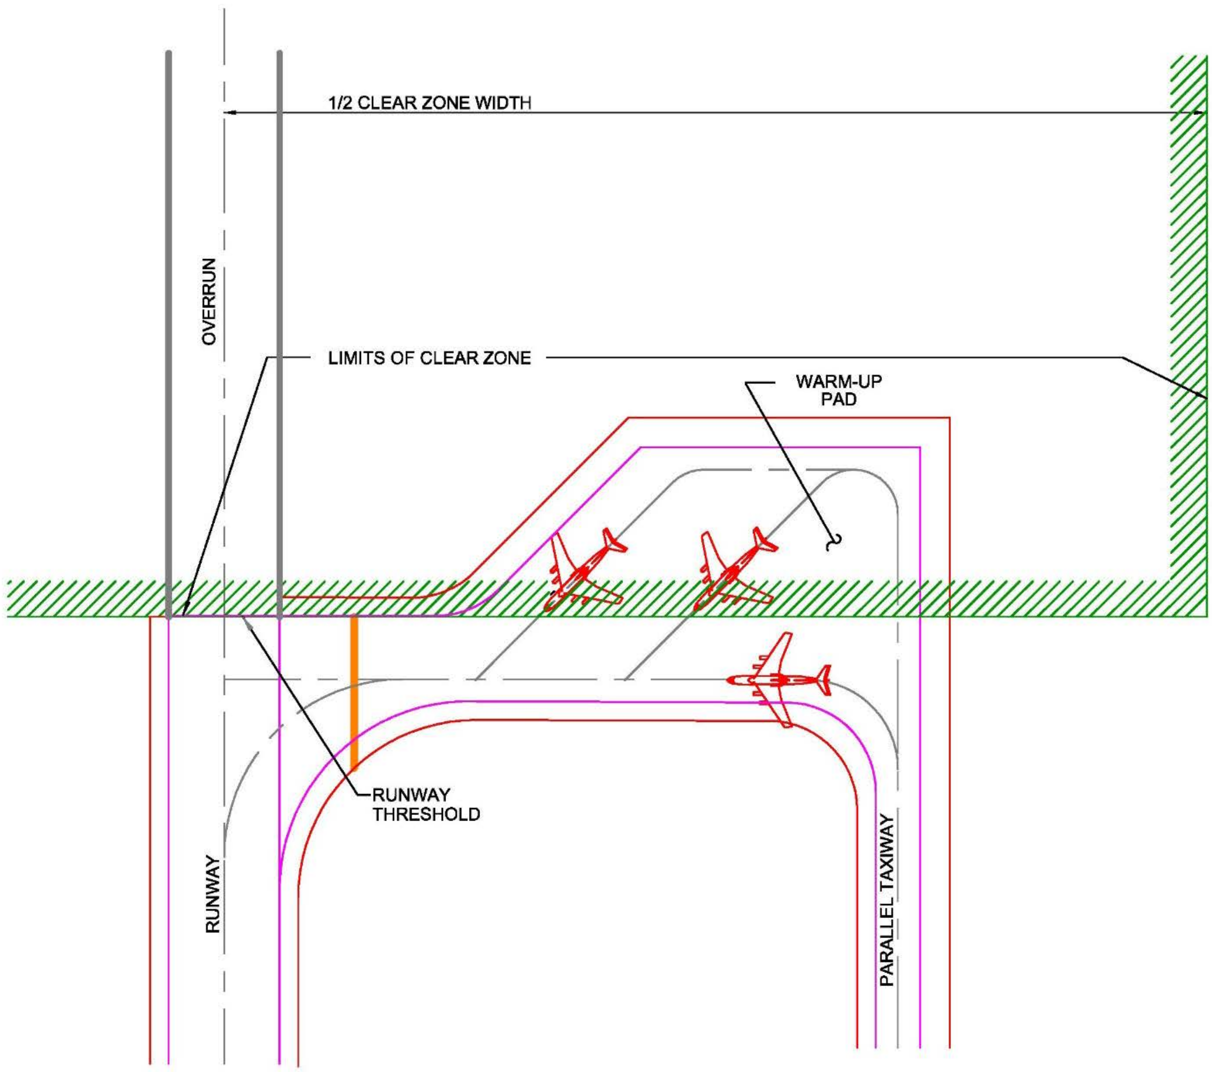

Figure 6-16. Warm-Up Pad Located in Approach-Departure Clearance Surface

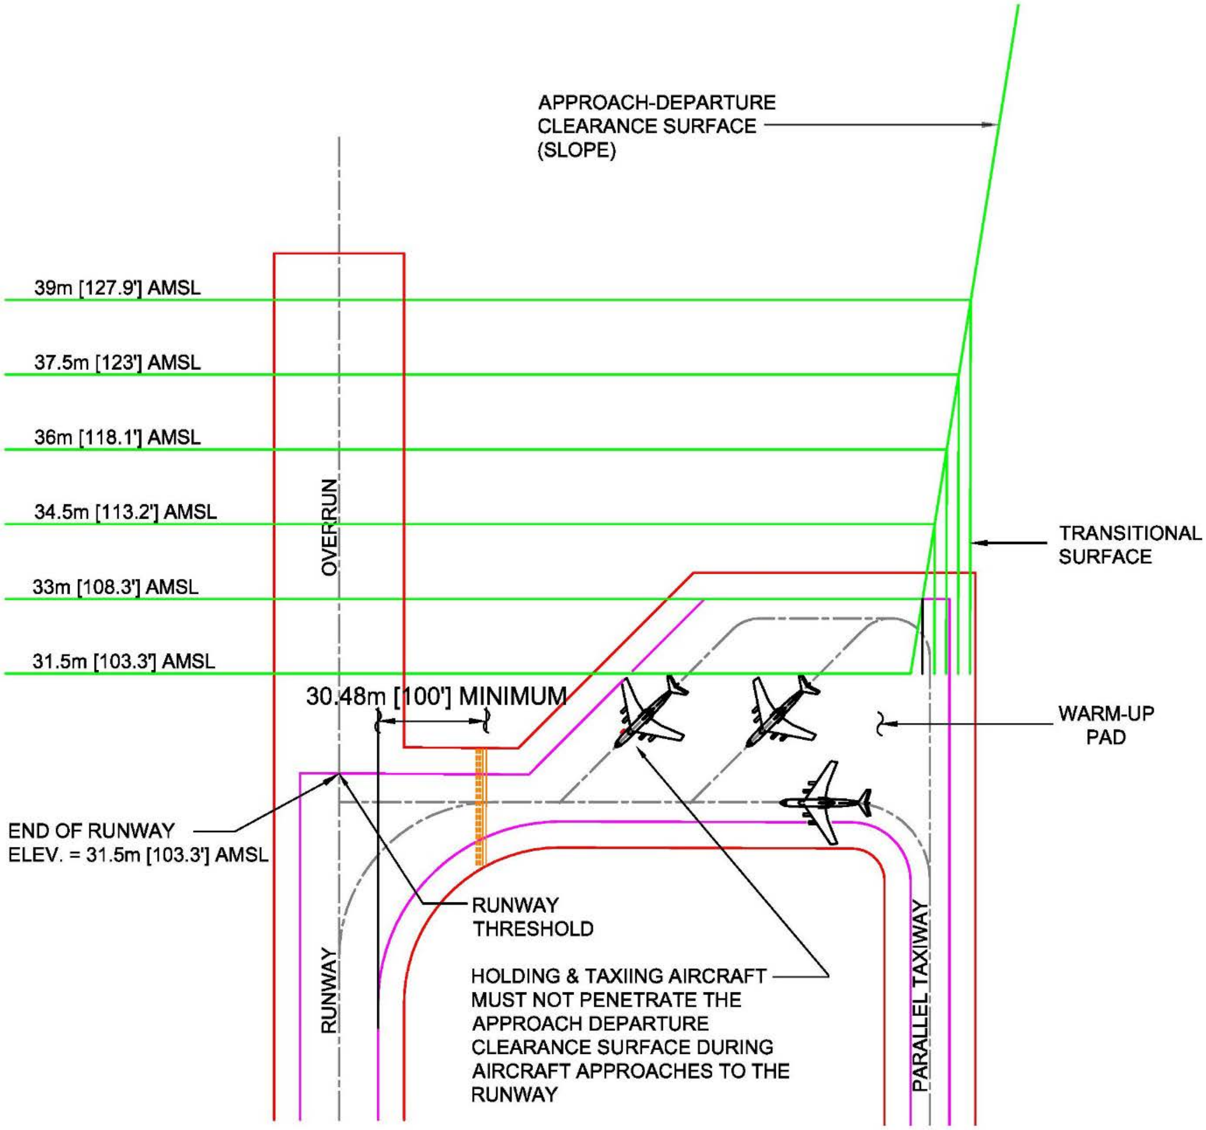

N.T.S.

Figure 6-17. Warm-Up Pad/Localizer Critical Area

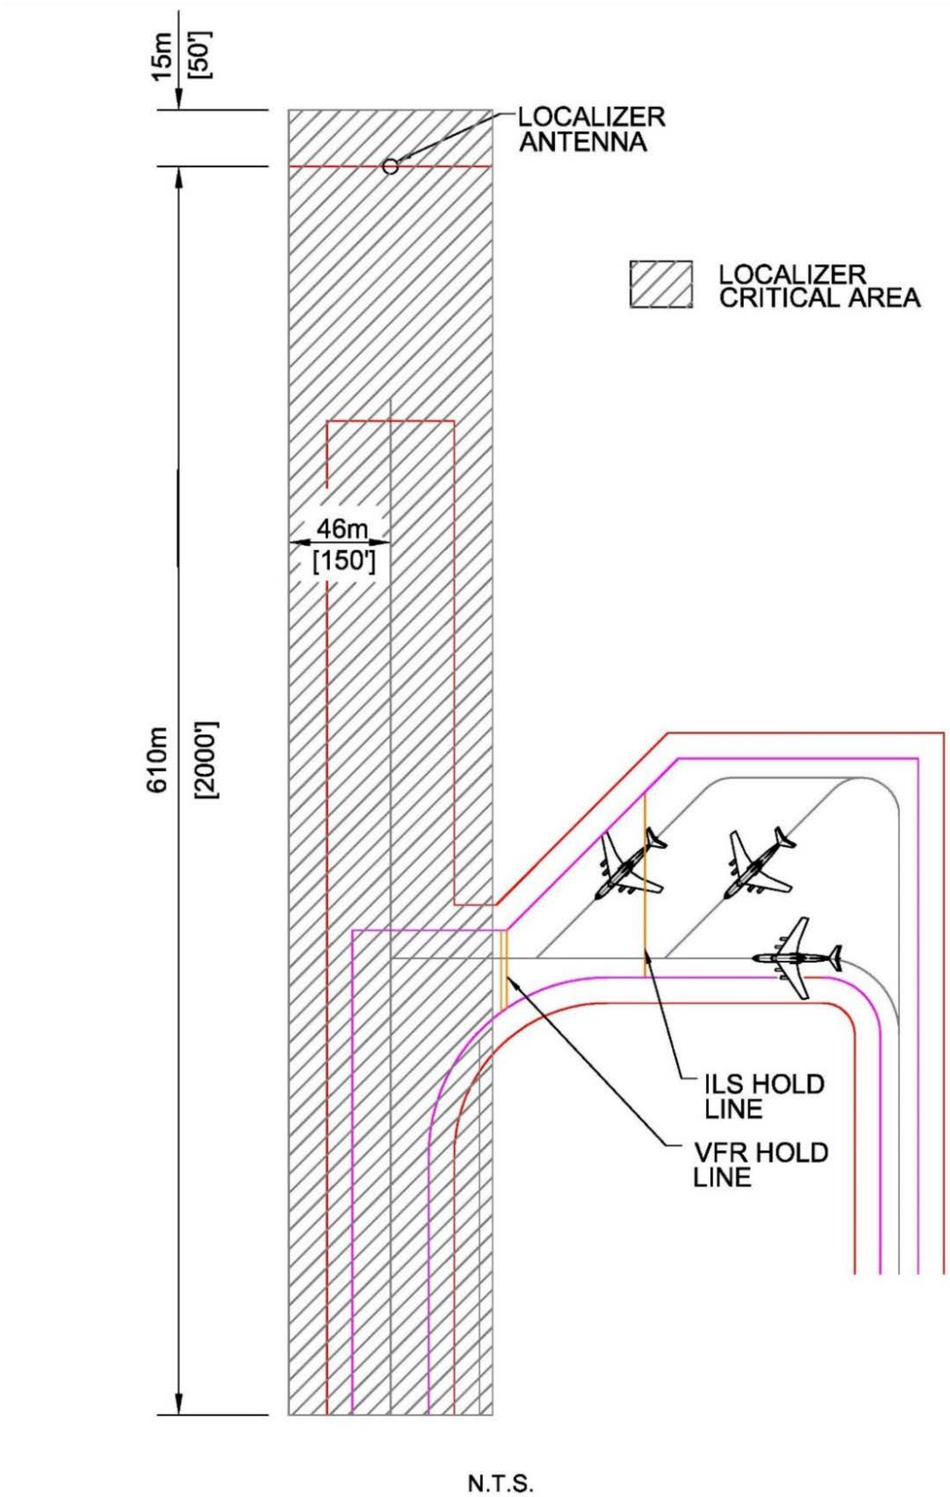

Figure 6-18. Warm-Up Pad/Glide Slope Critical Area

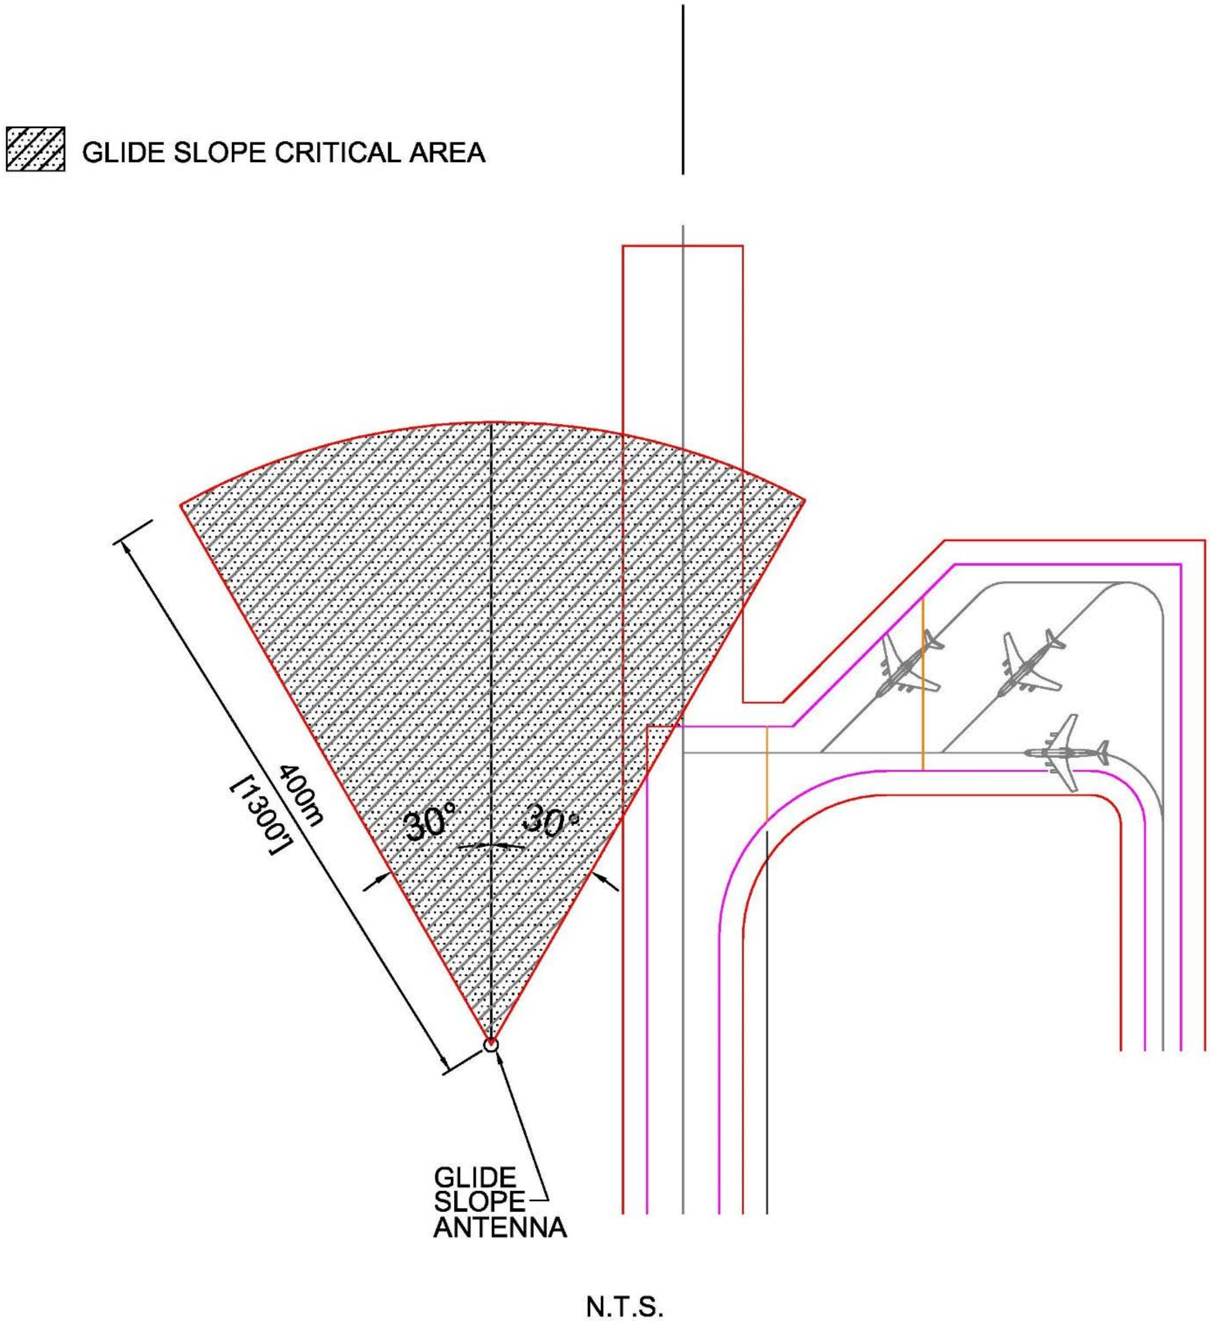

Figure 6-19. Warm-Up Pad/CAT II ILS Critical Area

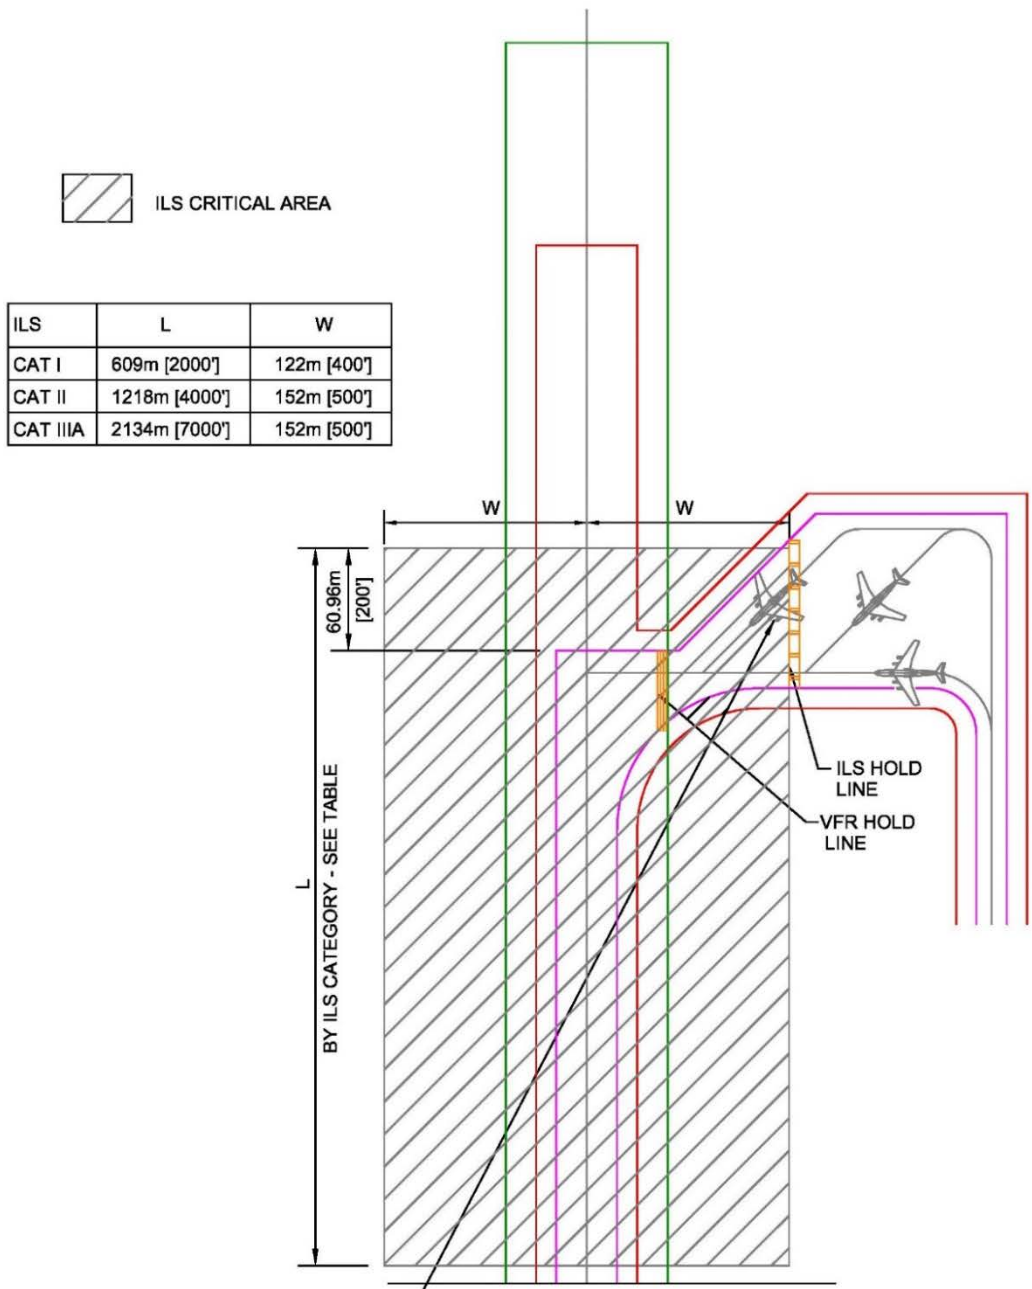
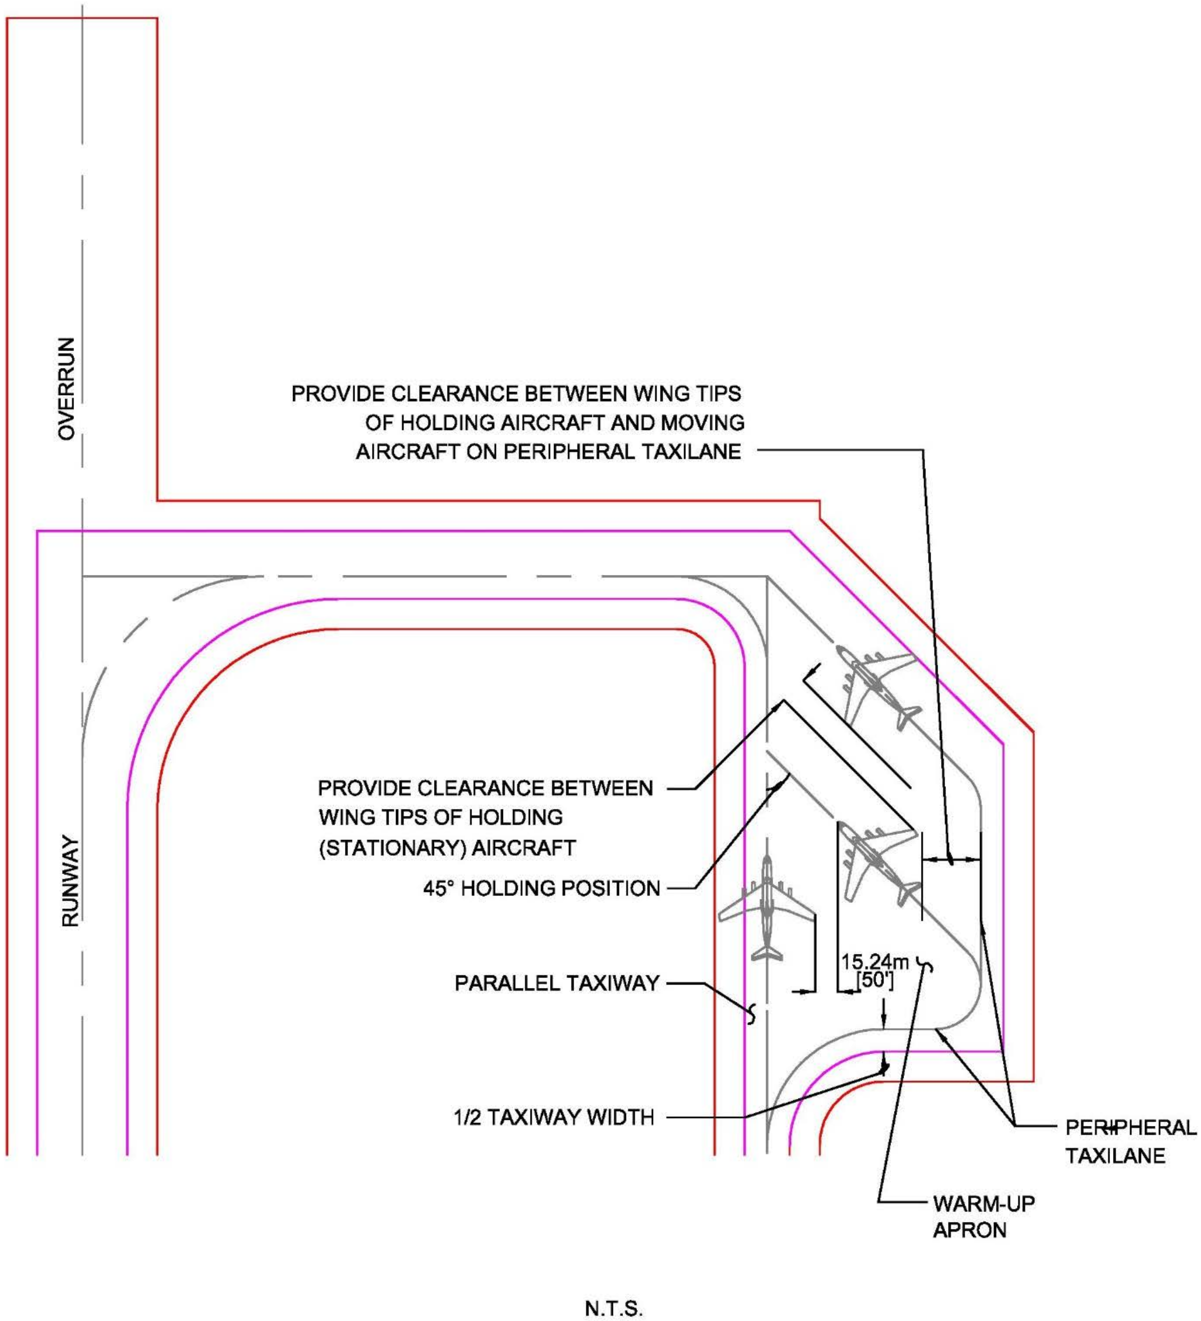


ILS	L	W
CAT I	609m [2000']	122m [400']
CAT II	1218m [4000']	152m [500']
CAT IIIA	2134m [7000']	152m [500']

NOTES

1. THIS HOLDING SPOT CANNOT BE USED DURING IFR CONDITIONS. AIRCRAFT IN THIS PARTICULAR POSITION ARE WITHIN THE LOCALIZER CRITICAL AREA IDENTIFIED BY THE ILS HOLD LINE. UNDER INSTRUMENT FLIGHT CONDITIONS THIS AREA SHOULD BE CLEAR OF OBJECTS THAT COULD REFLECT OR BLOCK THE ILS SIGNAL.
2. SITING OF WARM-UP PAD BASED ON CAT 1 CRITERIA MAY LIMIT FUTURE USE OF FIRST HOLD POSITION IF HIGHER CATEGORY APPROACHES ARE INSTALLED.

Figure 6-20. Warm-Up Pad Taxiing and Wingtip Clearance Requirements



6-8.6 Parking Angle.

Aircraft should be parked at a 45-degree angle to the parallel taxiway to divert the effects of jet blast away from the parallel taxiway. (See Appendix B, Section 7, for minimum standoff distances.) This is shown in Figure 6-20.

6-8.7 Turning Radius.

The turning radius on warm-up pads will be designed to provide the minimum allowable turn under power for the largest aircraft assigned to the base.

6-8.8 Taxilanes on Warm-Up Pads.

Taxilanes on the warm-up pad will meet the lateral clearance requirements discussed in Table 6-1. Lateral and wingtip clearance for a taxilane on a warm-up pad is illustrated in Figure 6-20.

6-8.9 Tie-Downs and Grounding Points.

Tie-downs, mooring points, and grounding points are not required on warm-up pads.

6-9 POWER CHECK PAD.

An aircraft power check pad is a paved area, with an anchor block in the center, used to perform full-power engine diagnostic testing of aircraft engines while the aircraft is held stationary.

6-9.1 Location and Siting Considerations.

Unsuppressed power check pads should be located near maintenance hangars, but at a location where full-power engine diagnostic testing of jet engines can be performed with minimal noise exposure to inhabited areas on and off the base.

6-9.2 Unsuppressed Power Check Pad Layout.

Power check pads may be rectangular, square, or circular.

6-9.2.1 Army and Air Force.

Power check pad layouts for Army and Air Force aviation facilities are shown in Figures 6-21, 6-22, and 6-23.

6-9.2.2 Navy and Marine Corps.

Power check pad layouts for Navy and Marine Corps aviation facilities are found in UFC 4-212-01N.

6-9.3 Access Taxiway/Towway.

An access taxiway will be provided for access from the primary taxiway to the power check pad. If the aircraft is to be towed to the unsuppressed power check pad, the access pavement should be designed as a towway. Taxiway and towway design requirements are presented in Chapter 5.

6-9.4 Grading.

The surface of the unsuppressed power check pad must slope 3.5% away from the anchor block in the direction of jet blast to the pavement edge to divert the effect of jet blast away from the concrete surfaces and pavement joints. See Figure 6-24.

6-9.5 Thrust Anchors/Mooring Points.

Thrust anchors (Air Force) or mooring points (Army) or tie-down mooring eyes (Navy and Marine Corps) are required on unsuppressed power check pads. Layout for these anchors is interdependent of joint spacing, and the two should be coordinated together. Tie-down and grounding points are discussed further in Appendix B, Section 11.

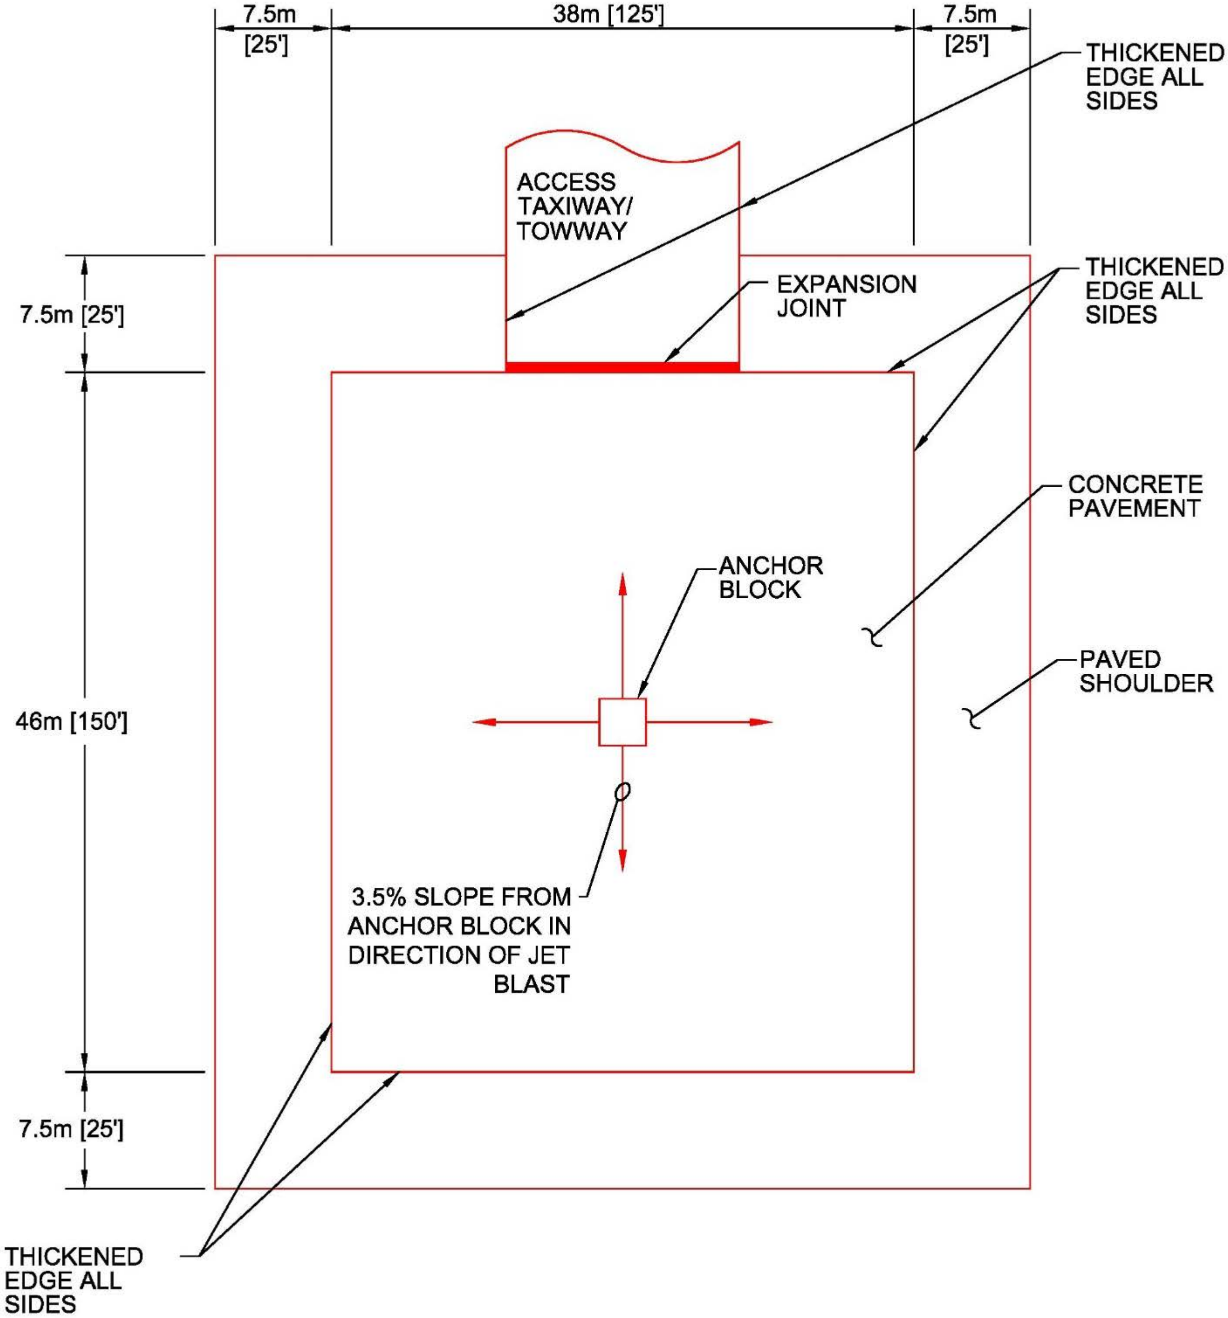
6-9.5.1 Army and Air Force.

Power check pad thrust anchors designed for 267 kilonewtons (kN) (60,000 lbf) (Army and Air Force aviation facilities) and for 445 kN (100,000 lbf) are provided in Appendix B, Section 15.

6-9.5.2 Navy and Marine Corps.

Power check pad tie-down mooring eye designed for Navy and Marine Corps aviation facilities are found in UFC 4-212-01N.

Figure 6-21. Geometry for Rectangular Power Check Pad



N.T.S.

Figure 6-22. Geometry for Square Power Check Pad

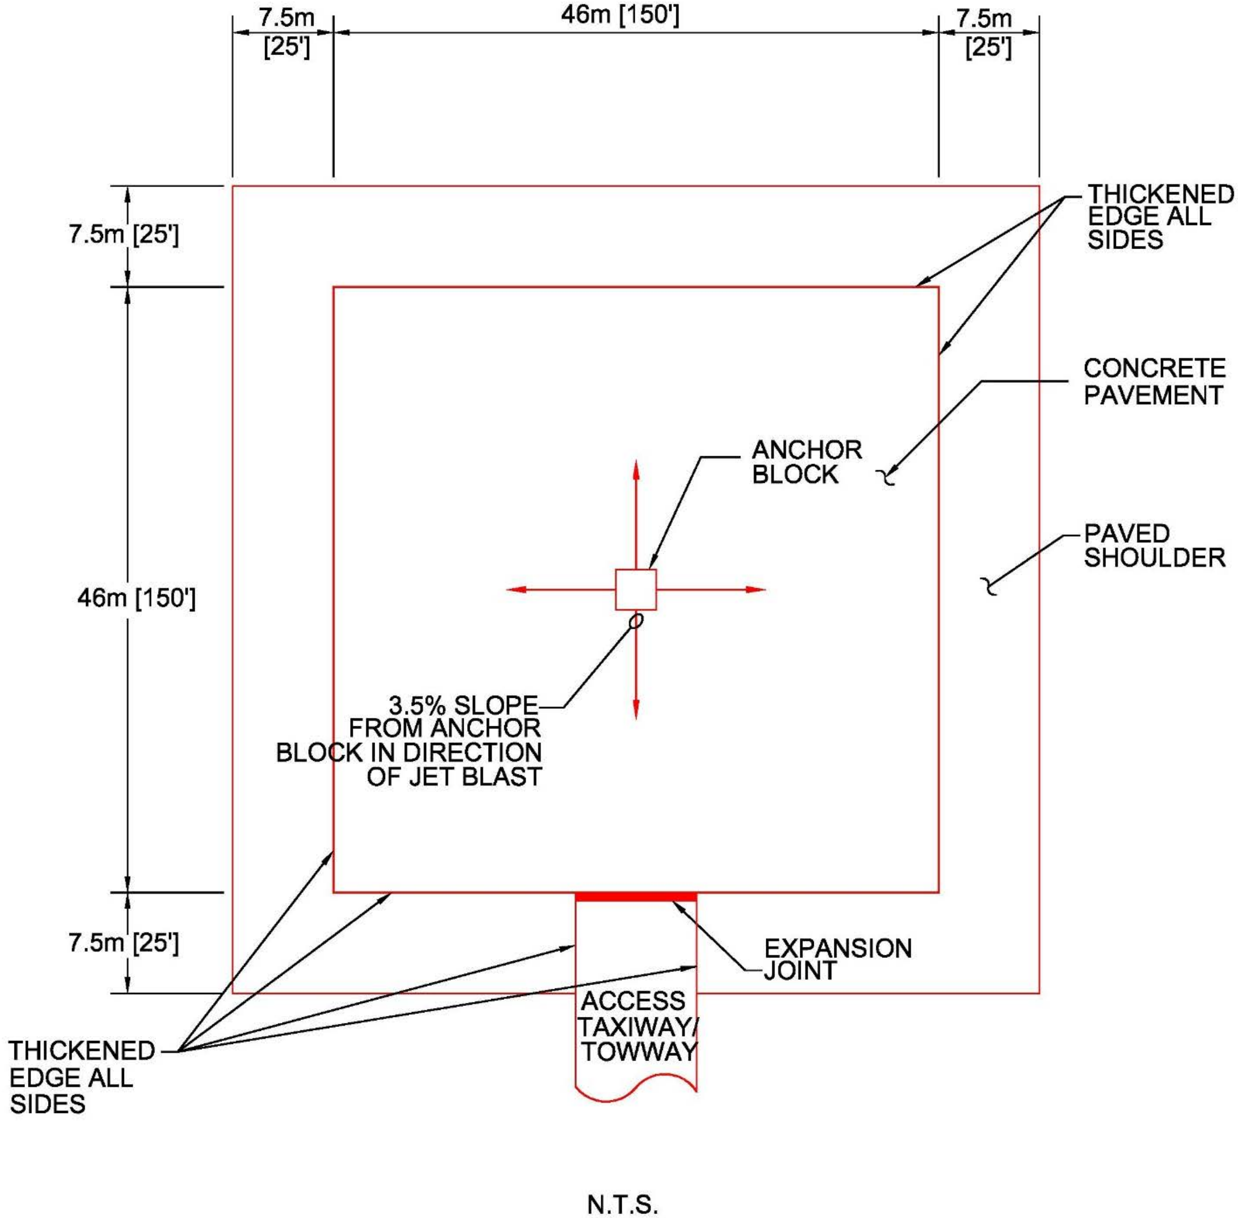


Figure 6-23. Geometry for Circular Power Check Pad

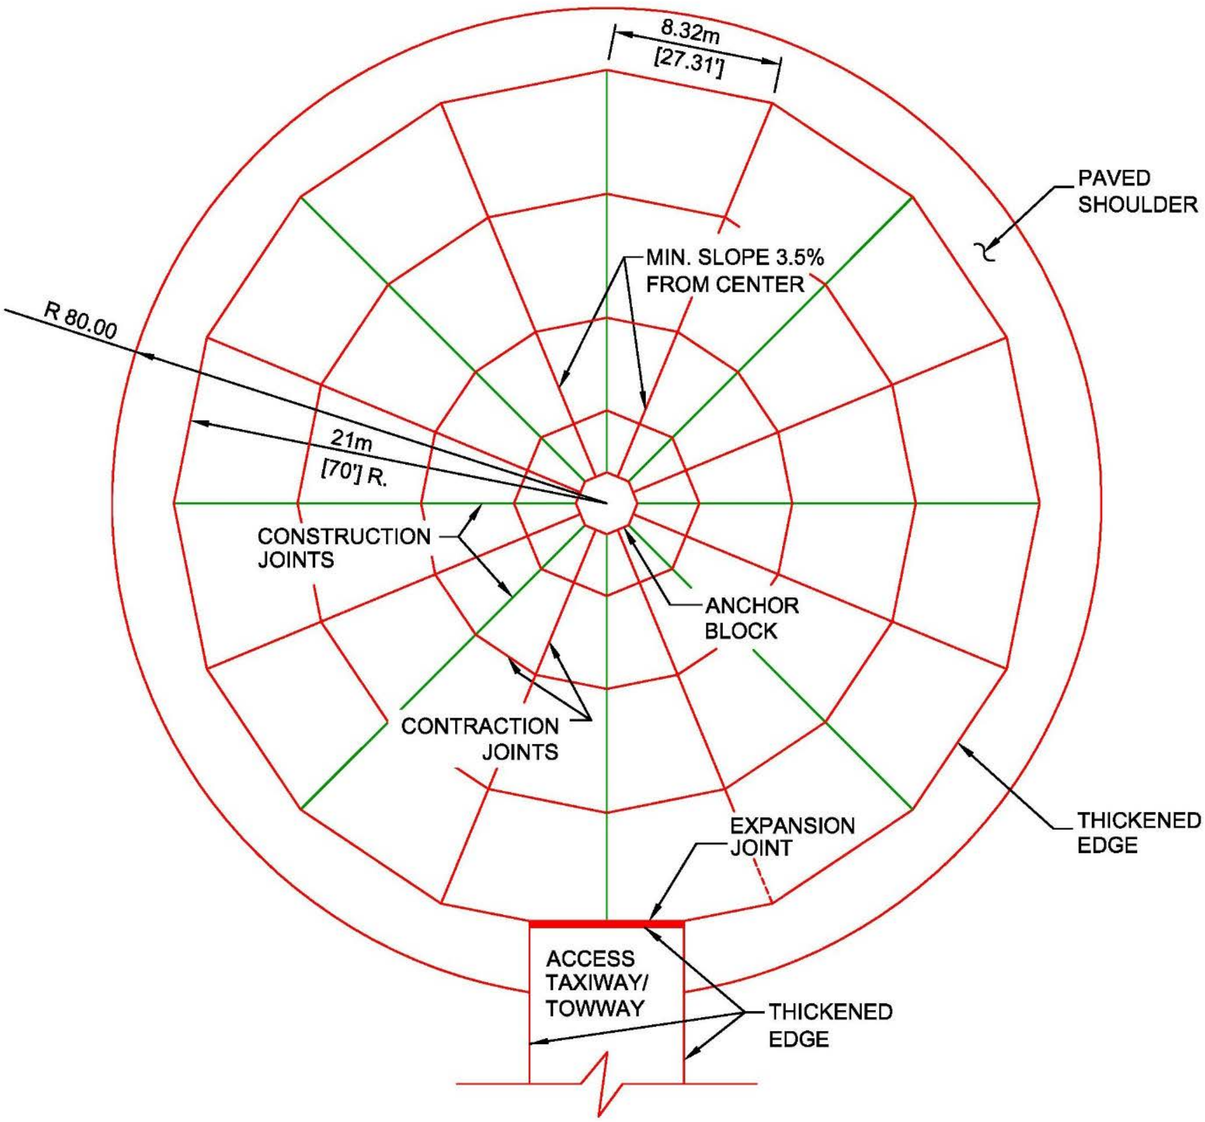
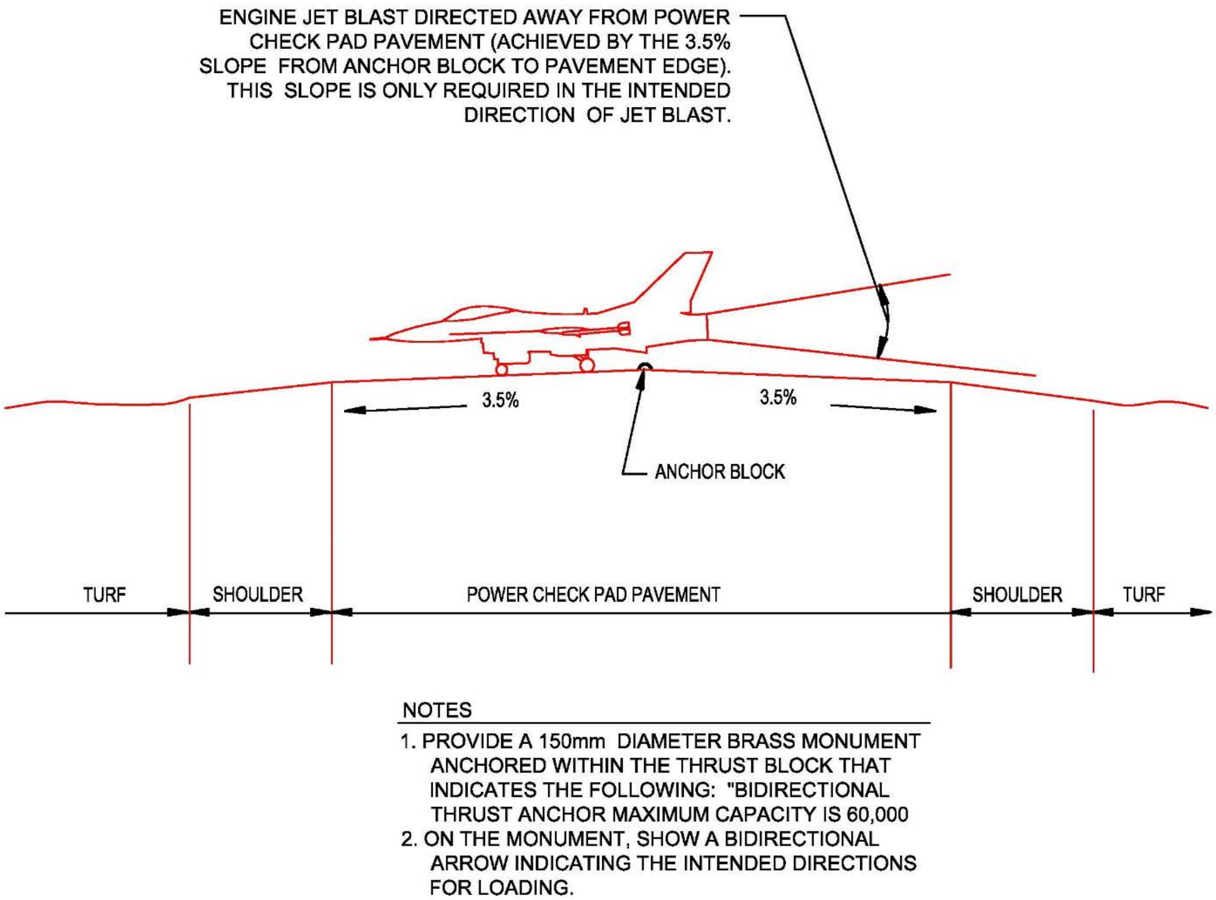


N.T.S.

Figure 6-24. Power Check Pad Grading



6-9.6 Anchor Blocks.

All unsuppressed power check pads have a thrust anchor block installed in the center of the power check pad to anchor the aircraft during engine testing. Anchor blocks are structurally designed for each individual aircraft. The designer must verify structural adequacy of the anchor block for the mission aircraft and engine type.

6-9.6.1 Army and Air Force.

Thrust anchor blocks for Army and Air Force aviation facilities are provided in Appendix B, Section 15.

6-9.6.2 Navy and Marine Corps.

Thrust anchor blocks for Navy and Marine Corps aviation facilities are provided in UFC 4-212-01N.

6-9.7 Power Check Pad Facilities.

Power check pads for Navy and Marine Corps aviation facilities are provided in UFC 4-212-01N

6-9.7.1 Required Facilities.

The unsuppressed power check pad should consist of these required items:

- Paved surface
- Paved shoulders (see Appendix B, Section 7, for minimum standoff distances)
- A thrust anchor or anchors for aircraft serviced at the pad
- Blast deflectors if required to protect the surrounding area from jet blast damage

6-9.7.2 Optional Facilities.

The unsuppressed power check pad may include these items:

- Floodlighting for night operations
- Water supply to wash down fuel spills
- Oil separators, holding tanks, and fuel treatment to address fuel spillage prior to discharge into sanitary or storm sewer
- Communication link with the maintenance control room
- Fire hydrants
- A paved roadway to the unsuppressed power check pad for access by firefighting, towing, and aircraft maintenance support vehicles

6-9.8 Noise Considerations.

The noise level at unsuppressed power check pads may exceed 115 decibels (dB(a)) during power-up engine tests. Caution signs should be placed around the power check pad indicating both the presence of hazardous noise levels and the need for hearing protection.

6-10 ARM/DEARM PADS.

The arm/dearm pad is used for arming aircraft immediately before takeoff and for dearming (safing) weapons retained or not expended upon their return. Do not site arm/dearm pads, other aprons, hot cargo spots, or taxiways to these facilities in a way that will allow penetration of the approach-departure clearance surface.

6-10.1 Navy and Marine Corps Requirements.

Navy and Marine Corps requirements for arm/dearm pads are provided in UFC 2-000-05N.

6-10.2 Location.

Air Force arm/dearm pads should be located adjacent to runway thresholds and sited such that armed aircraft are oriented in the direction of least populated areas or towards revetments.

6-10.3 Siting Considerations.

6-10.3.1 Aircraft Heading.

The criteria for establishing the exact heading of the parked aircraft depends on the type of aircraft and associated weapons. This information is contained within the classified portion of the aircraft manuals. The most economical means of parking aircraft on the arm/dearm pads is at 45 degrees to the taxiway; however, because of the requirement to orient armed aircraft away from populated areas, this angle may vary.

6-10.3.2 Forward Firing Munitions Protection Zone.

Coordinate with the responsible safety office to determine the specific risks associated with the mission aircraft and establish protection zones or available measures to mitigate risk. It is good practice to keep all buildings out of this protection zone to prevent damage from accidental weapon firing. This forward firing munitions protection zone may cross a runway, taxiway, or runway approach as long as the landing and taxiing aircraft can be seen by the arm/dearm quick check crews and the arming/dearming operations can cease for the period in which the aircraft passes. Parked aircraft or parked vehicles must not be located in the forward firing munitions protection zone. If a protection zone appropriate for the type of munitions to be used cannot be obtained, earth revetments or similar risk mitigation measures (barricades, etc.) should be used, but must be sited properly relative to wingtip and airspace clearance requirements.

6-10.3.3 Electromagnetically Quiet Location.

Prior to construction of any pad, local field measurements must be taken or verified with the installation weapons safety manager to ensure that the location is electromagnetically quiet. To avoid potential electromagnetic interference from taxiing aircraft, pads should be located on the side of a runway opposite the parallel taxiway. Use concrete encased rigid steel conduits for any electrical conductors located within 200 ft of the pad. Navy and Marine Corps aviation facilities must have an electromagnetic compatibility (EMC) background study by SPAWARSYSCEN Charleston, as described in NAVAIR 16-1-529. The Air Force conducts electromagnetic radiation (EMR) surveys with regard to explosives safety in accordance with AFI 91-

208. The specific information for each emitting device should be available through the installation communications squadron.

6-10.4 Arm/Dearm Pad Size.

Each arm/dearm pad should be capable of servicing four or six aircraft at a time. The dimensions of the pad must be based on the length, wingspan, and turning radius of the aircraft to be served. Jet blast must also be taken into account. Typical layouts of arm/dearm pads are shown in Figures 6-25, 6-26, 6-27, and 6-28.

6-10.5 Taxi-In/Taxi-Out Capabilities.

The parking locations should have taxi-in/taxi-out capabilities to allow aircraft to taxi to their arm/dearm location under their own power.

6-10.6 Parking Angle.

The parking angle depends on the type of aircraft, type of weapons, and the associated uninhabited clear zone location.

6-10.7 Turning Radius.

The turning radius for taxilanes on arm/dearm pads should be designed to provide the minimum allowable turn under power of the largest aircraft that will use the arm/dearm pad.

6-10.8 Access Road.

An all-weather access road should be constructed to the arm/dearm pad from outside the airfield's taxiway and runway clearance areas. Design this road in accordance with UFC 3-250-18FA and UFC 3-250-01FA. Access roads must not encroach on taxiway clearances or taxilane wingtip clearance requirements (except at necessary intersections with these areas), nor shall any parking area associated with the access road be sited so that maintenance vehicles will violate the approach-departure clearance surface or any NAVAID critical area.

6-10.9 Tie-downs and Grounding Points.

Tie-downs and mooring points are not required on arm/dearm pads. See Appendix B, Section 11, for grounding requirements.

6-10.10 Ammunition and Explosives Safety Standards.

Ammunition and explosives safety standards are discussed in Appendix B, Section 9.

Figure 6-25. Arm-Dearm Pad for F-15 Fighter

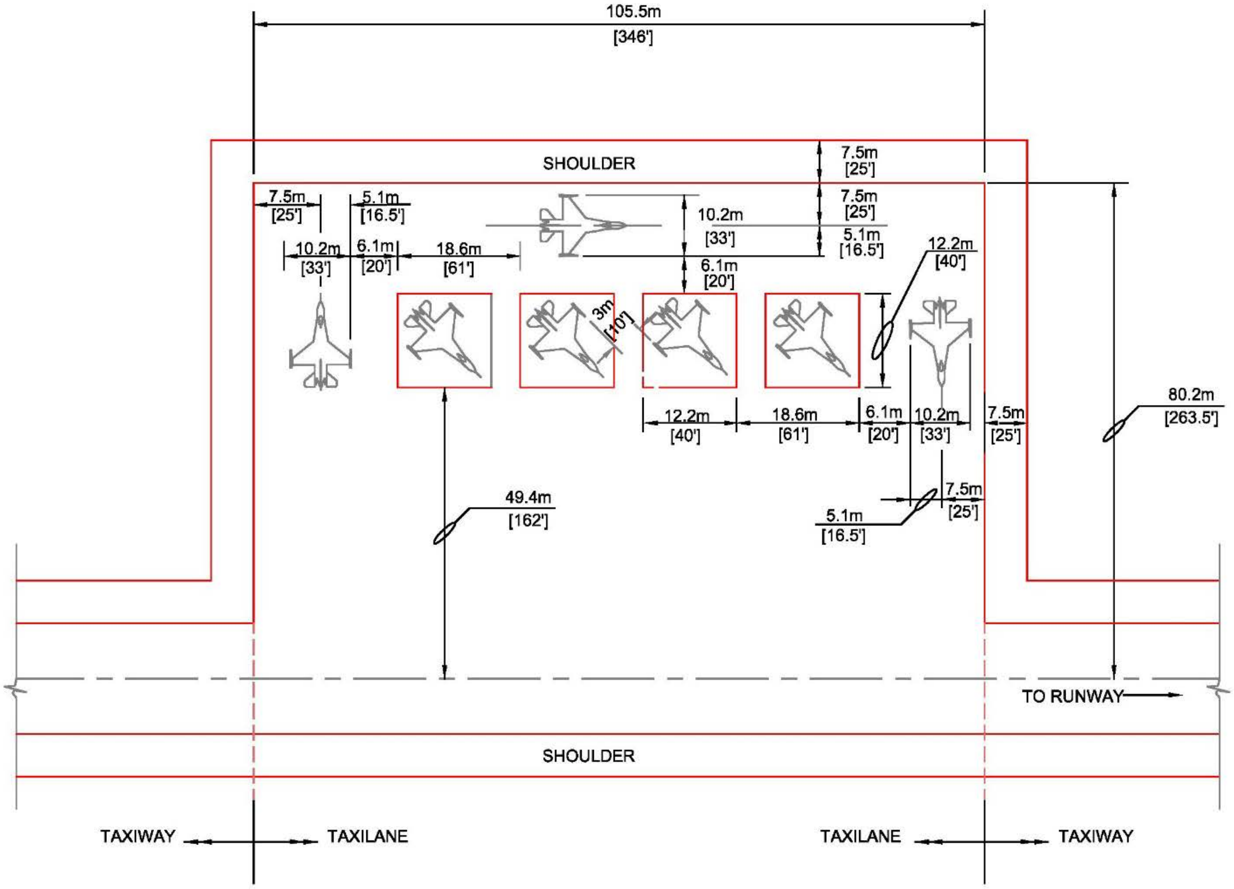
Figure 6-26. Arm-Dearm Pad for F-16 Fighter



N.T.S.

Figure 6-27. Arm-Dearm Pad for F-22 Fighter

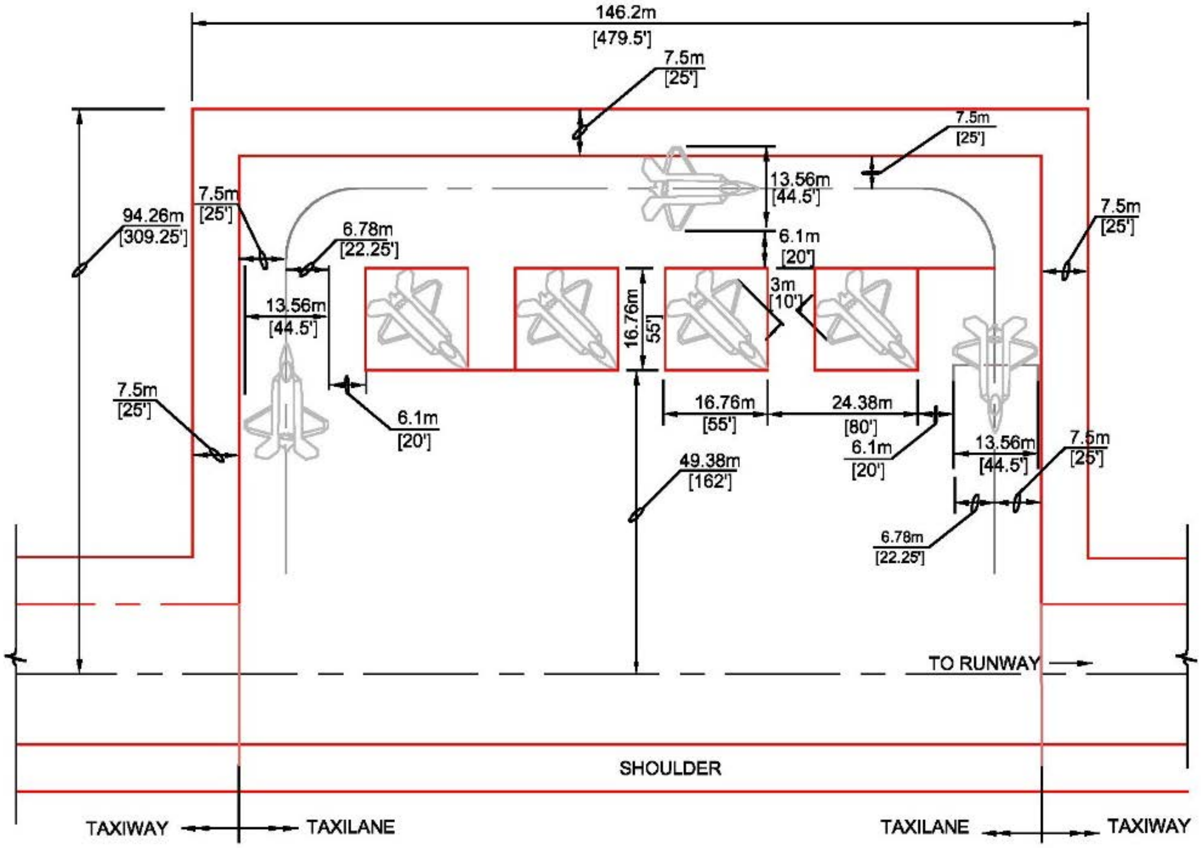


Figure 6-28. Arm-Dearm Pad for F-35 Fighter (JSF)

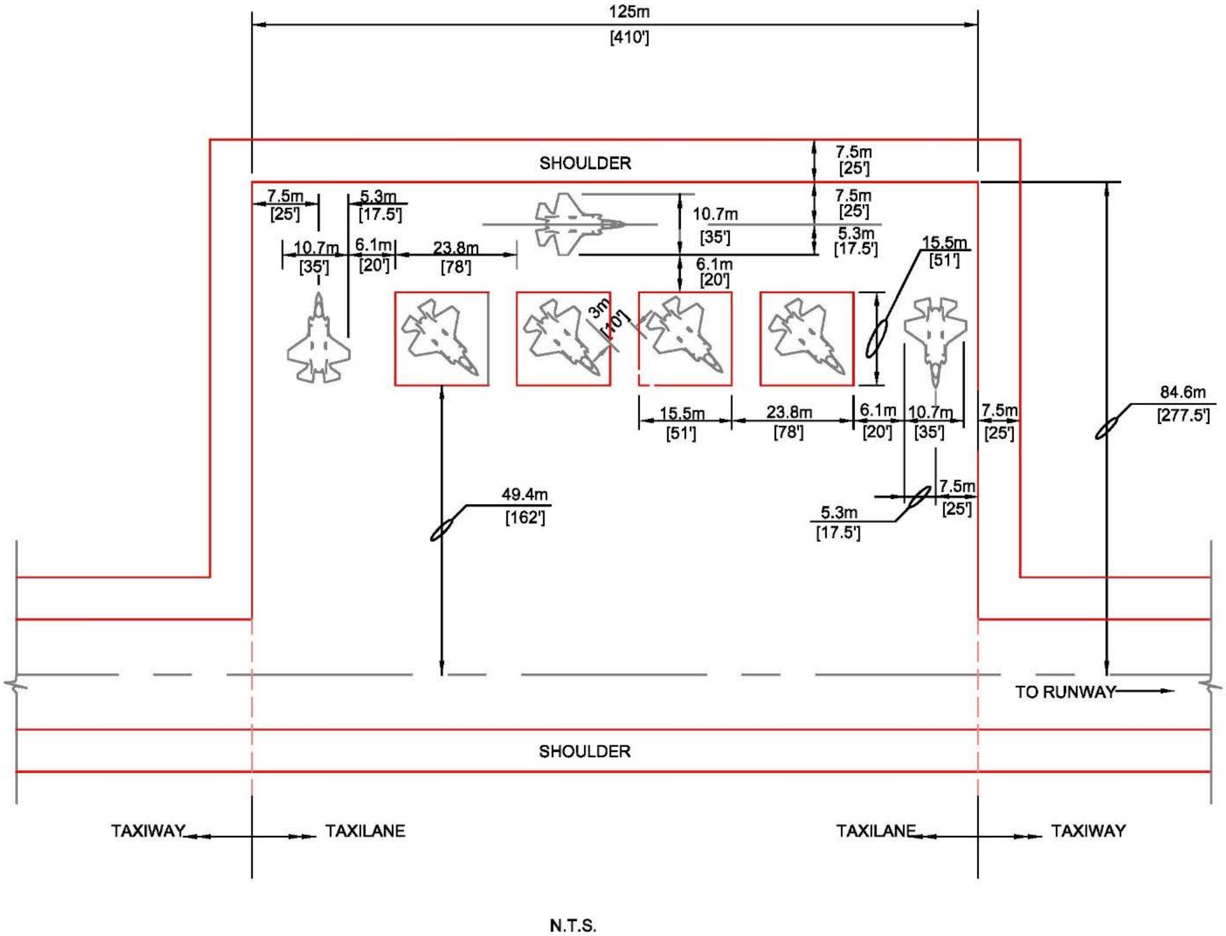


6-11 COMPASS CALIBRATION PAD (CCP).

An aircraft CCP is a paved area in a magnetically quiet zone where an aircraft's compass is calibrated.

6-11.1 Army.

A CCP is not required by the Army, but if one is provided, or used, then requirements of Paragraph 6-11 and applicable subparagraphs apply.

6-11.2 Air Force.

The Air Force has the option of using the criteria presented here or using the criteria provided in FAA AC 150/5300-13.

6-11.3 Navy and Marine Corps.

Prior to construction of, or major repair of, a CCP, a validation of need shall be filed through the maintenance department to NAVAIR for approval. For CCP marking requirements, use the controlling aircraft NAVAIR Technical Manual or use the criteria contained in Appendix B, Section 10, for general purpose CCPs.

6-11.4 Location.

The CCP should be located off the side of a taxiway at sufficient distance to satisfy the runway and taxiway lateral clearance distance and airspace criteria in Chapters 3, 4, and 5. Do not site CCPs, other aprons, hot cargo spots, or taxiways to these facilities in a way that will allow penetration of the approach-departure clearance surface.

6-11.5 Siting Consideration.

6-11.5.1 Separation Distances.

To meet the magnetically quiet zone requirements and prevent outside magnetic fields from influencing the aircraft compass calibration, efforts must be taken to make sure that minimum separation distances are provided. See Appendix B, Section 10 for CCP separation distances.

6-11.5.2 Preliminary Survey.

During the site selection process, the proposed sites for CCPs must be checked for magnetic influences to ensure that the area is magnetically quiet regardless of adherence to separation distances. A preliminary survey as described in Appendix B, Section 10, must be conducted to determine if the proposed site is magnetically quiet. A survey similar to the preliminary survey must be conducted after construction of any new item or building, within or near the separation distances of the pad. This will ensure that the newly constructed item has not created new magnetic influences in the magnetically quiet zone.

6-11.5.3 Magnetic Survey and Re-marking Requirements.

The CCP magnetic survey is an airfield engineering survey used to ensure that the CCP area is magnetically quiet, to determine the magnetic variation (MagVar) of the area, and to layout the markings for the pad. A magnetic survey shall be conducted after construction of a new CCP and at regular intervals thereafter to ensure the CCP remains suitable for aircraft magnetic compass calibrations. The procedure to conduct magnetic surveys is outlined in Appendix B, Section 10.

6-11.5.3.1 Magnetic Survey Frequency.

Because the Magnetic North Pole is constantly moving, the MagVar at any location on the Earth is constantly changing at varying rates. Check the MagVar and the MagVar rate of change for any latitude/longitude using https://www.ngdc.noaa.gov/geomag/declination.shtml. Every CCP must be re-surveyed periodically to update the MagVar, update the alignment with Magnetic North, and update the CCP markings. The CCP markings shall be removed and replaced when the new MagVar differs by more than 30 arc-minutes (0.5 degrees) from the existing CCP markings. In addition, periodic re-surveys ensure the CCP area remains a magnetically quiet zone, which is essential for accurate aircraft magnetic compass calibrations.

A CCP must be re-surveyed and the markings updated when the MagVar changes by more than 30 arc-minutes from the existing markings. For CCPs where the MagVar rate of change is low (7 arc-minutes or less per year), a re-survey must be conducted at an interval of 5 years or less. At locations where the MagVar rate of change is greater than 7 arc-minutes per year, more frequent re-surveys are required. Table 6-3 lists the re-survey frequency needed based on MagVar rates of change. If at any time the difference exceeds the tolerance of the aircraft compass or calibration equipment, the Airfield Manager may schedule a survey more frequently.

Periodic surveys to re-calibrate the marked directions on the CCP are required at a minimum every five years. In locations where the magnetic variation over time is high, more frequent re-calibration is required. Table 6-3 lists re-survey frequency needed to keep the difference between marked north and magnetic north less than 50 arc-minutes. If the difference exceeds the tolerance of the aircraft compass or calibration equipment, the Airfield Manager may schedule a survey more frequently.

Table 6-3. Magnetic Survey Frequency Requirements

Magnetic Variation Rate of Change [arc-minutes per year]	Re-Survey Frequency
≤ 7	5 years
8	4 years
9-10	3.5 years (42 months)
11	3 years
12-14	2.5 years (30 months)
15-18	2 years
≥ 19	1.5 years (18 months)

.

6-11.5.3.2 Additional Information.

The Naval Air Warfare Center-Aircraft Division (NAWCAD-4.5.3), an authority on CCPs, substantially contributed to this criteria. For additional information on CCP survey and maintenance, contact:

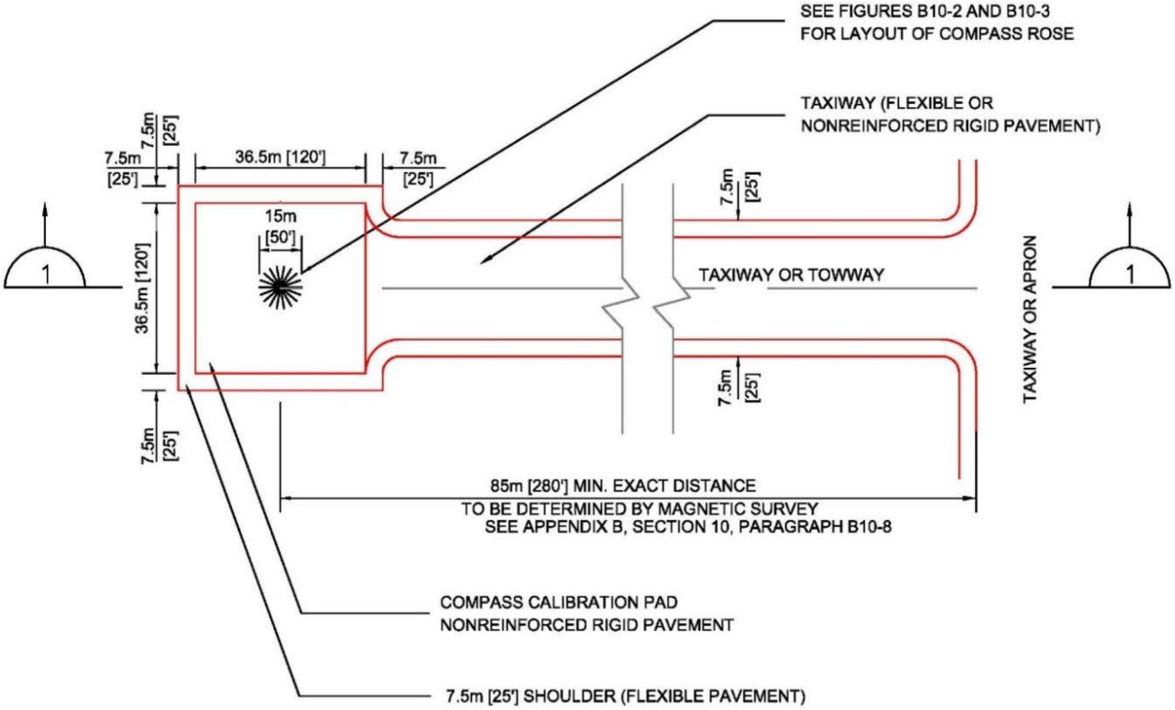
Naval Air Warfare Center-Aircraft Division
NAWCAD-4.5.3, Core Avionics Engineering Division

Building 2187
NAS Patuxent River, MD
(301) 342-9122

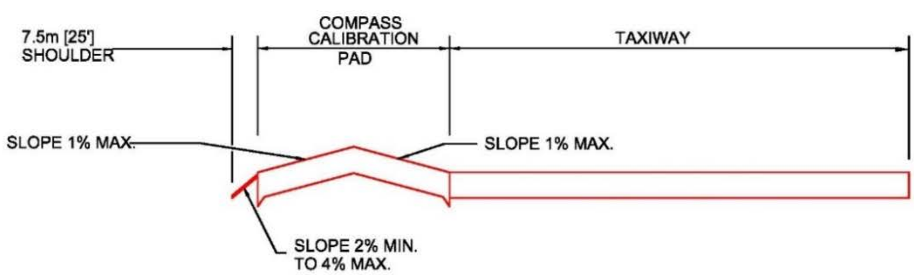
6-11.6 Compass Calibration Pad (CCP) Size.

Typical CCP size is shown in Figure 6-29.

Figure 6-29. Compass Calibration Pad



PLAN
N.T.S.



NOTE

THICKNESS OF CONCRETE AND BASE COURSE, BASE COURSE DENSITY, TYPE OF SHOULDER SURFACING AND CBR OF SHOULDER BASE COURSE ARE GOVERNED BY EXISTING CRITERIA OR ARE DEPENDENT UPON SITE CONDITIONS.

SECTION 1
N.T.S.

6-11.7 Access Taxiway/Towway.

An access taxiway will be provided for access from the primary taxiway to the CCP. The access taxiway must be oriented to facilitate moving the aircraft onto the CCP on a magnetic north heading. At Army and Air Force aviation facilities, if the aircraft should be towed to the CCP, the access taxiway must be designed as a towway. At Navy and Marine Corps facilities, the taxiway should be designed as a taxiway. Taxiway and towway design requirements are presented in Chapter 5.

6-11.8 Grading.

CCPs will be graded as specified in this section.

6-11.8.1 Perimeter Elevation.

The elevation of the perimeter of the pad will be the same elevation around the entire perimeter.

6-11.8.2 Cross Slope.

The CCP should be crowned in the center of the pad with a constant cross slope of 1% in all directions to provide surface drainage while facilitating alignment of the aircraft pad.

6-11.9 Tie-Down/Mooring Point.

Do not place any aircraft tie-down/mooring points, tie-down/mooring eyes, or static grounding points in the CCP pavement.

6-11.10 Embedded Material.

Due to the influence of ferrous metal on a magnetic field, the PCC pavement for the CCP and access taxiway must not contain any embedded ferrous metal items such as dowels bars, reinforcing steel, steel fibers, or other items. In addition, ferrous metal must not be placed in or around the CCP site.

6-11.11 Control Points.

A control point will be set in the center of the CCP. This point will consist of a brass pavement insert into which a bronze marker is grouted in accurate alignment. This point will be stamped with "Center of Calibration Pad." The layout of the control points is discussed further in Appendix B, Section 10.

6-11.12 CCP Markings.

See Appendix B, Section 10.

6-12 HAZARDOUS CARGO PADS.

Hazardous cargo pads are paved areas for loading and unloading explosives and other hazardous cargo from aircraft. Hazardous cargo pads are required at facilities where the existing aprons cannot be used for loading and unloading hazardous cargo. Do not site hazardous cargo pads, other aprons, hot cargo spots, or taxiways to these facilities in a way that will allow penetration of the approach-departure clearance surface. A Hazardous Cargo Pad is not authorized in a Runway Clear Zone.

6-12.1 Navy and Marine Corps Requirements.

Hazardous cargo pads are not normally required at Navy and Marine Corps facilities; however, where operations warrant or an Air Force hazardous cargo aircraft is continuously present, hazardous cargo pads can be justified with proper documentation.

6-12.2 Siting Criteria.

Hazardous cargo pads require explosives site planning as discussed in Appendix B, Section 9.

6-12.3 Hazardous Cargo Pad Size

6-12.3.1 Circular Pad.

At aviation facilities used by small cargo aircraft, the hazardous cargo pad is a circular pad as shown in Figure 6-30.

6-12.3.2 Semicircular Pad.

At aviation facilities used by large cargo aircraft and at aerial ports of embarkation (APOE) and aerial ports of debarkation (APOD), the hazardous cargo pad is semicircular, as shown in Figure 6-31. The semicircular pad is adequate for aircraft up to and including the dimensions of the C-5.

6-12.3.3 Other Pad Size.

The hazardous cargo pad geometric dimensions as shown in Figures 6-30 and 6-31 are minimum requirements. Hazardous cargo pads may be larger than these dimensions if the design aircraft cannot maneuver on the pad. Sources for obtaining information concerning minimum turning radii for various aircraft are presented in Army USACE TSC Report 13-2..

6-12.4 Access Taxiway.

An access taxiway will be provided for access from the primary taxiway to the hazardous cargo pad. The taxiway should be designed for the aircraft to taxi into the hazardous cargo pad under its own power.

6-12.5 Tie-Down and Grounding Points.

Tie-down/mooring points and tie-down/mooring eyes must be provided on each hazardous cargo pad. Grounding points must be provided on each hazardous cargo pad. Tie-down and grounding points are discussed further in Appendix B, Section 11.

6-12.6 Miscellaneous Considerations.

These items need to be considered for hazardous cargo pads:

6-12.6.1 Utilities.

Telephone service, apron flood lighting, airfield lighting, and water/fire hydrants are required for safety.

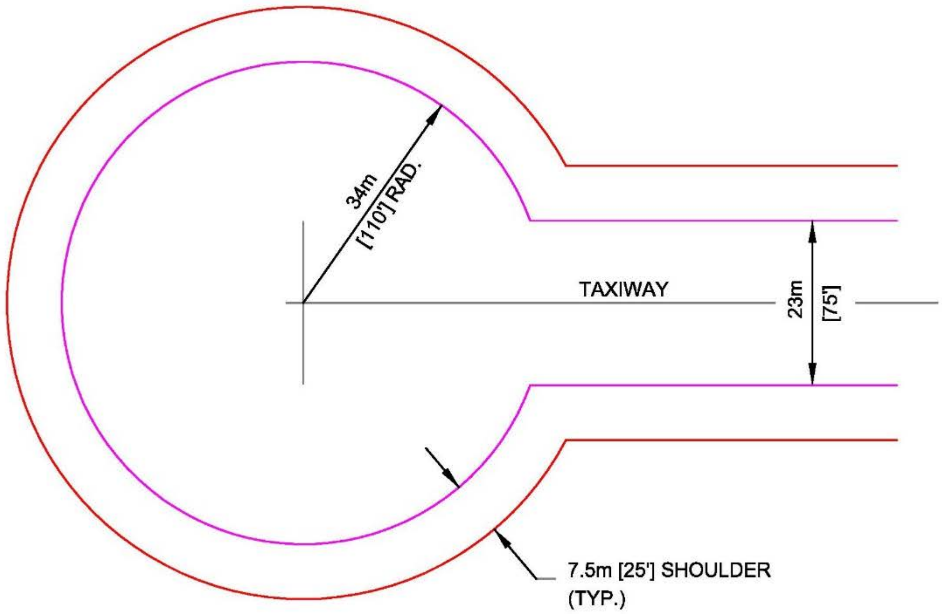
6-12.6.2 Access Road.

Consider providing a paved roadway to the hazardous cargo pad for access by trucks and other vehicles.

6-13 ALERT PAD.

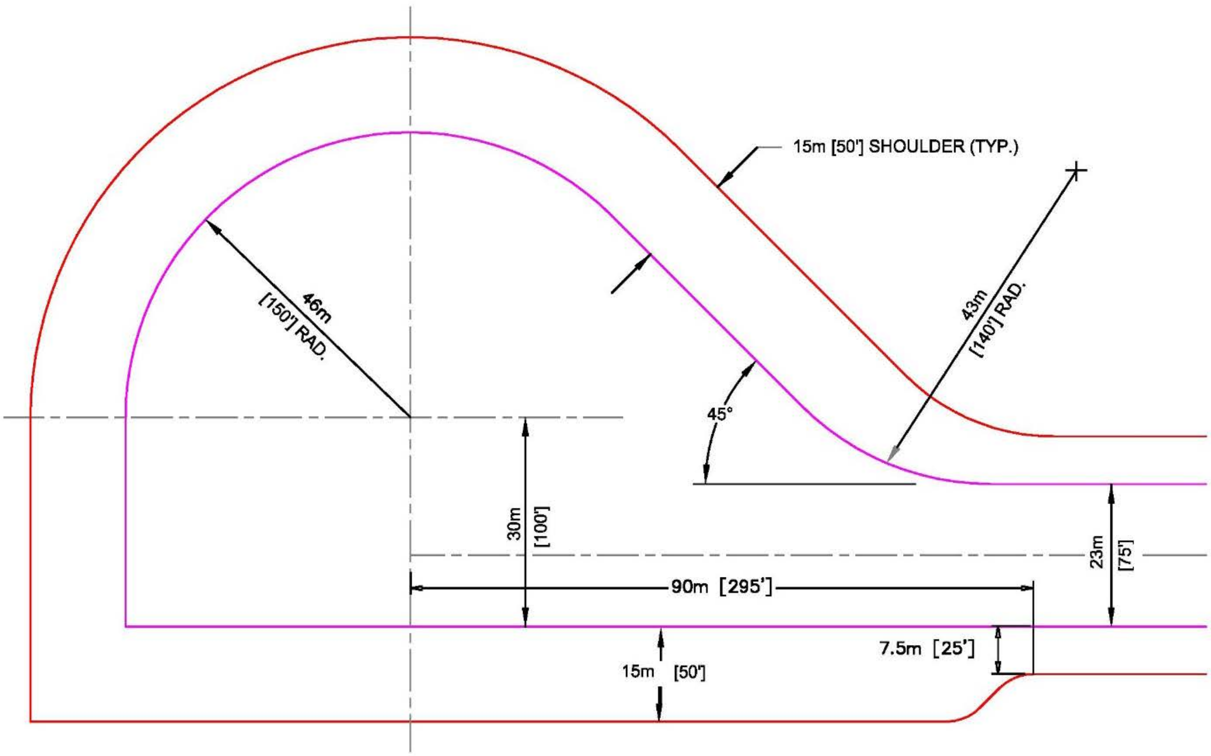
An alert pad, often referred to as an alert apron, is an exclusive paved area for armed aircraft to park and have immediate, unimpeded access to a runway. In the event of a declared alert, alert aircraft must be on the runway and airborne in short notice. This chapter will refer to both alert aprons and alert pads as "alert pads." An alert apron is shown in Figure 6-32. An alert pad is shown in Figure 6-33.

Figure 6-30. Hazardous Cargo Pad Other than APOE/Ds



N.T.S.

Figure 6-31. Typical Hazardous Cargo Pad for APOE/Ds

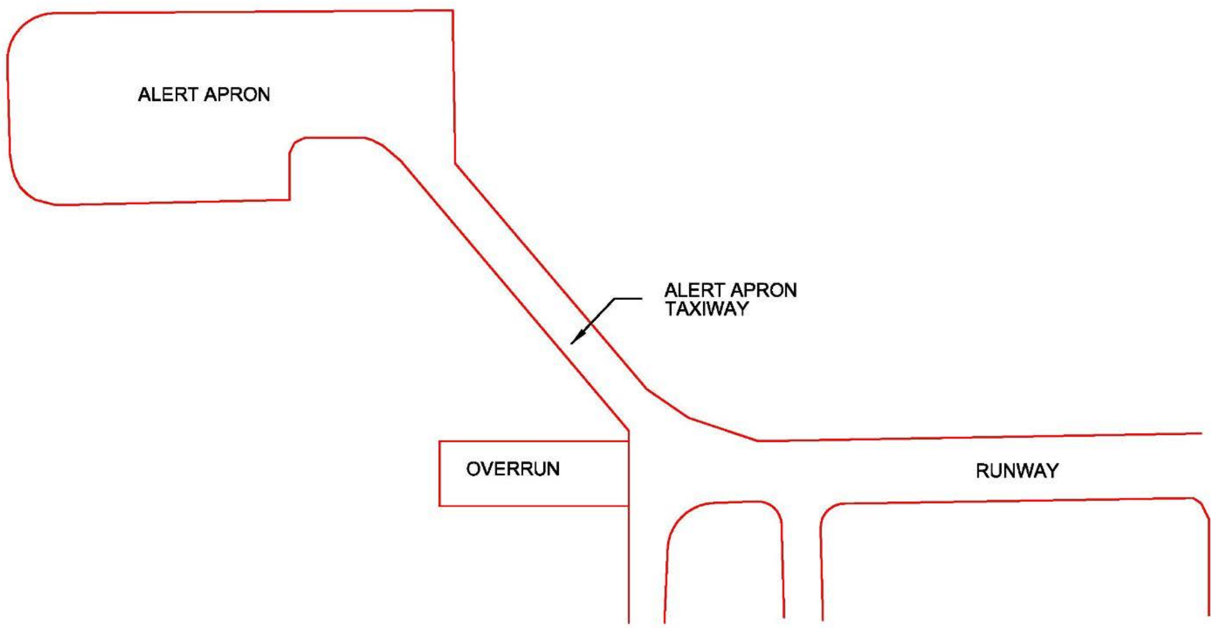


N.T.S.

NOTE

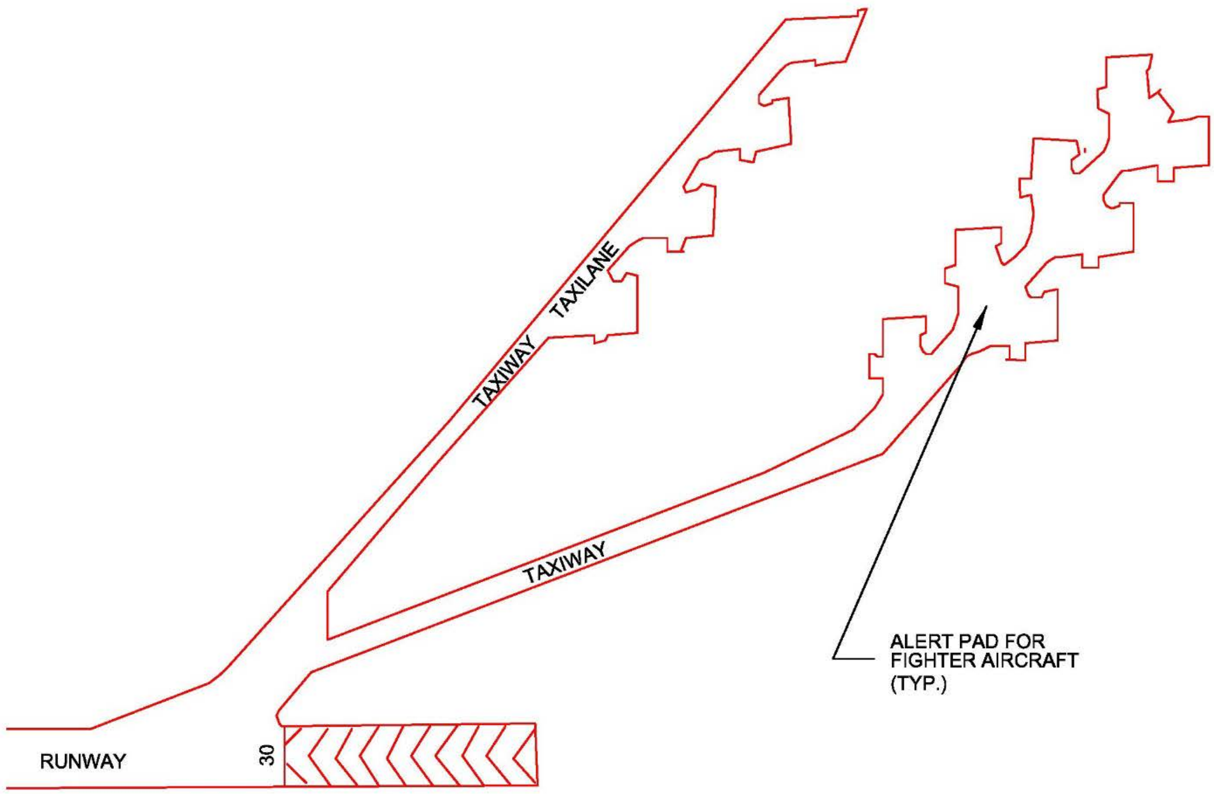
THIS HAZARDOUS CARGO PAD IS ADEQUATE FOR AIRCRAFT UP TO AND INCLUDING THE C-5. THE DIMENSIONS MAY BE ADJUSTED TO ACCOMMODATE LIMITING CONSTRAINTS AT INDIVIDUAL FACILITIES.

Figure 6-32. Typical Alert Apron for Bombers and Tanker Aircraft



N.T.S.

Figure 6-33. Typical Alert Pad for Fighter Aircraft



N.T.S.

6-13.1 Navy and Marine Corps Requirements.

Alert pads are not normally required at Navy and Marine Corps facilities. When justified, the criteria provided in this UFC will be used.

6-13.2 Location.

Locating the alert pad adjacent to a runway end will allow alert aircraft to proceed directly from the apron to the runway threshold without interruptions from other traffic. Alert pads must be located close to the runway threshold to allow alert aircraft to be airborne within the time constraints stipulated in their mission statements. The preferred location of alert pads is on the opposite side of the runway, away from normal traffic patterns to allow aircraft on the alert pad direct, unimpeded access to the runway. Alert pads and alert aprons must not be located so that the aircraft or shelters are within the graded area of the clear zone, or penetrate the approach-departure clearance surface.

6-13.3 Siting Criteria.

6-13.3.1 Airspace Imaginary Surfaces.

As discussed in paragraph 6-8.3.2, aircraft parked on alert pads must not project into airspace imaginary surfaces.

6-13.3.2 Explosives Consideration.

Aircraft loaded with explosives on alert pads should be located to minimize the potential for explosive hazards. Explosives safety site plans must be prepared for explosive-loaded alert aircraft. See Appendix B, Section 9.

6-13.4 Alert Pad Size.

6-13.4.1 General Dimensions.

Alert pads should be sized to park all of the aircraft on alert. The dimensions of the pad should vary with the length and wingspan of the aircraft to be served and the explosives on the aircraft. Wingtip clearances, presented in Table 6-4, are minimum separation distances to be observed at all times.

Table 6-4. Minimum Separation Distance on Tanker or Bomber Alert Aprons from the Centerline of a Through Taxilane to a Parked Aircraft

Aircraft	Standard (m)	Standard (ft)	Minimum (m)	Minimum (ft)
B-52 or B-52 mixed force B-1 B-2	45.72	150	38.10	125
KC-46	41.91	137.5	34.29	112.5
KC-135	38.10	125	30.48	100
KC-10	30.48	100	22.86	75

6-13.4.2 Air Force Waivers.

6-13.4.2.1 Wingtip Clearances.

The MAJCOM may grant waivers to the 15.24 m (50 ft) wingtip clearance requirement when sufficient ramp area is not available. In no case will the wingtip clearance be waived to less than 9.14 m (30 ft).

6-13.4.2.2 Wingtip Clearances Based on Taxilane Width.

When the minimum separation distance between a taxilane centerline and the nose/tail of a parked aircraft is reduced below the distance shown in Table 6-1, the minimum waiver wingtip clearance distance of 9.14 m (30 ft) must be increased 0.3 m (1 ft) for each 0.3-m (1-ft) reduction in separation distance. Example: Referencing Table 6-4, the standard B-52 nose to taxiway centerline distance is 150 ft. If a B-52 nose to taxilane centerline is 43 m (140 ft)—minimum waiver wingtip distance 12 m (40 ft), adding the reduction in separation distance (10 ft) to the minimum waiver wingtip clearance (30 ft); if the nose to centerline distance is 40 m (130 ft) or less—no waiver permitted or required, since the reduction in separation distance (20 ft) added to the minimum waiver wingtip clearance (30 ft) would equal 50 ft, the standard wingtip clearance requirement, therefore for value of 130 ft or less, comply with 15-m (50-ft) minimum wingtip clearance.

6-13.5 Design Aircraft.

To facilitate flexibility in future operations, new alert ramp construction should conform to B-52 standards. Aircraft parked in shelters are exempt from the parking separation criteria in 6-13.4.2.1.

6-13.6 Alert Aircraft Parking Arrangements.

6-13.6.1 Fighter Arrangements.

Fighter aircraft are parked at 45-degree angles to dissipate the heat and velocity of jet blast.

6-13.6.2 Non-Fighter Arrangements.

Non-fighter aircraft should be parked in rows.

6-13.7 Jet Blast Distance Requirements.

Jet blast safe distances should be considered when planning and designing parking locations on alert pads. Safe distance criteria are presented in Appendix B, Section 7.

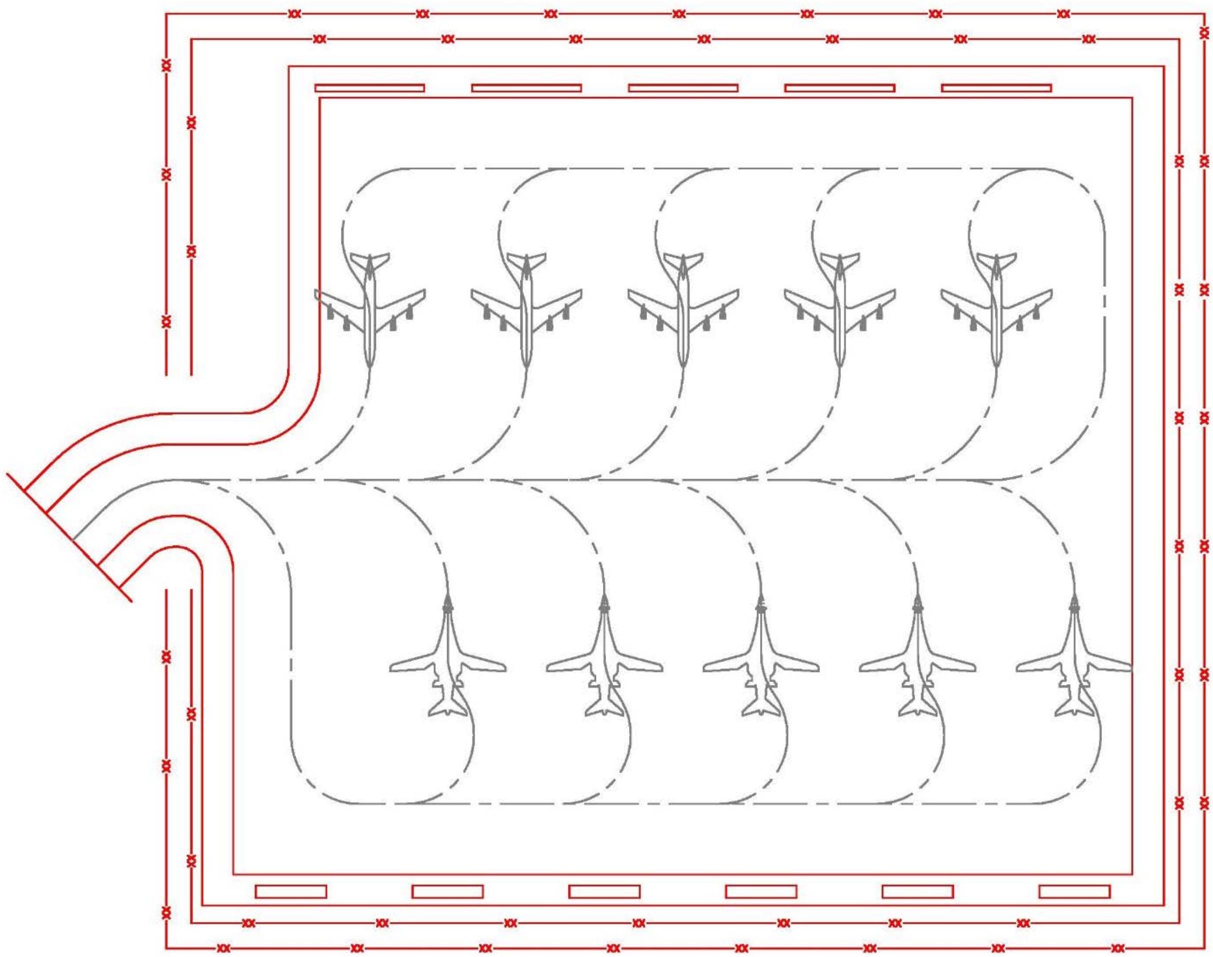
6-13.8 Taxi-In/Taxi-Out Capabilities.

Alert aprons and pads should be designed either for taxi-in/taxi-out parking or for push-back parking. Taxi-in/taxi-out parking, shown in Figure 6-34, is preferred because alert aircraft can be taxied quickly into position under their own power. Back-in parking, shown in Figure 6-35, requires less paved area.

6-13.9 Turning Radius.

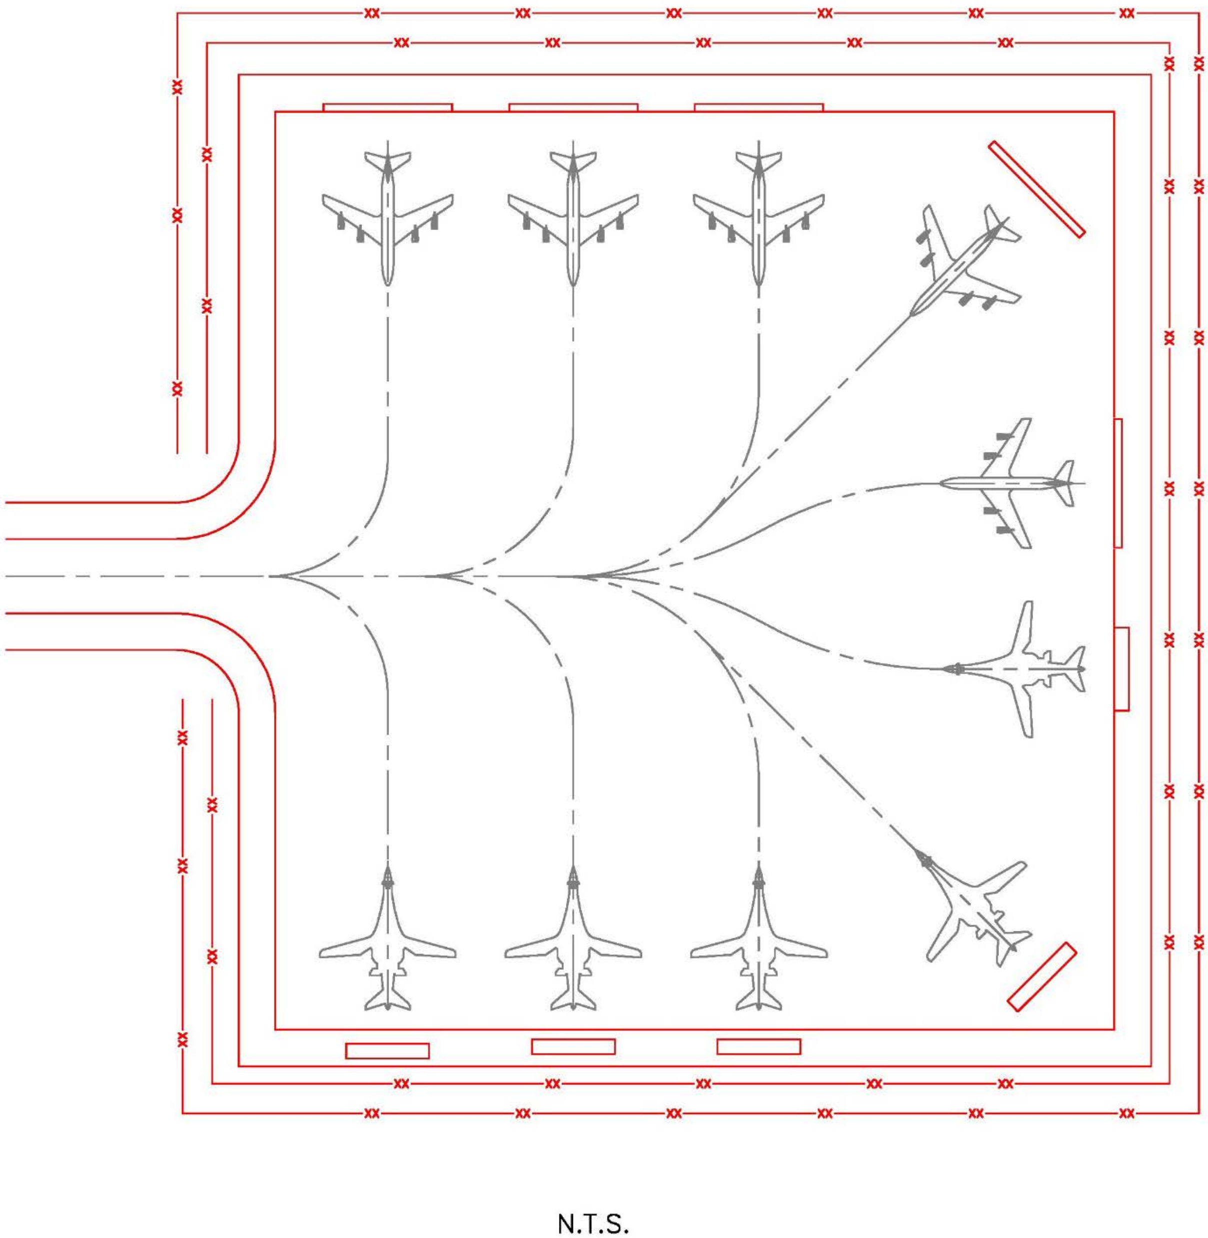
The turning radius on alert pad taxilanes will be designed to provide the minimum allowable turn under power of the largest aircraft that will use the alert pad. In no case will the initial turnout from the alert apron parking space to the through taxilane exceed 90 degrees. For Air Force alert pads for bombers and tankers, the initial turn radius from the parking space will equal the distance from the taxilane centerline to the nose of the aircraft. This is shown in Figure 6-34.

Figure 6-34. Alert Apron Taxi-In/Taxi-Out Parking



N.T.S.

Figure 6-35. Alert Apron Back-In Parking



6-13.10 Dedicated Access Taxiway.

At alert pads, provide a single dedicated taxiway from the alert pad to the runway for aircraft to progress directly without traffic interruptions. Having no other taxiways intersect the dedicated taxiway is the ideal way to ensure that the dedicated taxiway is not obstructed.

6-13.11 Tie-Down and Grounding Points.

Tie-down/mooring points, tie-down/mooring eyes, and grounding points will be provided at each aircraft parking location as discussed in Appendix B, Section 11.

6-14 AIRCRAFT WASH RACKS.

Aircraft wash racks are paved areas or facilities provided at all aircraft base facilities for the purpose of cleaning aircraft in conjunction with periodic maintenance and corrosion control activities.

This Section applies to Exterior Aircraft Wash Racks which are defined as open (non-environmentally controlled), covered or uncovered paved areas designed for the purpose of washing aircraft. Where required, the wash rack must be provided with a cover to protect the aircraft from sun induced heat or inclement weather preventing efficient wash operations. Interior Aircraft Wash Racks are addressed in UFC 4-211-02, Aircraft Corrosion Control Facilities.

6-14.1 Location.

Covered and uncovered aircraft wash racks should be located adjacent to the hangar area or maintenance facilities and contiguous to aircraft parking or access aprons. Existing pavements can be used where curbing can be installed, drainage adjusted as necessary, and other required facilities such as utilities can be provided to make a usable wash rack. Where possible, wash racks should be located near existing facilities where existing utility and pollution control systems are accessible. In siting wash racks, support facilities such as pump houses and tanks should be located either outside apron clearance distances or below grade. Follow aircraft wingtip clearance requirements presented in this chapter for siting the washrack in relation to parked aircraft and adjacent facilities.

6-14.2 Size and Configuration.

There are two standard shapes of wash racks for fixed wing aircraft as indicated in Figures 6-37 and 6-38: Type F, which accommodates fighters and other small aircraft; and Type L, which accommodates heavy bombers and large cargo aircraft. The Wash Rack Selection Chart, Figure 6-36, may be used to assist in determining the Wash Rack Type. Figure 6-40 represents a wash rack for rotary-wing facilities.

At mixed mission facilities, it may be possible to accommodate several smaller (fighter) aircraft on one larger Type F aircraft wash rack pavement. Size the pavement area to accommodate the larger of four small aircraft or one larger aircraft. The dimensions for wash racks to accommodate multiple smaller aircraft must include the minimum clearances indicated between aircraft and from the aircraft to the curb.

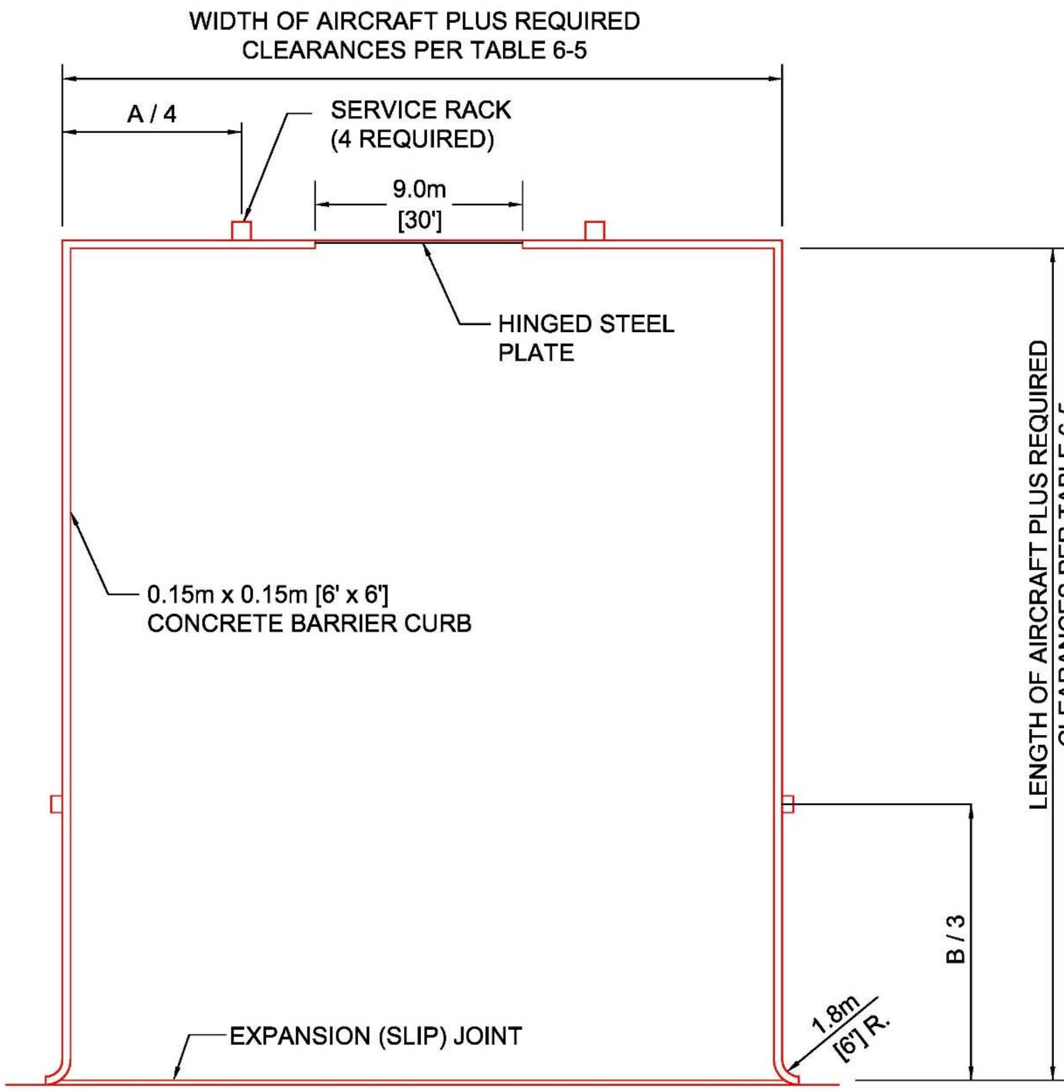
Figure 6-36. Wash Rack Selection Chart

AIRCRAFT WINGSPAN or ROTOR DIAMETER

AIRCRAFT LENGTH	0' - 20'	20' - 40'	40' - 60'	60' - 80'	80' - 100'	100' - 120'	120' - 140'	140' - 160'	160' - 180'	180' - 200'	200' - 250'	
0' - 20'	**Normal Aspect Ratio (L/WS)**											
20' - 40'			MQ-1	MQ-9					**Long Wingspan**			
40' - 60'		F-16 F-35	A-10 C-12	F-15	E-2		RQ-4C MQ-4C					**Type "F"**
60' - 80'			F-22 UH-60			U-2			B-2			
80' - 100'				CH-47 CH-53	CH-53K (future)		C-130					
100' - 120'					P-3	C-40	MC_130					
120' - 140'							C-135 KC-135 P-8					
140' - 160'							B-1	E-3, E-6 E-8		B-52		
160' - 180'		**Long Length**						KC-46	C-17			
180' - 200'									KC-10			**Type "L"**
200' - 250'										E-4 (AF-1)	C-5A	

NOTE: SEE FIGURE 6-40 FOR HELICOPTER WASH RACKS. HOWEVER, DUAL USE (FIXED AND ROTARY WING) WASHRACKS MAY USE FIGURE 6-36.

Figure 6-37. Wash Rack Type "F"



N.T.S.

Figure 6-38. Wash Rack Type "L"

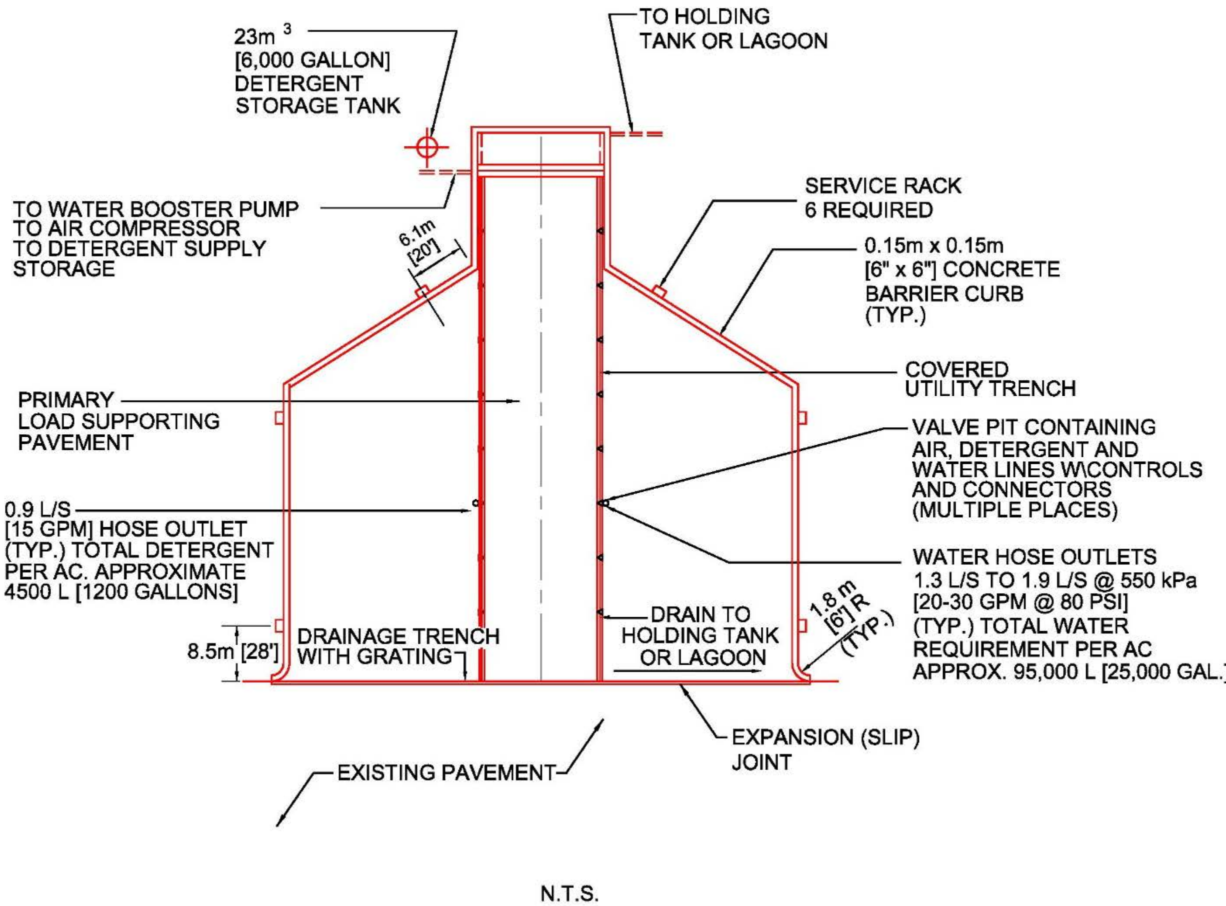

Figure 6-40. Helicopter Wash Rack (Single Helicopter)

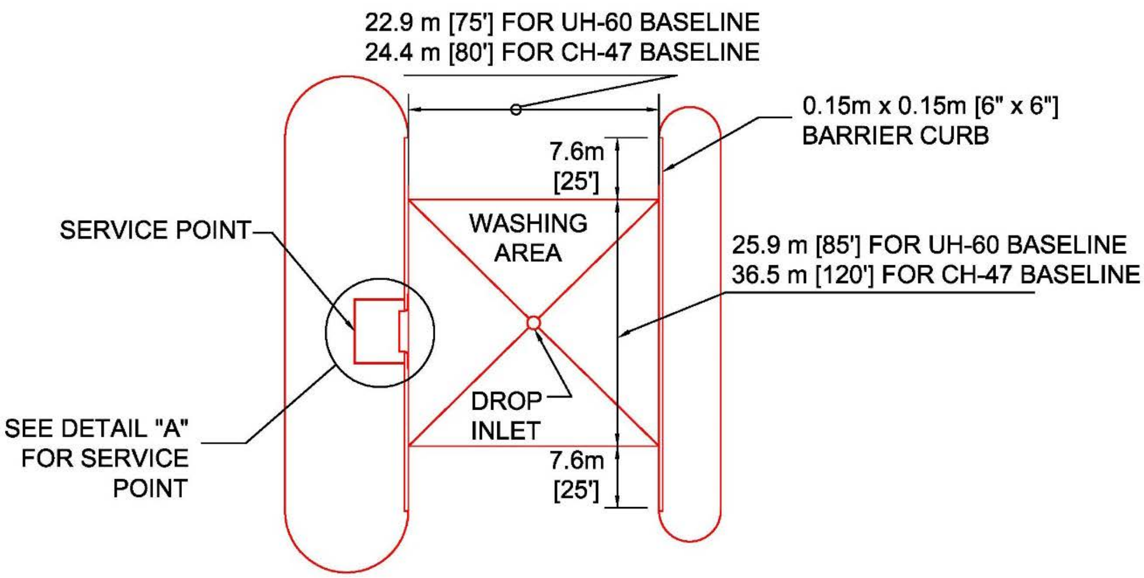
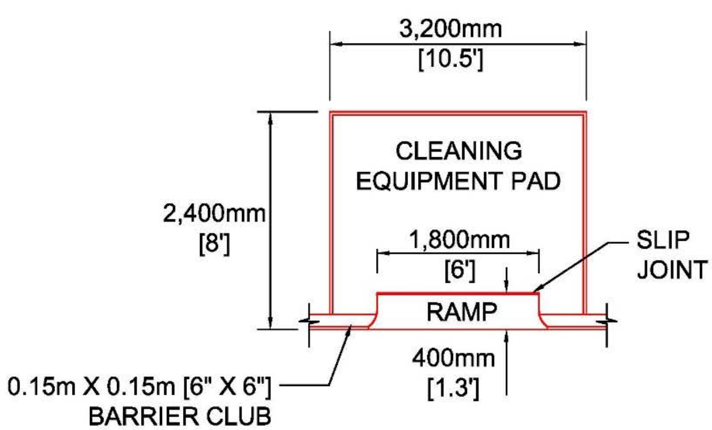


PLAN
N.T.S.



DETAIL A
N.T.S.

6-14.3 Wash Rack Size.

The size and configuration of an aircraft wash rack is determined by the type of mission aircraft expected to use it. The dimensions of the largest aircraft plus the clearances shown in Table 6-5 determine the minimum wash rack pavement dimensions. At mixed mission facilities, it may be possible to accommodate several smaller (fighter) aircraft on one larger aircraft wash rack pavement.

Table 6-5. Wash Rack Clearances From Aircraft to Curb

Wash Rack Clearances From Aircraft to Curb					
Aircraft	**From**	**To**	**Direction**	**Distance (m)**	**Distance (ft)**
Heavy bomber, medium bomber, and cargo	Wingtip	Curb	Horizontally	4.6	15
	Tail	Curb	Horizontally	4.6	15
	Nose	Curb	Horizontally	4.6	15
Fighter	Wingtip	Curb	Horizontally	3.1	10
	Tail	Curb	Horizontally	3.1	10
	Nose	Curb	Horizontally	3.1	10
Helicopter	Rotor-tip	Curb	Horizontally	See note 1.	See note 1.
	Tail	Curb	Horizontally	See note 2.	See note 2.
	Nose	Curb	Horizontally	See note 3.	See note 3.

NOTES:

1. For light to medium helicopter (UH-60 baseline), the width of the wash rack is based on the addition of 3.1-m (10-ft) buffers to the rotor diameter. For heavy helicopter (CH-47 baseline), the width of the wash rack is based on the addition of 3.1-m (10-ft) buffers to the rotor diameter. For wash racks servicing multiple aircraft, a 6.1-m (20-ft) buffer is required between rotor tips.
2. 3.1 m (10 ft) for light and medium helicopter (UH-60 baseline). 10.4 m (34 ft) for heavy helicopter (CH-47 baseline).
3. 6.7 m (22 ft) for light and medium helicopter (UH-60 baseline). 10.4 m (34 ft) for heavy helicopter (CH-47 baseline).

6-14.4 Wash Rack Facilities.

The wash rack should consist of these required items:

- Paved surface
- Concrete curbs
- Paved shoulder (for rotary-wing only)
- In-pavement structures
- Wastewater collection
- Wastewater treatment

- Utility control building
- Utilities

6-14.5 Wash Rack Grading.

The pavement surface of the wash rack will be sloped at 1.5% to assure positive drainage to waste drains. UFC 3-260-02 *Pavement Design for Airfields* addresses configuration and grading criteria for aircraft wash racks. Wash racks are considered as Type "C" traffic area. See UFC 3-260-02 for type "C" traffic area requirements.

6-14.6 Tie-Down and Grounding Points.

Tie-down/mooring points, tie-down/mooring eyes, and grounding points are not required for wash racks.

6-14.7 Concrete Curbs.

Concrete curbs will be constructed on the perimeter of the wash rack pavement to confine wastewater to the wash rack pavement. Do not install curbs in wash racks which must be built within an active apron due to mission or space constraints. At these locations, concrete trenches with heavy duty flush metal grating must be utilized to carry the wash water to the central holding basin separator, or pump pit. The existing slope should be utilized as much as possible to minimize the amount of concrete apron which must be replaced.

6-14.8 Service Points.

6-14.8.1 Army and Air Force.

Wash racks are designed with service points incorporated into the pavement floors. The following in-pavement structures should be considered for wash rack design:

- Valve pits containing air, detergent, and water lines with controls and connectors
- Water hose outlets
- Covered utility trench
- Service rack – Point of service for wash rack equipment (i.e. hose reels, high pressure nozzle sprayers, etc.)

Typical locations for these structures are shown in Figure 6-39.

6-14.8.2 Navy and Marine Corps.

Wash rack service points are required for the Navy and Marine Corps.

6-14.9 Wash Rack Utilities.

6-14.9.1 Required Wash Rack Utilities.

Aircraft wash racks contain utilities that are not normally considered in airfield geometric design; however, the designer may need to be aware that they are an integral part of the wash rack. Design guidance for these utilities has not been included in this UFC. The following utilities are considered integral to the design of the Wash Rack and must be provided to the service outlets located along the perimeter as noted in the diagrams provided:

- Hot and cold water
- Detergent/Water solution
- Compressed Air
- Electrical power as required for portable lighting and/or portable hot water generating systems

Utilities must be run from the Utilities Control Building (or other enclosed mechanical space) to the Wash Rack via below grade installation or Service Trenches. Portable hot water generating systems may be utilized in lieu of a permanent water heater and tank arrangement. Designers must check the maximum flow rates required for mission aircraft and size utilities appropriately. Provide freeze protection for areas where environmental conditions require. Ensure backflow prevention is included to create positive separation from the potable water system.

6-14.9.2 Utility Controls Building.

Wash Racks are generally supported by an adjacent Utilities Control Building. This building houses detergent make-up equipment, a detergent mixing tank, a water heater, pumps, and operating controls. An enclosed space inside the nearby serving hangar may also be utilized to house the Wash Rack mechanical equipment. Storage and sanitary facilities may also be provided as the operational requirements dictate. The Utilities Control Building must be located a sufficient distance away from the Wash Rack to preclude fire hazards associated with heating and associated electrical equipment.

6-14.9.3 Service Utility Connections (Service Points).

Wash racks must be provided with an adequate number of service utility connections proportionate to the number of personnel required to wash the aircraft. The service connections must be installed in sub-surface pits and include all appropriate valving for each service with the appropriate number of outlets with quick disconnects. Typical locations for the Service Points are shown in Figure 6-39. Electrical outlets, where required, will be provided in separate or isolated pits appropriately designed for subsurface electrical installations.

6-14.9.4 Lighting.

Provide exterior lighting at the washrack at a minimum of 50-foot candles (FC) to accommodate night washing operations. Lighting can be provided via either installed or portable systems. Portable lighting equipment as allowed by and coordinated with ramp operations is recommended for active flight line areas. If the wash operation is of a reduced and non-elevated scale, consideration may be given to the reduction in light level down to a minimum of 25 FC. A safe environment for the operating personnel, however, is primary and must be considered first and foremost in equipping the wash rack with lighting.

6-14.9.5 Wastewater Collection/Treatment.

Locate waste drains in the center of the wash rack pavement to collect wash water contaminates (oils, alkaline, salts, and other contaminants) generated from aircraft washing operations. Off-center waste and trench drains are permitted only where necessitated by the aircraft landing gear configuration or where the off-center drains reduce construction costs or suit existing conditions. Sewers must drain wastewater from waste drains to a holding tank sized appropriately for the anticipated workload or flow. Due to the wash soap, the tank will not act as oil water separators. Oil-water separators or other water treatment/disposal systems appropriate for the expected contaminates must be incorporated into the wash facility design.

6-14.9.6 Wastewater System Design.

Wastewater collection/treatment systems must be designed in accordance with the following documents:

- UFC 3-240-01, *Wastewater Collection*
- UFC 4-832-01N, *Design: Industrial and Oily Wastewater Control*

Provide diversion systems for rainfall events to prevent treating excessive amounts of rainfall as wastewater or overflowing the holding tank due to rain events.

6-14.10 Aircraft Wash Equipment.

6-14.10.1 Storage and Mixing Capability for Aircraft Cleaning Compounds.

Generally, bulk storage tanks are recommended for high use wash facilities for dispensing the soap solutions onto the aircraft. These tanks are used in conjunction with cleaning compounds and equipment capable of mixing the detergents with water in the proper dilution ratios. However, in situations where relatively small quantities of cleaning compounds are expected to be used (i.e. at bases with a limited number of small aircraft), it may be appropriate to omit bulk storage capability from the facility design and incorporate storage space and handling capability for 55-gallon barrels.

6-14.10.2 Pressurized Cleaning Dispensing and Rinse Water Systems.

Pressurized dispensing systems will be used for the application of diluted cleaning compounds and rinse water generally and provide reductions in man-hours expended and quantities of water and cleaning materials used.

Refer to service specific guidance for recommendations or limitations on pressures and temperatures for pressurized cleaning systems.

6-14.11 Safety and Health.

6-14.11.1 Eyewash Units and Emergency Showers.

- Emergency shower and eyewash units must be provided in areas where harmful materials may be splashed into the eyes or on parts of the body. Follow UFC 3-420-01 Appendix D for guidance on design and installation of Eyewash Units and Emergency Showers. Also see AFOSHSTD 91-17 and ANSI Z358.1 for additional information.
- Emergency shower and eyewash units must be located in accessible locations that require no more than 10 seconds to reach and must be within 100 feet of the harmful substance
- Permanently installed units and self-contained units installed in fixed locations must be identified with a highly visible sign. The area around or behind the unit, or both, may be painted with green and white stripes if needed to increase visibility. If highlighted, the painted area will be large enough to be easily identified by the user.
- Emergency units must be well lighted. Where practical, a minimum of 50-foot candles of illumination must be provided.
- Units will be connected to a supply of water that is free from contamination and equal in purity to potable water.

6-14.11.2 Fall Protection.

Adequate fall protection is required in most newly constructed aircraft wash facilities. Primarily, personnel should avoid walking on wet surfaces to the greatest extent possible and utilize separate elevated work platforms and long-handle brushes to the maximum extent possible. However, experience has shown that it is impossible to adequately access most upper surfaces of large aircraft by these means. Therefore, personnel often must walk on aircraft wings or other surfaces during washing operations, which creates the possibility that they may fall 4 feet or more. In these situations, fall arrest or fall restraint systems are mandatory. Experience has shown that systems which utilize a lifeline, to which safety harnesses can be attached, are the most effective means of accessing upper surfaces of the aircraft during aircraft wash operations. Refer to AFOSHSTD 91-100, EM 385-1-1, Section 5, Personal Protective and Safety Equipment, and Section 21, Safe Access and Fall Protection, and AFOSHSTD 91-501 for complete guidance on fall protection requirements.

Due to the significant impact loads that the lifeline and anchor points impart to the building structure, attention must be given to installation of the fall restraint system in the earliest stages of facility design so that the loads are included in the design of the building's structural components. See UFC 4-211-02, *Aircraft Corrosion Control and Paint* Facilities, Paragraph 3-8.2 for a detailed description of fall protection systems and design requirements.

6-14.11.3 Personal Amenities.

In remote areas, where personal amenities must be provided to support the installed Wash Rack, these amenities must conform to the General Construction section of this guide and EM 385-1-1, Section 2, Safety and Health Requirements- Sanitation.

6-14.12 Aircraft Rinse Facilities – Birdbaths.

An Aircraft Rinse Facility referred to as a "Birdbath" provides an unattended taxi-through treadle operated freshwater deluge system to rinse aircraft typically subjected to accelerated corrosion due to low-level over water operations or a corrosive atmosphere at the installation.

See UFC 2-000-05N Section 116 15 for information concerning the requirements for a typical Birdbath. The following requirements and associated Figure 6-41 are for a Type "F" size aircraft (ref. Fig, 6-36). The information presented may be used as a guide and modified as appropriate for the configuration of the specific aircraft. If the aircraft manufacturer has recommended guidelines for a specific aircraft, the wash facility must be designed and constructed in accordance with the manufacturer's recommendations.

Aircraft Rinse Facility – Requirements

a) Constant water pressure of 100 to 150 pounds per square inch (690 to 1034 kPA). A booster pump and storage tank must be provided to maintain specified quantity and pressure of water. Provide backflow prevention or an air gap.

b) Provide drainage into sanitary sewer at an acceptable flowrate to prevent overloading downstream pump stations or the treatment facility. Verify with Base Environmental if an oil water separator is required. Provide diversion for rain events to prevent overloading the sewer and treatment plant with non-process water.

c) Pavement must be Portland cement concrete designed to the same criteria as the aircraft wash rack. If aircraft exhaust will be directed directly at pavement for extended periods of time, give consideration to using high temperature concrete to mitigate damage that may be caused by hot exhaust.

d) Each nozzle must have adjustable tips that can be adjusted with a swivel mount.

e) Three nozzle types: A; B; and C

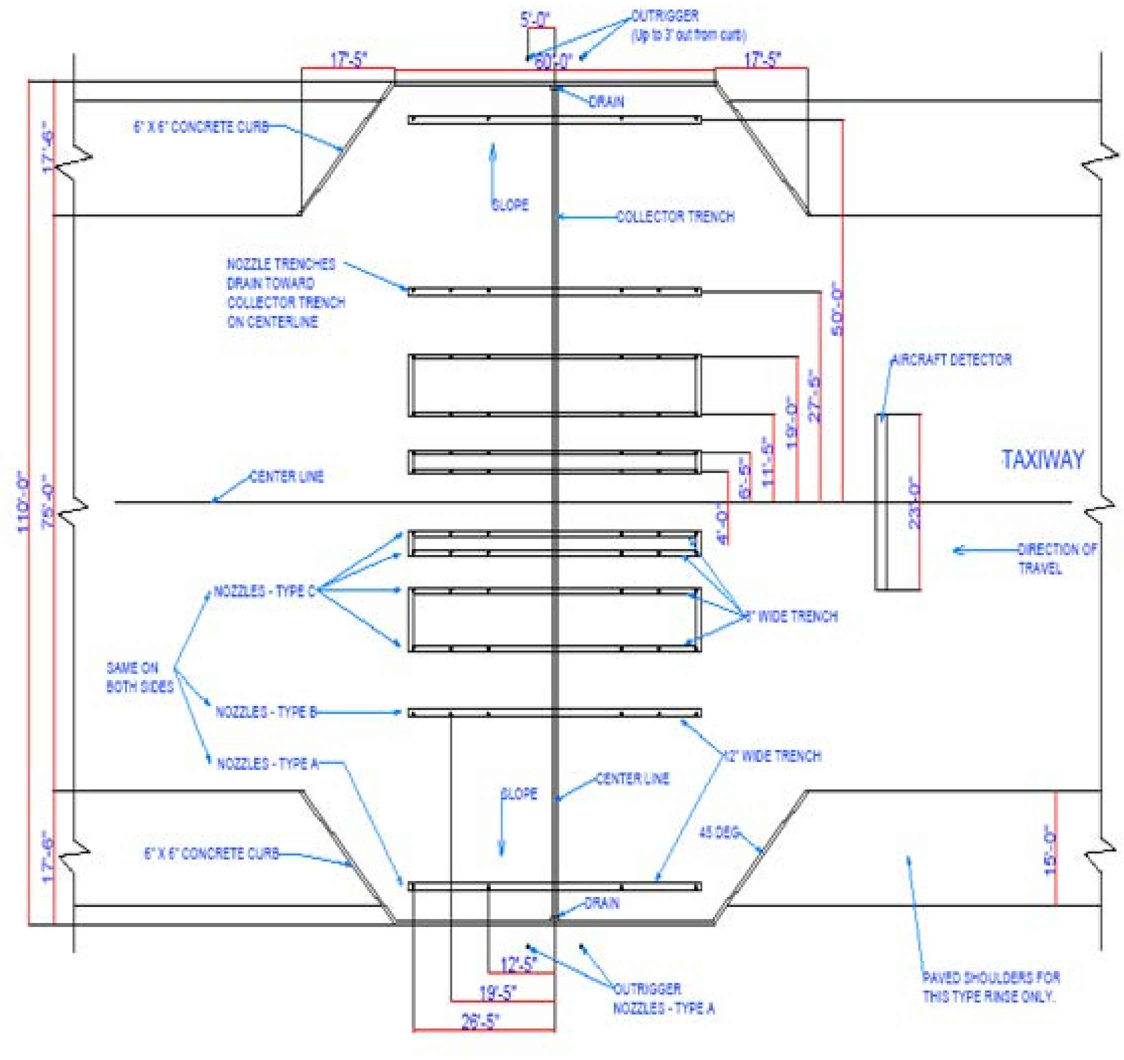
- Type A – (12) Used on the outriggers and in the edge of pavement trench. 50 gallons per minute (0.19 m^3/minute) flow, solid stream. Tip set at 55 degrees F (12.8 degrees C).
- Type B – (12) Used in the fifth trench from the centerline on both sides. 10 to 12 gallons per minute (0.04 to 0.05 m^3/minute) flow, 15 degree flat spray. Tip set at 55 degrees F (12.8 degrees C).
- Type C – (48) Used in the inside four trenches on both sides. 10 to 12 gallons per minute (0.04 to 0.05 m^3/minute) flow, 30 degree flat spray.

f) All nozzles are to be trenched with the exception of the outriggers. Each trench is to be covered with steel plate that has slots providing for the nozzle and water spray. The outriggers are elevated 1 foot off of the ground.

g) Include freeze protection in areas prone to freezing.

h) Include “soft-start” pump to prevent damage to the system when energized.

Figure 6-41. Aircraft Rinse Facility (Birdbath)



TYPE "4" RINSE FACILITY - V-22 AIRCRAFT

6-15 HANGAR ACCESS APRONS.

Hangar access aprons provide access to the hangars from the parking apron and allow free movement of aircraft to the various hangar maintenance facilities. Hangar access aprons should be provided as a supporting item for each authorized hangar and should be sized for the type of hangar and aircraft to be accommodated.

6-15.1 Dimensions.

Generally, hangar access aprons should be as wide as the hangar doors and extend from the edge of the apron to the hangar door. Hangar access apron dimension requirements are summarized in Table 6-6.

6-15.2 Grades for Aircraft Fueling Ramps.

Grades for hangar access ramps on which aircraft fueling will occur must slope away from aircraft hangars in accordance with NFPA Standard 415.

6-15.3 Grades for Aircraft Access into Hangars.

The grades in front of the hangar must allow access into the hangar. When aircraft are backed into the hangar, a tug vehicle pushes the aircraft in, tail first. Due to the location of the aircraft gear and the slope of the hangar access apron, the tail of the aircraft may be higher than the top of the hangar door. The hangar access apron grades may require adjustment to allow the aircraft tail to clear the hangar door.

Table 6-6. Hangar Access Apron

Table 6-6. Hangar Access Apron				
Item		Class A Runway	Class B Runway	
No.	Description	Requirement	Requirement	Remarks
1	Length	30 m (100 ft)	40 m (125 ft)	Army facilities for fixed-wing aircraft
		Distance to adjoining operational pavement		Air Force facilities for fixed-wing aircraft. **NOTE:** If the distance from the main operational pavement to the hangar exceeds the apron clearance distance (see Table 6-1, item 15), consider constructing a maneuvering area immediately outside the hangar, large enough to allow turning the aircraft around. The width of the maneuvering area should be equal to the width of the hangar door opening. Connect this maneuvering area to the main apron with a taxiway or towway.
		23 m (75 ft)		Army facilities for rotary-wing aircraft, except as noted below.
		30 m (100 ft)		Air Force facilities for rotary-wing aircraft, except as noted below Includes additional 50ft vehicular buffer required in front of hangars.
		15 m (50 ft)		Navy and Marine Corps facilities for fixed- and rotary-wing aircraft
		See Remarks		Access aprons are located between the apron and the front of the hangar. The hangar cannot be located within the apron clearance distance.

Table 6-6. Hangar Access Apron

Item		Class A Runway	Class B Runway	
No.	**Description**	**Requirement**	**Requirement**	**Remarks**
2	Width	At least as wide as the hangar door width		Pavement should be sized for type of aircraft, number of hangar bays, and location of hangar bays.
3	Grades in direction of drainage	Min ±0.5% Max ±1.5%		Avoid grades that prevent aircraft tails from clearing hangar doors.
		Min -1.0% first 15 m (50 ft) from hangar		NFPA 415 requires aircraft fueling ramps to slope away from terminal buildings, aircraft hangars, aircraft loading walkways, or other structures.
4	Width of shoulders (total width including paved and unpaved)	7.5 m (25 ft)		
5	Width of paved shoulders	Not required		
6	Sight distance	N/A (See note 1.)		
7	Transverse grade of unpaved shoulder	(a) 40 mm (1.5 in) drop-off at edge of pavement. (b) 2.0% min, 4.0% max.		
8	Wingtip clearance to fixed or mobile obstacles	7.6 m (25 ft)		Along length of access apron. Wingtip clearance at entrance to hangar may be reduced to 3.05 m (10 ft).
9	Grade (area between access apron shoulder and wingtip clearance line)	Max 10.0% (See note 2.)		If the wingtip clearance line falls within the access apron shoulder, no grading is required beyond the access apron shoulder.

NOTES:
1. N/A = not applicable
2. Bed of channel may be flat.
3. Metric units apply to new airfield construction and, where practical, modification to existing airfields and heliports, as discussed in paragraph 1-3.4.
4. The criteria in this manual are based on aircraft specific requirements and are not direct conversions from inch-pound (English) dimensions. Inch-pound units are included only as a reference to the previous standard.
5. Airfield and heliport imaginary surfaces and safe wingtip clearance dimensions are shown as a direct conversion from inch-pound to SI units.

6-16 TAXIING CHARACTERISTICS ON APRONS FOR ROTARY-WING AIRCRAFT.

Taxi routes across parking aprons are marked to provide safe passage of the aircraft across the apron. A hoverlane is a designated aerial traffic lane used exclusively for the movement of helicopters. A taxilane is a designated ground traffic lane.

6-16.1 Hoverlane/Taxilane Width at Army Facilities.

At Army Facilities, the hoverlane/taxilane widths are fixed distances based on type of aircraft, as noted in Table 6-2.

6-16.2 Hoverlane/Taxilane Width at Air Force Facilities.

At Air Force facilities, the hoverlane/taxilane width is based on the rotor diameter of the largest helicopter generally using the apron.

6-17 FIXED-WING AND ROTARY-WING GRADING STANDARDS.

6-17.1 Fixed-Wing Aircraft.

Grading standards for fixed-wing parking aprons and shoulders are presented in Table 6-1. All parking aprons, pads, and miscellaneous pavements should follow these grading standards unless a particular mission requirement, such as a power check pad, dictates otherwise. Surface drainage patterns with numerous or abrupt grade changes can produce excessive pavement flexing and structural damage of aircraft and therefore should be avoided.

6-17.2 Rotary-Wing Aircraft.

Grading standards for rotary-wing parking aprons are presented in Table 6-2 for Army facilities. Air Force activities should use the grading criteria for the Army presented in this UFC for all rotary-wing aircraft except CH-53 and CH-54. For those aircraft, see the Mission Design Series Facility Requirements Documents.

6-17.3 Grades for Aircraft Fueling Ramps.

Grades for ramps on which aircraft fueling will occur should be in accordance with NFPA Standard 415.

6-18 SHOULDERS.

Paved shoulders are provided around the perimeter of an apron to protect against jet blast and FOD, to support blast deflectors, for support equipment storage, to provide paved access to fire hydrants, and to facilitate drainage. Criteria for apron shoulders are presented in Table 6-1 for fixed-wing aprons, Table 6-2 for Army rotary-wing aprons, and AFMAN 32-1084 for Air Force rotary-wing facilities. To prevent storm water from ponding on the outside edge of the shoulder, the turf adjacent to the paved shoulder should be graded to facilitate drainage. See Paragraph 2-12 for requirements for designing buried utility structures in shoulders.

6-19 MISCELLANEOUS APRON DESIGN CONSIDERATIONS.

In addition to the apron design criteria, consider providing room for support structures, equipment (e.g., aerospace ground equipment, hydrant refueling systems), and facilities.

6-19.1 Jet Blast Deflectors.

Jet blast deflectors will substantially reduce the damaging effects of jet blast on structures, equipment, and personnel, as well as the related noise and fumes associated with jet engine operation. Additional information on jet blast deflectors is provided in Appendix B, Section 8.

6-19.2 Line Vehicle Parking.

Vehicle parking areas are provided for parking mobile station-assigned and squadron-assigned vehicles and equipment (e.g., aerospace ground equipment). Additional information on line vehicle parking is located in Appendix B, Section 12.

6-19.3 Utilities.

The items listed here are normally found on parking aprons. These items are not a part of airfield geometric design; however, the designer needs to be aware that they are an integral part of a parking apron and should make provisions for them accordingly.

- Storm water runoff collection system, including inlets, trench drains, manholes, and pipe
- De-icing facilities and de-icing runoff collection facilities
- Apron illumination
- Fire hydrants
- Refueling facilities
- Apron edge lighting

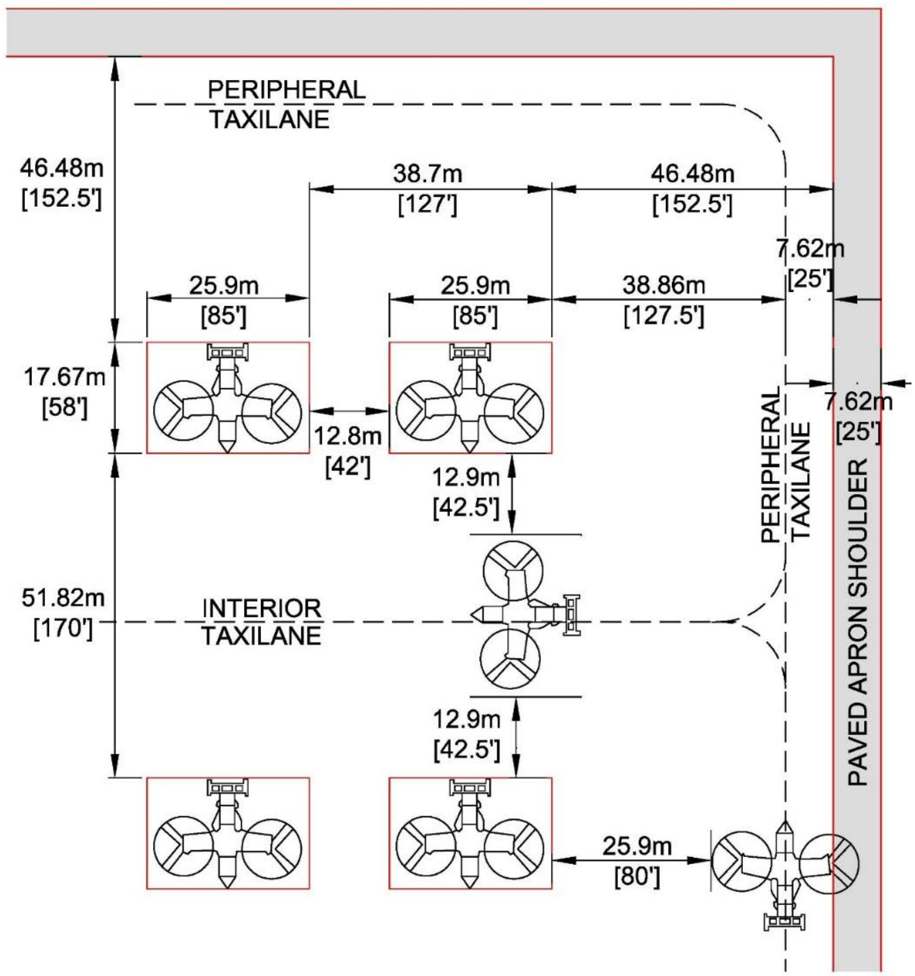
6-20 V-22 APRON CLEARANCES.

Figure 6-42 provides parking block dimensions as well as peripheral and interior taxilane clearance requirements. The V-22 Parking Block will not overhang the apron shoulder.

6-21 US NAVY AND MARINE CORPS AIRCRAFT BLOCK DIMENSIONS.

Figures 6-43 and 6-44 and Tables 6-7 through 6-10 provide Navy/Marine Corps aircraft parking apron criteria. The source of this information is UFC 2-000-05N and provided here for convenience. See source document for additional apron requirements.

Figure 6-42. V-22 Apron Clearance Requirements



NORMAL PARKING ARRANGEMENT

NOT TO SCALE

NOTE: FOR NAVY ONLY - WHERE 7.6m [25'] PAVED SHOULDER IS NOT PROVIDED AROUND APRON, MOVE PERIPHERAL TAXILANE CENTERLINE TO 12.9m [42.5'] FROM APRON EDGE.

CHAPTER 7
LANDING ZONES FOR C-130 AND C-17

7-1 GENERAL INFORMATION.

Landing zones (LZ) for C-130 and C-17 are special use airfields for aircrew training or contingency operations. This chapter provides guidance for planning, design, construction and evaluation of LZs. It includes criteria for the runway, taxiways, aprons, and airspace requirements, and addresses construction of non-airfield-related facilities near the airfield for both austere and built-up areas.

7-1.1 Differences in Service Criteria.

Air Force, Army, Navy and Marine Corps have generally agreed to the same criteria, except where noted in the text, tables or figures.

7-1.2 Landing Zone Marking and Lighting Standards.

This chapter currently includes LZ marking and lighting criteria. However, that criteria may get incorporated into other UFCs in the future.

7-1.3 LZ Grade Evaluation.

The minimum transverse slopes for LZ runways, taxiways, aprons, shoulders, graded areas and maintained areas are intended for use during the construction and maintenance of the LZ to promote adequate drainage and prolong service life. When evaluating an existing LZ, if these areas are level or less than the minimum and the slope does not impact the suitability of the LZ for aircraft operations, a waiver is not required.

7-2 DEFINITIONS.

The terms in this section are defined only as they are used in this chapter.

7-2.1 Accident Potential Zone–Landing Zone (APZ-LZ).

The land use control area beyond the clear zone of an LZ that possesses a significant potential for accidents; therefore, land use is a concern. See Figures 7-2 and 7-5.

7-2.2 Clear Zone-LZ.

A surface on the ground or water, beginning at the runway threshold and symmetrical about the extended runway centerline, graded to protect aircraft operations and in which only properly sited NAVAIDs are allowed. See Figures 7-1, 7-2, and 7-5.

7-2.3 Contingency Operations.

Typically, short-term operations conducted in support of conflicts or emergencies.

7-2.4 Exclusion Area.

Areas required for all paved and semi-prepared (unpaved) LZs. The purpose of the exclusion area is to restrict the development of facilities around the LZ. Only features required to operate the LZ or an adjacent airfield are permissible in the exclusion area, such as operational surfaces (e.g., runways, taxiways, and aprons), NAVAIDs, aircraft and support equipment, and cargo loading and unloading areas and equipment. Personnel formations, encampments, parked vehicles, storage areas, buildings, etc. are excluded from this area; roads, fences and trees are acceptable. In addition, only properly sited facilities are allowed in this area (see Appendix B, Section 13). The exclusion area extends the length of the runway, plus the clear zone on each end. See Figures 7-1, 7-2, and 7-5, and Table 7-8.

7-2.5 Flashing Strobe Light (FSL).

A flashing light used to mark the beginning or end of the usable runway surface when an LZ is used for night operations and configured in airfield marking pattern (AMP) -1 or AMP-3.

7-2.6 Graded Area.

An area beyond the runway shoulder where grades are controlled to prevent damage to aircraft that may depart the runway surface (see Figure 7-6 and Table 7-1). Graded areas will not have any obstacles over 75 millimeters (3 inches) high, except vegetation, visual landing zone marker panels (VLZMP), or other visual or electronic navigational aids which must be sited in this area due to their function. Culverts, headwalls, and elevated drainage structures are not allowed in this area. Properly sited, frangible NAVAIDs are allowed.

7-2.7 Imaginary Surfaces-LZ.

Surfaces in space established around an LZ in relation to runways, helipads, or helicopter runways, and designed to define the protected airspace around the airfield. The imaginary surfaces for LZs are the primary surface and approach-departure clearance surface. See Figures 7-1, 7-2, and 7-5, and Table 7-8. Minimum clearances over highways, railroads, waterways and trees are defined in Chapter 3, Table 3-8.

7-2.8 Infield Area.

The area between runways and between runways and taxiways that is graded or cleared for operational safety. All obstructions must be removed from the infield area.

7-2.9 Landing Zone (LZ).

Consists of a runway, a runway and taxiway, or other aircraft operational surfaces (e.g., aprons, turnarounds). It is a prepared or semi-prepared (unpaved) airfield used to conduct operations in an airfield environment similar to forward operating locations. LZ runways are typically shorter and narrower than standard runways. Because training airfields are constructed for long-term operations, semi-prepared surface structural requirements are more stringent than those for contingency airfields.

7-2.10 Overrun-LZ.

An area the width of the runway, plus prepared shoulders, extending 91.5 meters (300 feet) from the end of the runway into the clear zone. This portion is an elongation of the runway and is constructed to support aircraft traffic. See Figure 7-1, and Table 7-5.

7-2.11 Maintained Area.

A land area, extending outward at right angles to the runway centerline and the extended runway centerline, that is outside the graded area but still within the exclusion area. This area must be free of obstructions. Culvert and culvert headwalls are permitted in the maintained area, provided headwalls are flush with the surrounding grade. The maintained area is 21.5 m (70 ft) wide for C-17 operations or 18.5 m (60 ft) wide for C-130 operations. The grade may slope up or down to provide drainage but may not exceed +10% nor -20% slope. See Figure 7-6 and Table 7-1.

7-2.12 Parking Maximum on Ground (MOG).

The highest number of aircraft that will be allowed on the ground at any given time based on airfield configuration limitations and safety considerations.

7-2.13 Paved Landing Zone (LZ).

A prepared and surfaced LZ designed to carry aircraft traffic. **NOTE:** Paved LZs were formerly called “shortfields” and later known as “prepared assault landing zones” (ALZ). The principal components of a paved LZ include one of the following:

- A flexible or non-rigid pavement, or one that includes a bituminous concrete surface course designed as a structural member with weather- and abrasion-resistant properties
- A rigid pavement, or one that contains PCC as an element
- A combination of flexible and rigid pavement layers, such as an overlay, where a flexible pavement is placed over an existing rigid pavement layer to strengthen the rigid pavement layer

7-2.14 Primary Surface-LZ.

An imaginary surface symmetrically centered on the LZ. The elevation of any point on the primary surface is the same as the elevation of the nearest point on the runway centerline or extended runway centerline. See Figures 7-1, 7-2, and 7-5 and Table 7-7, Item 1.

7-2.15 Runway End.

As used in this chapter, the runway end is where the normal threshold is located. When the runway has a displaced threshold, the responsible airfield authority will evaluate each individual situation and, based on this evaluation, will determine the point of beginning for runway and airspace imaginary surfaces. See Figure 7-1.

7-2.16 Semi-Prepared Landing Zone (LZ).

A semi-prepared LZ (formerly called a “semi-prepared ALZ”) refers to an unpaved LZ. The amount of engineering effort required to develop a semi-prepared LZ depends on the planned operation, the service life needed to support these operations, and the existing soil and weather conditions. Semi-prepared construction/maintenance preparations may range from those sufficient for limited use to those required for continuous, routine operations. Options for surface preparation may include stabilization, adding an aggregate course, compacting in-place soils, or matting.

7-2.17 Turnaround (or Hammerhead).

An operational surface with dimensions to allow an aircraft to execute 180-degree turns without using reverse operations. Turnarounds can provide loading/off-loading capability on LZs with a parking MOG of one. See Figure 7-3 and 7-11.

7-2.18 Visual Landing Zone Marker Panels (VLZMP).

Vertical, colored panels installed along runway edges to indicate the threshold location and distance remaining. See Figures 7-7, 7-8a, 7-8b, 7-12, 7-13, and 7-14.

7-3 SITE PLANNING FOR LANDING ZONES (LZ).

When planning the layout of an LZ that will be used for extended operations (generally defined as more than one year), site conditions beyond the safety of the aircraft-related operations must be considered. These conditions include land use compatibility with clear zones, primary surfaces, exclusion areas, and approach-departure surfaces, and with existing and future use of the areas that surround the LZ. In planning an LZ, consider the use and zoning of surrounding land for compatibility with aircraft operations. The purpose is to protect the operational capability of the LZ and prevent incompatible development, thus minimizing health and safety concerns in areas subject to high noise and accident potential resulting from frequent aircraft overflights. The minimum criteria in this chapter establish standards for a safe environment for aircraft and ground operations. For long-term-use LZs, restricting use of available land beyond the minimum distances contained in this chapter is highly recommended. This will protect operational capability and enhance the potential for future mission expansion. Land use and zoning restrictions for training LZs must also comply with AFH 32-7084. The goal is to provide an LZ environment that provides the greatest margin of safety and compatibility for personnel, equipment, and facilities.

7-3.1 Future Development (Land or Aircraft Technology).

Adequate land for future aviation growth must be considered when planning an LZ. The LZ should be compatible with the existing installation plan. Potential instrument meteorological conditions/instrument flight rules (IMC/IFR) capability will require additional criteria considerations.

7-3.2 Prohibited Land Uses.

LZ criteria prohibit certain land uses within the exclusion area, clear zone, and APZ. These restrictions are described in Tables 7-6, 7-7 and 7-8.

7-3.3 APZs not on DoD Property.

APZs that are not on DoD property may require easements to control development and removal of vegetation that may violate the approach-departure clearance surface. The need must be determined on a case-by-case basis.

7-4 SITING CONSIDERATIONS.

Site considerations include topography, vegetative cover, existing construction, weather elements, wind direction, soil conditions, flood hazard, natural and man-made obstructions, adjacent land use, availability of usable airspace, accessibility of roads and utilities, and potential for expansion. Also consider the effects of ambient lighting for operations with night vision goggles (NVG). The potential for encroachment and the effects of noise on the local community must also be considered.

7-4.1 Training Landing Zones (LZs).

For training LZs, it is preferred to site the runway within an airfield environment to take advantage of existing runway and taxiway clearance areas. To maximize the training environment, avoid aligning LZ runways parallel to existing runways.

7-4.2 Siting Landing Zones (LZs).

Siting of LZs must take into account noise levels on existing facilities.

7-4.3 FAA Requirements.

When a new LZ is sited, in addition to local permitting requirements, file FAA Form 7480-1 in accordance with FAA Order 7400.2.

7-4.4 Siting LZs in Built-Up Areas.

When siting a training LZ runway within an existing built-up and occupied area, use a 305-m-wide (1000-ft-wide) exclusion area rather than the 213.5-m (700-ft) exclusion area for LZs in unoccupied areas. The 305-m-wide (1,000-ft-wide) exclusion zone extends from clear zone end to clear zone end, centered on the runway centerline. In addition, the APZ-LZ is widened to 305 m (1,000 ft) wide. Built-up and occupied locations are defined as locations where occupied buildings/facilities exist around the potential LZ site that are not related to the LZ mission. Unoccupied locations are where no buildings/facilities exist around the proposed LZ except those that are LZ mission-related. The same rules apply for siting future facilities near existing LZs. If the facility and occupants are not related to the LZ mission, then the wider exclusion zone and APZ-LZ apply.

7-4.5 Siting LZs Superimposed on Class A or B Runways.

When an LZ is marked on a Standard Class A or B runway, conduct and document a risk assessment to determine any risk associated with the operation or impact on current mission aircraft. This will include an evaluation of any existing waivers to UFC 3-260-01 that exist for current obstructions/non-compliant conditions and any portion of the LZ area that may have been built to a previous standard. New waivers will be needed for any non-compliant condition to the required LZ criteria. All non-compliant conditions will be identified and documented and any risk associated with these conditions will be coordinated with the aircraft unit using the LZ and approved by the responsible airfield authority.

7-5 GEOMETRIC CRITERIA FOR RUNWAYS AND OVERRUNS.

Tables 7-1 through 7-5 provide dimensional criteria for the layout and design of LZ runways, taxiways, aprons, and overruns.

Table 7-1. Runways for LZs

Table 7-1. Runways for LZs						
Item		Paved		Semi-Prepared (Unpaved)		
No.	Description	C-130	C-17	C-130	C-17	Remarks
1	Length	Min. 914 m (3000 ft)	Min. 1067 m (3500 ft) See Remarks.	Min. 914 m (3000 ft)	Min. 1067 m (3500 ft) See Remarks.	See paragraph 7-5.1 and Table 7-2 for LZ length requirements for the C-17. For lengths less than 1067 m (3500 ft), a waiver from the responsible airfield authority is required prior to initiating flying operations (see paragraph 7-7).
2	Width	18.5 m (60 ft)	27.5 m (90 ft)	18.5 m (60 ft)	27.5 m (90 ft)	See Note.

Table 7-1. Runways for LZs						
Item		**Paved**		**Semi-Prepared (Unpaved)**		
No.	**Description**	**C-130**	**C-17**	**C-130**	**C-17**	**Remarks**
3	Width of shoulders	Min. 3 m (10 ft)				Remove all tree stumps and loose rocks in shoulder areas. Shoulders for paved LZs will be paved. Shoulders for semi-prepared LZs should be stabilized to prevent erosion by jet blast. Where adequate sod cover cannot be established, the shoulders should be chemically stabilized.
4	Longitudinal grades of runway and shoulders	Max. 3% at any location on profile C-17: Effective Gradient 2% Maximum				Hold to minimum practicable. Grades may be both positive and negative but must not exceed the limit specified. Effective Gradient = (Max LZ Centerline elevation – Min LZ Centerline elevation)/Total LZ Length.
5	Longitudinal runway grade change	Max. 1.5% per 61 m (200 ft)				Grade changes should be held to a minimum and should be gradual. Minimum distance between grade changes is 61 m (200 ft). Grade changes cannot exceed 1.5% measured at 61 m (200 ft) intervals.
6	Transverse grade of runway	0.5% Min. 3.0% Max.				Transverse grades should slope down from the runway centerline. The intent of the transverse grade limit is to provide adequate cross slope to facilitate drainage without adversely affecting aircraft operations.
7	Transverse grade of runway shoulders	1.5% Min. 5.0% Max.				Transverse grades should slope down from the runway edge. The intent of the transverse grade limit is to facilitate drainage.
8	Width of graded area	10.5 m (35 ft)				Cut trees flush with the ground. Remove or embed rocks such that no parts of rocks protrude more than 75 mm (3 in) above surrounding surface. Remove vegetation (excluding grass) to within 75 mm (3 in) of the ground. Jet blast may cause erosion of the graded area. For paved LZs where adequate vegetation cannot be established to prevent erosion, the graded area may be covered with a thin 38 mm to 51 mm (1.5 in. to 2.0

Table 7-1. Runways for LZs						
Item		Paved		Semi-Prepared (Unpaved)		
No.	Description	C-130	C-17	C-130	C-17	Remarks
						in) asphalt layer or with an engineered surface such as articulated concrete blocks or a stone bed (4” to 8” stones in 12” layer on geotextile fabric) spread and compacted to present an even surface with no protrusions or indentations more than 75 mm (3 inches). Open culverts, headwalls, and elevated drainage structures are not allowed in this area.
9	Transverse grade of graded area	2.0% Min. 5.0% Max.				Grades may slope up or down, but may not penetrate the primary surface. Grade changes (including positive to negative) are permitted within the graded area.
10	Width of maintained area	18.5 m (60 ft)	21.5 m (70 ft)	18.5 m (60 ft)	21.5 m (70 ft)	Remove obstructions; cut trees flush with ground. Remove or embed rocks that protrude more than 75 mm (3 in) above grade. Remove vegetation (excluding grass) to within 150 mm (6 in) of the ground.
11	Maintained area: transverse grade	Maximum range: +10.0% to -20.0%				Grades may slope up or down to provide drainage, but may not exceed +10.0% nor -20.0% slope.
12	Runway-Taxiway Separation	81 m (265 ft)		93 m (305 ft)		

NOTE: For C-17 LZs without parallel taxiways, turnarounds must be provided at both ends of the runway. Turnarounds for C-17 aircraft should be 55 m (180 ft) long and 50.5 m (165 ft) wide (including the overrun/runway width), with 45-degree fillets. The aircraft must be positioned within 3 m (10 ft) of the runway edge prior to initiating this turn. If provided, turnarounds for C-130 aircraft should be at least 30 m (100 ft) in diameter.

7-5.1 LZ Runway Lengths.

Table 7-1 provides minimum runway lengths for C-130 LZs and Table 7-2 provides minimum runway lengths for C-17 LZs. Consult with flying group to determine runway length required to support the mission. For a C-17 LZ located between sea level and 915 m (3,000 ft) pressure altitude, the minimum length requirement for C-17 operations is 1067 m (3,500 ft) with 91.5-m (300-ft) overruns on each end. This length requirement, based on a runway condition reading (RCR) of 20, assumes an ambient temperature of 32.2 degrees Celsius (90 degrees Fahrenheit) and a landing gross weight of 202,756 kg (447,000 lb). Based on these same temperature and weight assumptions, the runway length will vary with different RCRs. Typically, paved surfaces will have RCRs of 23 dry, 12 wet, and 5 icy. Mat surfaces will have RCRs of 23 dry and 10 wet. A semi-prepared runway with stabilized soil surfaces will have RCRs of 20 dry and 10 wet. Unstabilized soil surfaces will have RCRs of 20 dry and 4 wet.

Table 7-2. C-17 LZ Runway Lengths

Table 7-2. C-17 LZ Runway Lengths		
202,756 kg (447,000 lb): NORMAL Max Weight for *Soil Surfaced LZs*		
RCR	**Pressure Altitude, m (ft)**	**Runway Length, m (ft) ***

	915 (3001) to 1524 (5000)	1981 (6500)
	1525 (5001) to 1829 (6000)	2134 (7000)
227,703 kg (502,000 lb): Max Weight for Contingency Operations on *Paved LZs*		
RCR	**Pressure Altitude, m (ft)**	**Runway Length, m (ft)**
23 (dry pavement)	0 to 609 (2000)	1067 (3500)
	610 (2001) to 914 (3000)	1219 (4000)
	915 (3001) to 1219 (4000)	1372 (4500)
	1220 (4001) to 1524 (5000)	1524 (5000)
	1525 (5001) to 1829 (6000)	1676 (5500)
	1830 (6001) to 2134 (7000)	1829 (6000)
12 (wet pavement)	0 to 609 (2000)	1676 (5500)
	610 (2001) to 914 (3000)	1829 (6000)
	915 (3001) to 1524 (5000)	1981 (6500)
	1525 (5001) to 1829 (6000)	2134 (7000)
	1830 (6001) to 2134 (7000)	2286 (7500)
5 (icy pavement)	0 to 304 (1000)	2134 (7000)
	305 (1001) to 914 (3000)	2438 (8000)
	915 (3001) to 1219 (4000)	2591 (8500)
	1220 (4001) to 1524 (5000)	2744 (9000)
	1525 (5001) to 1829 (6000)	2897 (9500)
	1830 (6001) to 2134 (7000)	3048 (10000)

***NOTE:** Runway lengths **do not** include overruns.

7-5.2 LZ Runway Widths.

Table 7-1 provides the minimum width for LZ runways. The widths of these landing surfaces provide the minimum-width operating surface for the given aircraft.

7-5.3 Operating Surface Gradient Allowances.

Operational surface gradient constraints are based on reverse aircraft operations conducted on hard surfaces. See Tables 7-2, 7-3, 7-4, and 7-5 for specific allowances.

7-5.4 LZ Shoulders.

Shoulders are graded and cleared of obstacles and slope downward away from the operating surface, where practical, to facilitate drainage. See Tables 7-2, 7-3, 7-4, and 7-5.

Table 7-3. Taxiways for LZs

Table 7-3. Taxiways for LZs						
Item		**Paved**		**Semi-Prepared (Unpaved)**		
No.	**Description**	**C-130**	**C-17**	**C-130**	**C-17**	**Remarks**
1	Width	9 m (30 ft)	15.0 m (50 ft)	9 m (30 ft)	15.0 m (50 ft)	
2	Turning radii	21.5 m (70 ft)	27.5 m (90 ft) See Remarks.	21.5 m (70 ft)	27.5 m (90 ft) See Remarks.	C-17 aircraft can execute “star turns,” which require forward and reverse taxi within 27.5 m (90 ft); however, for normal 180-degree turn maneuvers, the C-17 turn radius is 35.36 m (116 ft).
3	Shoulder width	3 m (10 ft)				Shoulders for paved LZs should be paved. Shoulders for semi-prepared LZs should be stabilized to prevent erosion by jet blast. Where adequate sod cover cannot be established, the shoulder should be chemically stabilized. Remove all tree stumps and loose rocks.
4	Longitudinal grade	Maximum 3.0%				Hold to minimum practicable. Grades may be both positive and negative.

Table 7-3. Taxiways for LZs						
Item		**Paved**		**Semi-Prepared (Unpaved)**		
No.	**Description**	**C-130**	**C-17**	**C-130**	**C-17**	**Remarks**
5	Rate of longitudinal grade change	Maximum 2.0% per 30 m (100 ft)				Grade changes should be held to a minimum and should be gradual. Minimum distance between grade changes is 30 m (100 ft). Grade changes cannot exceed 2.0% measured at 30 m (100 ft) intervals.
6	Transverse grade of taxiway	0.5% to 3.0%				Transverse grades should slope down from the taxiway centerline. The intent of the transverse grade limitation is to provide adequate cross slope to facilitate drainage without adversely affecting aircraft operations. The surfaces should slope so that the centerline of the taxiway is crowned.
7	Transverse grade of taxiway shoulder	1.5% to 5.0%				Transverse grades should slope down from the taxiway edge. The intent of the transverse grade limit is to facilitate drainage.
8	Runway-Taxiway Separation	81 m (265 ft)	93 m (305 ft)	81 m (265 ft)	93 m (305 ft)	Measured from the runway centerline to the taxiway centerline.
9	Infield area					All areas located between the runway and taxiways must be cleared of obstructions.
10	Clearance to fixed or mobile obstacles	29 m (95 ft)	33.5 m (110 ft)	29 m (95 ft)	33.5 m (110 ft)	Measured from the taxiway centerline. Required to provide minimum 7.5-m (25-ft) wingtip clearance.

Table 7-3. Taxiways for LZs						
Item		Paved		Semi-Prepared (Unpaved)		
No.	Description	C-130	C-17	C-130	C-17	Remarks
11	Taxiway clear area – width	21.5 m (70 ft) for C-130 22.9m (75 ft) for C-17				Measured from the outer edge of the taxiway shoulder to the obstacle clearance line. Remove or embed rocks that protrude more than 75 mm (3 in) above the surrounding surface. Cut tree stumps, brush, and other vegetation (excluding grass) to within 150 mm (6 in) of the ground.
12	Taxiway clear area – grade	Maximum range: +10.0% to -5.0%				Transverse grades may slope up or down to provide drainage but may not exceed a +10% nor -5% slope.
13	Taxiway Edge Safety Margin	2.1 m (7 ft)	2.1 m (7 ft)	2.1 m (7 ft)	2.1 m (7 ft)	Distance between outside of main gear and edge of full strength runway or taxiway.

Table 7-4. Aprons for LZs

Table 7-4. Aprons for LZs						
Item		Paved		Semi-Prepared (Unpaved)		
No.	Description	C-130	C-17	C-130	C-17	Remarks
1	Apron size	See Remarks.			See Note.	Sized to accommodate mission. Maximum visibility must be maintained at all times. As a minimum, the pilot must be able to clearly see all parked aircraft when taxiing. On paved aprons, clearance between wing tips of parked aircraft will be minimum 7.5 m (25 ft). Clearance between wing tips of taxiing aircraft and parked aircraft will be minimum 7.5 m (25 ft) for paved aprons and 15 m (50 ft) for semi-prepared aprons.
2	Apron grades in the direction of drainage	1.5 to 3.0%				
3	Width of apron shoulder	3 m (10 ft)				Apron shoulders for paved LZs should be paved. Shoulders for semi-prepared LZs should be stabilized to prevent erosion by jet blast. Where adequate sod cover cannot be established, the shoulders should be chemically stabilized.
4	Transverse grade of shoulder away from the apron edge	1.5 to 5.0%				Apron shoulder should be graded to carry storm water away from the apron. In shoulder areas, remove all tree stumps and loose rocks.
5	Apron Parking Setback	58 m (190 ft)	65.5 m (215 ft)	58 m (190 ft)	65.5 m (215 ft)	Measured from the runway centerline to the setback line. Aprons may be contiguous with the runway, but parked aircraft and vehicles must be behind this line. See Figure 7-4.
6	Clearance from edge of apron to fixed or mobile obstacles	26 m (85 ft)	30.5 m (100 ft)	26 m (85 ft)	30.5 m (100 ft)	Measured from the outer edge of the apron to obstacle clearance line. Remove or embed rocks that protrude more than 75 mm (3 in) above the surrounding surface. Cut tree stumps, brush, and other vegetation (excluding grass) to within 150 mm (6 in) of the ground.

Table 7-4. Aprons for LZs						
Item		Paved		Semi-Prepared (Unpaved)		
No.	Description	C-130	C-17	C-130	C-17	Remarks
7	Apron clear area grade	Maximum range: +10.0% to -5.0%				Grades may slope up or down to provide drainage, but may not exceed a +10% nor -5% slope. Centerline of drainage ditches must be established away from apron shoulders to prevent water from backing up onto the shoulder area.

NOTE: To eliminate the potential for FOD created by jet blast to parked and taxiing aircraft, individual parking aprons should be provided for each C-17 aircraft on semi-prepared LZs (other than AM-2 mat surfaced). Each apron should be a minimum of 61 m (200 ft) wide and 68.5 m (225 ft) long. Topography, mission, and obstructions determine the location and spacing between multiple aprons, but the aprons should not be located less than 152.5 m (500 ft) apart. All loose material must be stabilized or removed before the aprons can be operational.

Table 7-5. Overruns for LZs

Table 7-5. Overruns for LZs						
Item		Paved		Semi-Prepared (Unpaved)		
No.	Description	C-130	C-17	C-130	C-17	Remarks
1	Overrun length	91.5 m (300 ft)				The overruns must be constructed to the same standards as the runway. Overruns for mat surfaced runways must also be mat.
2	Overrun width	18.5 m (60 ft)	27.5 m (90 ft)	18.5 m (60 ft)	27.5 m (90 ft)	
3	Longitudinal grade of overruns	Maximum 3%				After first 30.5m (100 ft), overrun will be 0.0% or downward to avoid penetrating the ADCS.
4	Longitudinal Overrun Grade Change	Max. 2.0% per 30.5 m (100 ft)				First 30.5 m (100 ft) of overrun grade must match runway grade. Vertical curve at grade transition is desirable, but not required. No more than one grade change is allowed within the overrun. For Training LZs, minimize grade changes within the overrun and always use vertical curves at transitions.
5	Transverse grade of overruns	0.5% min. 3.0% max.				Grades should slope downward from overrun centerline.

Table 7-5. Overruns for LZs						
Item		Paved		Semi-Prepared (Unpaved)		
No.	Description	C-130	C-17	C-130	C-17	Remarks
6	Width of overrun shoulder	3m (10 ft)				Overrun shoulders for paved LZs should be paved. Shoulders for semi-prepared LZs should be stabilized to prevent erosion by jet blast. Where adequate sod cover cannot be established, the shoulders should be chemically stabilized.
7	Transverse grade of overrun shoulders	1.5% min. 5.0% max.				Transverse grades should slope down from the overrun edge. The intent of the transverse grade limit is to facilitate drainage.

7-5.5 Turnarounds.

For C-17 LZs without parallel taxiways, turnarounds must be provided at both ends of the runway. In other cases, turnarounds may be located on overruns or taxiways, depending upon mission or terrain requirements. The shoulder, structural, gradient, and clearance requirements for a turnaround are the same as those for the overrun or taxiway area where the turnaround is constructed. Turnarounds for C-130 aircraft should be at least 30 m (100 ft) in diameter. Turnarounds for C-17 aircraft should be 55 m (180 ft) long and 50.5 m (165 ft) wide (including the overrun/taxiway width) with 45-degree fillets. The aircraft landing gear must be positioned within 3 m (10 ft) of the runway edge prior to initiating this turn.

7-6 IMAGINARY SURFACES AND LAND USE CONTROL AREAS.

Minimum requirements for APZ-LZs and Exclusion Areas, clear zones and imaginary surfaces must be established to provide a reasonable level of safety for LZs. These criteria are provided in Tables 7-6, 7-7, and 7-8, respectively. These areas and the imaginary surfaces are shown in Figures 7-1, 7-2, 7-5 and 7-6. Airfield airspace criteria prohibit certain land uses within the clear zone, APZ. These land uses include storage and handling of munitions and hazardous materials, and live fire weapons ranges. See DoDI 4165.57 for more information.

Table 7-6. Accident Potential Zones (APZs) and Exclusion Areas for LZs

Table 7-6. APZs and Exclusion Areas for LZs						
Item		Paved		Semi-Prepared (Unpaved)		
No.	Description	C-130	C-17	C-130	C-17	Remarks
1	APZ-LZ length	762 m (2,500 ft)				Limit the following, where possible within the APZ-LZ: Actions that release any substances into the air that would impair visibility or otherwise interfere with operating aircraft, such as steam, dust, and smoke. Actions that produce electrical emissions that would interfere with aircraft and/or communications or navigational aid systems. Actions that produce light emissions, direct or indirect (reflective), that might interfere with pilot vision. Items that unnecessarily attract birds or waterfowl, such as sanitary landfills, feeding stations, or certain types of crops or vegetation. Explosive facilities or activities. Troop concentrations, such as housing areas, dining or medical facilities, and recreational fields that include spectators.
2	APZ-LZ width	Unoccupied Area: 152.5 m (500 ft) Occupied and Built-Up Area: 305 m (1,000 ft)				For cases where a training LZ may be sited near permanently occupied facilities or where new facilities may be sited near an LZ, use a 305-m-wide (1,000-ft-wide) APZ-LZ. See section 7-5 for all necessary modifications and considerations.

Table 7-6. APZs and Exclusion Areas for LZs

Item		Paved		Semi-Prepared (Unpaved)		
No.	**Description**	**C-130**	**C-17**	**C-130**	**C-17**	**Remarks**
3	Exclusion area width	Unoccupied Area: 213.5 m (700 ft) Occupied and Built-Up Area: 305 m (1,000 ft) Navy/Marine Corps Permanent Training LZ: 305 m (1,000 ft)				Exclusion areas are required for all paved and semi-prepared LZs. The purpose of the exclusion area is to restrict development of facilities around the LZ. Only features required to operate the LZ, such as operational surfaces (e.g., taxiways, aprons), NAVAIDs, airfield lights and signs, aircraft and support equipment, and cargo loading and unloading areas and equipment, are permissible in the exclusion area. Personnel formations, encampments, parked vehicles, storage areas, buildings, etc. are excluded from this area. Roads, fences and trees are acceptable. The exclusion area is centered on the runway. For long-term use LZs, restricting use of available land beyond the minimum distances contained in this UFC is highly recommended. The goal is to provide the greatest margin of safety for personnel, equipment, and facilities. For cases where a training LZ may be sited near permanently occupied facilities or where new facilities may be sited near an LZ, use a 304.8-m-wide (1,000-ft-wide) exclusion area. See paragraph 7-4.4 for a clarification of built-up and occupied areas. Navy/Marine Corps Permanent Training LZs: Treat the Exclusion Zone like the primary surface, which must be clear of all above-grade obstacles.
4	Exclusion Area Length	Runway length + length of Clear Zones				See requirements in Item 3.

Table 7-7. Runway End Clear Zone for LZs

Table 7-7. Runway End Clear Zone for LZs						
Item		Paved		Semi-Prepared (Unpaved)		
No.	Description	C-130	C-17	C-130	C-17	Remarks
1	Length	152.5 m (500 ft)				Measured along the extended runway centerline; begins at the runway threshold.
2	Width at inner edge	82.5 m (270 ft)	98 m (320 ft)	82.5 (270 ft)	98 m (320 ft)	
3	Width at outer edge	152.5 m (500 ft)				
4	Longitudinal and transverse grade of surface	Maximum 5.0%				Grades are exclusive for clear zone and are not part of the overrun but are shaped into the overrun grade. Grades may slope up or down to provide drainage. Exception: Essential drainage ditches may be sloped up to 10% in the clear zones. Do not locate these ditches within 23 m (75 ft) of a C-130 runway centerline or within 27.5 m (90 ft) of a C-17 runway centerline. Such ditches should be essentially parallel with the runway. Remove or embed rocks that protrude more than 100 mm (4 in) above the surrounding grade. Cut tree stumps, brush, and other vegetation (excluding grass) to within 150 mm (6 in) of the ground.

Table 7-8. Imaginary Surfaces for LZs

Table 7-8. Imaginary Surfaces for LZs						
Item		Paved		Semi-Prepared (Unpaved)		
No.	Description	C-130	C-17	C-130	C-17	Remarks
1	Primary surface length	Runway length plus 305 m (1,000 ft)				Centered on the runway (includes lengths of clear zones)
2	Primary surface width	45.5 m (150 ft)	55 m (180 ft)	45.5 m (150 ft)	55 m (180 ft)	Centered on the runway
3	Primary surface elevation	See Remarks				The elevation of the primary surface is the same as the elevation of the nearest point on the runway centerline or extended runway centerline.
4	Approach-departure clearance surface (ADCS) -- inner edge	152.5 m (500 ft)				Measured from runway end
5	ADCS Width at inner edge	152.5 m (500 ft)				
6	ADCS Slope	35H:1V	20H:1V	35H:1V	20H:1V	Remains constant throughout length
7	ADCS Slope length	Minimum 3200 m (10,500 ft)				The desired slope length is 9733 m (32,000 ft).
8	ADCS Width at outer edge	762 m (2,500 ft) at 3200 m (10,500 ft) from inner edge				Width of ADCS is constant from 3200 m (10,500 ft) to 9753 m (32,000 ft) from the inner edge.

NOTES

1. A ± (1.5% TO 5.0%) GRADE MEANS THE SURFACE WILL BE SLOPED, EITHER POSITIVELY BETWEEN +1.5% AND +5.0% OR NEGATIVELY BETWEEN -1.5% AND -5.0%, BUT NOT LEVEL.
2. GRADE CHANGES (INCLUDING REVERSALS) ARE PERMITTED WITHIN THE RUNWAY GRADED AND MAINTAINED AREAS AND WITHIN THE TAXIWAY AND APRON CLEAR AREAS.

7-7 OPERATIONAL WAIVERS TO CRITERIA.

The criteria in this chapter are the minimum permissible for C-17 and C-130 operations. When deviations exist or occur at a specific location, an operational waiver must be obtained before beginning flying operations. Ensure a risk assessment is performed on all proposed operational waiver requests prior to submitting to the approval authority. The office of primary responsibility (OPR) for the mission or exercise will initiate the waiver request. If IFR procedures apply, proposed waivers must be coordinated with the appropriate TERPS office. The appropriate airfield survey team will verify existing LZ dimensions and grades. See Paragraph 1-7 and Appendix B, Section 1 for waiver processing procedures.

7-8 SEPARATION DISTANCES BETWEEN PERMANENT RUNWAYS/HELIPADS AND LZ RUNWAYS.

7-8.1 Separation Distances between Permanent Runways/Helipads and LZ Runways for Simultaneous Operations.

When simultaneous operations are desired on a permanent runway or helipad and an LZ runway, minimum separation distances are required as stipulated in Table 7-9.

7-8.2 Separation between Permanent Class A or Class B Runways and LZ Runways for Non-Simultaneous Operations.

At a minimum, LZ runways will be separated from permanent runways so as not to conflict with distance-remaining signs, runway edge lights, NAVAIDs (including glideslope signals), and other facilities associated with the runway.

Table 7-9. Runway Separation for Simultaneous Operations

Table 7-9. Runway Separation for Simultaneous Operations

Item		Requirement	Remarks
No.	Description		
1	Distance between centerlines of parallel runways	762 m (2,500 ft)	IFR using simultaneous operation (depart-depart) (depart-arrival)
		1310.6 m (4,300 ft)	IFR using simultaneous approaches
2	Distance from the centerline of a fixed-wing runway to the centerline of a parallel rotary-wing runway, helipad, or landing lane	Min 213.4 m (700 ft)	Simultaneous VFR operations for Class A runway and Army Class B runway
		Min. 304.8 m (1,000 ft)	Simultaneous VFR operations for Class B runway for Air Force, Navy, and Marine Corps
		Min 213.4 m (700 ft)	Non-simultaneous operations Distance may be reduced to 60.96 m (200 ft); however, waiver is required and must be based on wake-turbulence and jet blast. In locating the helipad, consideration must be given to hold position marking. Rotary-wing aircraft must be located on the apron side of the hold position markings (away from the runway) during runway operations.
		Min. 762 m (2,500 ft)	IFR using simultaneous operations (depart-depart) (depart-approach)
		Min. 1310.6 m (4,300 ft)	IFR using simultaneous approaches

7-9 SURFACE TYPES.

1\ Semi-prepared (unpaved) LZ surfaces may be composed of stabilized soils, aggregate surfaces, compacted native soils, or matting. Paved LZs may be surfaced with asphalt concrete (AC) or PCC pavement. On runways, taxiways, turnarounds, and aprons used by C-17 aircraft, asphalt pavement distress has been observed in areas where 90- to 180-degree turns are made; for this reason, PCC is preferred in areas where turning movements occur. Designers should consider durability and maintenance of the pavement, as well as economics, when selecting a surface type for an area associated with an LZ intended for long-term use. AC and PCC pavement structures will be designed to support the traffic level defined in UFC 3-260-02, *Pavement Design for Airfields*. /**1**/

7-9.1 Runways and Overruns.

7-9.1.1 Semi-prepared Runway and Overrun Surfaces.

Unpaved LZ runway and overrun surfaces will be designed to support the anticipated aircraft type, weight, and number of planned operations. Overruns will be designed to the same standard as the runway.

7-9.1.2 Paved Runway and Overrun Surfaces.

Paved runways and overruns may be surfaced with AC or PCC pavement. Sawcut grooving may be used to improve drainage characteristics on runway surfaces only. Overruns will be designed to the same standard as the runway. Special design consideration is needed if the overrun is used as a taxiway or turnaround area.

7-9.1.3 Runway and Overrun Shoulders.

For semi-prepared runways, the shoulder structure will be designed to the same standard as the runway. For paved runways, shoulders will be surfaced with AC or PCC pavement and will be designed to support the traffic level defined in UFC 3-260-02.

7-9.2 Turnarounds.

Semi-prepared Turnarounds. Unpaved turnarounds will be designed to support the anticipated aircraft type, weight, and number of operations. Designers should give special consideration to stabilization for turnarounds used by C-17 aircraft because the surface can be easily damaged by the turning action of the main landing gear.

7-9.2.1 Paved Turnarounds.

Paved turnarounds may be surfaced with AC or PCC. Special consideration should be given to surface durability for turnarounds used by C-17 aircraft; for this reason, PCC pavement is preferred.

7-9.3 Taxiways.

7-9.3.1 Semi-prepared Taxiways.

Unpaved taxiways will be designed to support the anticipated aircraft type, weight, and number of operations. Designers should give special consideration to stabilization at taxiway turns used by C-17 aircraft because the surface can be easily damaged by the turning action of the main landing gear.

7-9.3.2 Paved Taxiways.

Paved taxiways may be surfaced with AC, PCC. Special consideration should be given to surface durability for taxiways used by C-17 aircraft; for this reason, PCC pavement is preferred.

7-9.4 Aprons.

7-9.4.1 Semi-prepared Aprons.

Unpaved aprons will be designed to support the anticipated aircraft type, weight, and number of operations. Designers should give special consideration to stabilization on aprons used by C-17 aircraft because the surface can be easily damaged by the turning action of the main landing gear.

7-9.4.2 Paved Aprons.

Paved aprons may be surfaced with AC, PCC. Special consideration should be given to surface durability and fuel resistance for aprons used by C-17 aircraft; for this reason, PCC pavement is preferred.

7-10 VISUAL LANDING ZONE MARKER PANELS (VLSMP).

Various systems are used during daytime operations to provide visual cues to pilots about the location and dimensions of the LZ runway. The type of marker panels selected depends on the mission requirements and anticipated duration of LZ use. The following paragraphs describe requirements for temporary and long-term applications, respectively.

7-10.1 Minimum Marking Requirements for Temporary Applications.

7-10.1.1 Temporary Panels.

LZ runways intended for short-term or temporary use should be marked with one of the arrangements of airfield marking patterns (AMP) defined in AFI 13-217, *Drop Zone and Landing Zone Operations*. The special tactics team (STT) will decide which arrangement of panels will be installed. The AMP-1, AMP-2 and AMP-3 layouts are illustrated in Figures 7-8a, 7-8b, and 7-8c. Although AMP-2 is also defined in AFI 13-217, the AMP-2 configuration will not be used for newly constructed temporary or permanent LZs by AMC. AMP-4 does not require any marker panels or lights and is only used for appropriate special operations.

7-10.1.2 Materials and Size.

Temporary panels may be constructed of fabric, wood, or other materials determined to be suitable by the STT. Panel faces will be at least 1524 millimeters (60 inches) wide and 432 millimeters (17 inches) tall. Airfield signs with solid panels rated for 300 mph have been commonly used.

7-10.1.3 Orientation and Color.

Marker panels should be erected upright and facing toward the aircraft approach to increase visibility to the pilot. The panels will be orange (Federal Standard 595, Color FS 18913, *Fluorescent Red Orange*), cerise (Federal Standard 595, Color FS 28915, *Fluorescent Red*), or other color acceptable to the STT. The specific color used and layout must be briefed to all participating units before operations commence.

7-10.1.4 Frangibility.

For temporary applications, frangible marker panels and supports are preferred to avoid excessive damage if struck by an aircraft. If available, VS-17 marker panels (National Stock Number [NSN] 8345-00-174-6865, Part Number MIL-P-400-61) should be used to mark temporary LZs for daytime operations.

7-10.2 Marking Requirements for Long-Term Applications.

7-10.2.1 Permanent Panels.

LZs intended for long-term use should have permanently installed panels of the type described below. Panel locations are derived from the patterns shown in AFI 13-217, Figures 3.1, 3.3, and 3.5. Panels will be installed at the locations shown in Figures 7-8a or 7-8b, depending on the desired AMP. In AMP-1, spacing will be consistent through the intermediate panels. If a conflict with the panels exists on one or both sides of the LZ (e.g., at locations where a taxiway connects to the LZ), that panel should be omitted. For bi-directional operations, panels of the appropriate color will be attached to each side of the support posts. See Figures 7-8a and 7-8b, Note 2, for the distance between the panels and the runway edge. Panels should be 1.8 meters (6 feet) apart at locations where panels are placed in pairs.

7-10.2.2 Materials and Size.

Panel surfaces may be constructed of any lightweight yet durable material suitable for the environment. Panel surfaces will be at least 1524 millimeters (60 inches) wide and 610 millimeters (24 inches) tall. Airfield signs with solid panels rated for 300 mph have been commonly used.

7-10.2.3 Orientation and Color.

Marker panels should be erected upright and facing toward the aircraft approach to increase visibility to the pilot. The panels should be covered with reflective sheeting material or painted orange (Federal Standard 595, Color FS 18913, *Fluorescent Red Orange*), or cerise (Federal Standard 595, Color FS 28915, *Fluorescent Red*), the colors indicated in Figures 7-8a and 7-8b. (**Note:** Alternate colors may be used if all participating units are briefed and concur with the color selection. For example, all panels may be orange.) Reflective sheeting will be 3M™ diamond grade or equivalent. Panels must be designed to withstand jet blast effects. A panel design that has been used successfully is illustrated in Figure 7-7.

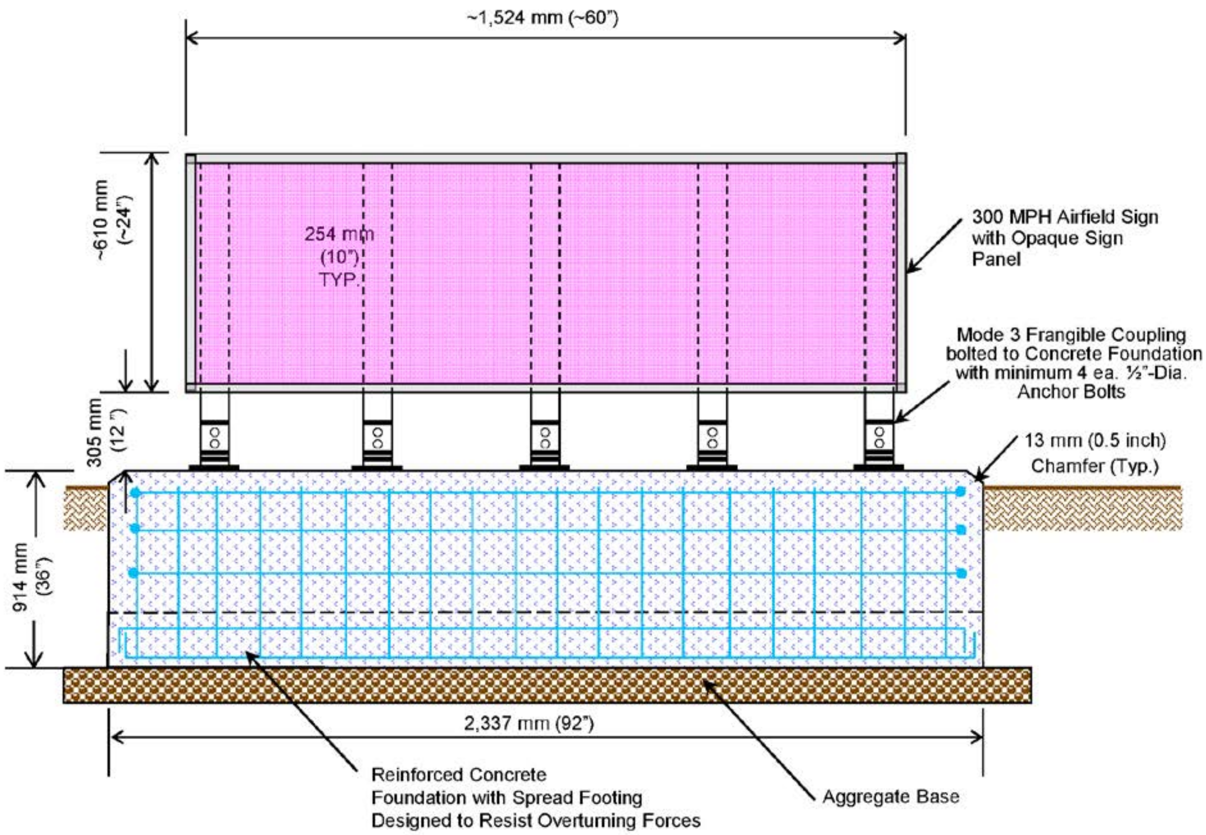
7-10.2.4 Foundations.

A reinforced concrete foundation pad should be used to support and anchor the panel support posts. Sample details for a foundation are shown in Figure 7-7.

7-10.2.5 Support Posts.

Support posts are needed to hold the panels upright. Posts must be strong enough to withstand jet blast and also frangible to break away upon impact. Posts will meet the frangibility definitions, acceptance criteria, analysis and testing requirements defined in Appendix B, Section 13. The support will have frangible points located 51 millimeters (2 inches) or less above the concrete pad. The frangible points will withstand wind loads due to jet blasts of 482 kilometers per hour (300 miles per hour) but will break or give way before reaching an applied static load over the surface of the sign of **\1** 19.3 kilopascals (2.8 pounds per square inch). **/1/**

Figure 7-7. Example VLZMP on Concrete Base Detail

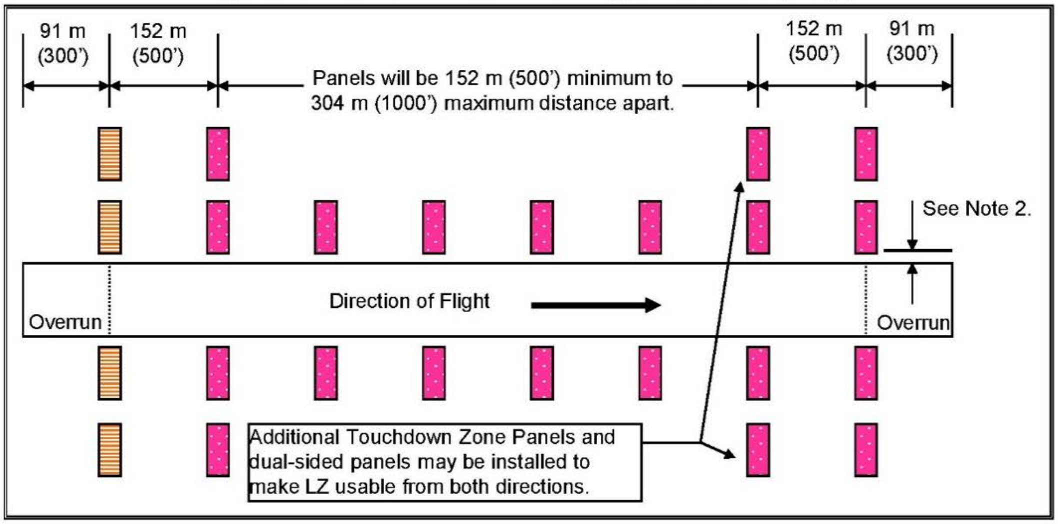


Notes:

1. Example panel design. Panel minimum dimensions must be met, but panel materials, posts, and foundation can be modified by the designer.
2. Refer to Figure 7-8a or 7-8b for locations and color scheme layout.
3. Foundation depth shall be minimum 914 millimeters (36 inches) or 152 millimeters (6 inches) deeper than the frost line. Foundation upper wall width shall be minimum 305 mm (12 inches). Foundation spread footing shall be minimum 305 mm (12 inches) thick. Spread footing width shall be as needed to resisting overturning moment created by jet blast and 300 mph wind on sign. Reinforcing shall be determined by designer.
4. Top of concrete pad shall be 13 millimeters (0.5 inch) above surrounding ground. Maximum allowable height above ground is 38 millimeters (1.5 inches). Slope concrete 6 millimeters (0.25 inch) per foot away from panel.
5. Frangible coupling or hinge point shall be located 13 millimeters (0.5 inch) above top of concrete pad.
6. For erosion protection and to ease mowing, install minimum 1.5 m (5 ft) asphalt pad around concrete foundation, flush with ground surface and sloped to promote drainage.

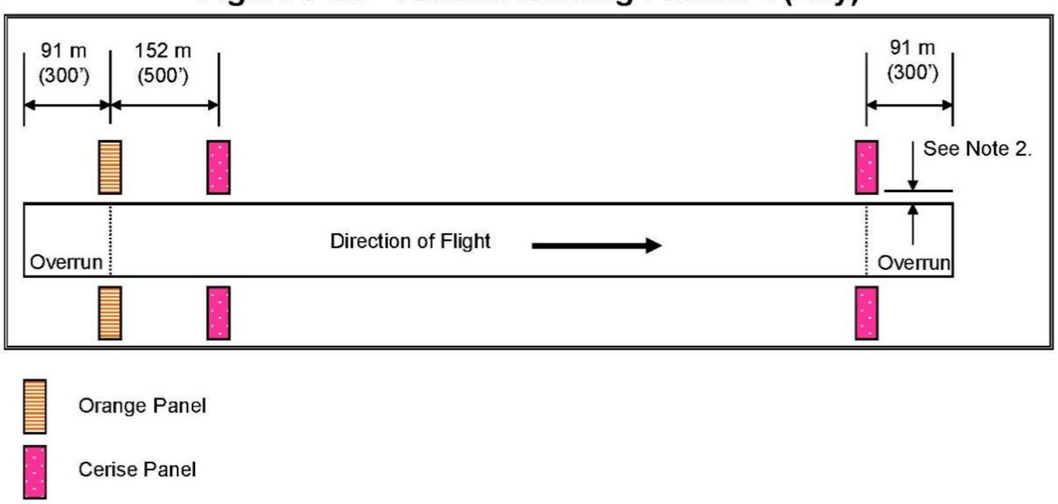
Figure 7-8. Airfield Marking Patterns (AMP)

Figure 7-8a – Airfield Marking Pattern 1 (Day)



Airfield Marking Pattern 2 (Day) - NOT USED

Figure 7-8b – Airfield Marking Pattern 3 (Day)



Notes:

1. Alternate colors may be used if all participating units are briefed and concur with the color selection. For example, all panels may be orange.
2. If runway edge lights are not installed on the LZ, place inner edge of panels 1.2 m (4') minimum, 3 m (10') maximum from the edge of the runway. If runway edge lights are installed, place inner edge of panels 3.6 m (12') minimum, 9 m (30') maximum from the edge of the runway so that panels do not block view of the runway edge lights.
3. See Figure 7-14 for additional panel layout dimensional details.

7-11 LZ LIGHTING.

Various systems are used during daytime operations to provide visual cues to pilots about the location and dimensions of the LZ runway. The type of marker panels selected depends on the mission requirements and anticipated duration of LZ use. The following paragraphs describe requirements for temporary and long-term applications, respectively.

7-11.1 Minimum Lighting Requirements for Temporary Applications.

7-11.1.1 Lights.

If available, lights should be omni-directional steady-burn or flashing with a minimum output rating of 15 candela for night operations. In accordance with AFI 13-217, virtually any type of lighting system is acceptable if all participating units are briefed and concur with its use. Contingency lighting kits (emergency airfield lighting system [EALS]) or other materials may be used as available and determined to be suitable by the STT.

7-11.1.2 Location.

There are three types of airfield lighting patterns for LZs, designated AMP-1, AMP-2, and AMP-3, as defined in AFI 13-217. AMP-4 is lights-out, no markings, and used only for appropriate special operations. The STT will decide which arrangement of lights will be installed. The AMP-1, AMP-2, and AMP-3 layouts are illustrated in Figures 7-9a, 7-9b, and 7-9c. Although AMP-2 is also defined in AFI 13-217, the AMP-2 configuration will not be used for newly constructed temporary or permanent LZs by the Air Force. When constructing new LZs, even if the immediate operational need is for AMP-3, consideration should still be given to installing the light bases and conduits to support the AMP-1 configuration.

7-11.2 Lighting Requirements for Permanent Applications.

When intended for long-term use, use permanently installed lights of the type and in the locations described below.

7-11.2.1 Light Fixtures.

Certify all light fixtures. Procure and install only those light fixtures listed in FAA AC 150/5345-53, *Airport Lighting Equipment Certification Program*, and FAA AC 150/5345-46, *Specification for Runway and Taxiway Light Fixtures*. IR filters will be used with fixtures listed in paragraph 7-11.7 when IR capabilities are required as part of the installation.

7-11.2.1.1 Runway Lights.

Runway high-intensity edge light fixtures will be used for permanent LZ lighting installations. Runway edge lights will be elevated FAA Type L-862. Use the L-850C when an inset light is required in place of the L-862. If the LZ is superimposed on an existing runway or taxiway where normal flight operations are conducted then use semi-flush light fixtures. If all edge lights are semi-flush edge lights, use the FAA Type L-850A, Style 3 (Runway, Uni-directional) towards the approach. (Where circling guidance is needed, bi-directional light fixtures may be used.) LZ light lens colors will be as indicated in Figures 7-9a, 7-9b, and 7-9c. Five-step regulators will be installed. (Steps 1 through 3 are compatible with NVG operations using a five-step regulator.)

7-11.2.1.2 Taxiway Lights.

Taxiway medium-intensity edge light fixtures will be used for permanent lighting installations. Taxiway edge lights will be elevated FAA Type L-861T. If needed, semi-flush edge lights will be FAA Type L-852T, Style 3 (Taxiway, Omni-directional). Taxiway and turnaround edge light lenses will be blue. Three-step regulators will be installed for intensity control.

7-11.2.1.3 Flashing Strobe Lights (FSL).

These light fixtures are located at the end of the LZ in the AMP-3 and AMP-2 configurations and at each side of the approach threshold in the AMP-1 configuration. These lights are uni-directional and must flash at a rate of 28 to 34 flashes per minute, producing a white light. Semi-flush fixtures (FAA-E-2952, Style A, white) will be installed with the edge of the fixture extending no more than 1.5 millimeters (0.0625 inch) below and 0.0 millimeter (0.0 inch) above the pavement top. Aim the fixture(s) down the runway parallel to the centerline for AMP-2 and AMP-3 and towards the approach for AMP-1.

7-11.2.2 Light Bases.

Light fixtures will be attached to full-depth light bases (L-868, Class IB). Light bases will be offset so the fixture center is a minimum of 0.6 meter (2 feet) from any pavement joint. Light bases will be installed in accordance with UFC 3-535-01. For elevated light fixtures, provide steel adaptor rings. Light construction tolerances are:

Longitudinal	± 13 millimeters (0.5 inch) from stationing
Transverse	± 13 millimeters (0.5 inch) transverse from centerline
Base orientation	Parallel to T/W centerline ± 0.5 degree
Elevation	+0 to -1.5 millimeters (+0 to –0.0625 inch) from finished pavement surface, flush with the surrounding grade or pavement.

7-11.3 Light Locations.

See paragraph 7-11.6 for guidance on LZ lights superimposed on Class A or Class B runways.

7-11.3.1 AMP-1.

Lights will be placed at each threshold and at 152 meters (500 feet) from each threshold. Intermediate lights will be 152 meters minimum/305 meters maximum (500 feet minimum/1000 feet maximum) spacing throughout the length of the runway, as illustrated in Figures 7-9a and 7-13. Spacing will be consistent through the intermediate lights. If a conflict with the lights exists on one or both sides of the LZ (e.g., at locations where a taxiway connects to the LZ), that light will be a semi-flush light. Synchronized FSLs will be installed at the threshold as illustrated in Figures 7-9a and 7-13. Steady-burning light fixtures will be installed at 1.6 meters (5 feet) plus 0.6 meter (2 feet) to minus 0.0 meter (0.0 foot) from the edge of the LZ surface (i.e., within the shoulder pavement). Light pairs will be perpendicular and equidistant from the runway centerline to be symmetrical about the runway or LZ centerline.

7-11.3.2 AMP-2.

Lights will be placed at each threshold and at 152 meters (500 feet) from each threshold. Intermediate lights will be 152 meters minimum/305 meters maximum (500 feet minimum/1000 feet maximum) spacing throughout the length of the runway, as illustrated in Figure 7-9b. Spacing will be consistent through the intermediate lights. If a conflict with the lights exists on one or both sides of the LZ (e.g., at locations where a taxiway connects to the LZ), that light will be a semi-flush light. An FSL is also installed on the centerline of the departure end threshold not more than 1.6 meters (5 feet) from the threshold or overrun end. Locate the FSL as close to the runway centerline as possible. Steady-burning light fixtures will be installed 1.6 meters (5 feet) plus 0.6 meter (2 feet) to minus 0.0 meter (0.0 foot) from the edge of the LZ surface (i.e., within the shoulder pavement). Installations requiring infrared capability will include the provisions of paragraph 7-11.7.

7-11.3.3 AMP-3.

Light locations and colors are derived from the AMP-3 configuration in AFI 13-217, Figure 3.6. Steady-burning lights will be placed at the threshold and at 152 meters (500 feet) from the approach end threshold, forming a box, as shown in Figures 7-9c, 7-14, and 7-15. An FSL is also installed on the centerline of the departure end threshold not more than 1.6 meters (5 feet) from the threshold or overrun end. Locate the FSL as close to the runway centerline as possible. Steady-burning light fixtures will be installed at 1.6 meters (5 feet) plus 0.6 meter (2 feet) to minus 0.0 meter (0.0 foot) from the edge of the LZ surface (i.e., within the shoulder pavement). Installations requiring infrared capability will include the provisions of paragraph 7-11.7.

7-11.3.4 Turnaround, Taxiway, and Apron Edge Lights.

All lights will be installed at 1.6 meters (5 feet) plus 0.6 meter (2 feet) or minus 0.0 meter (0.0 foot) from the edge of the load-bearing surface. On straight sections of taxiway or turnaround, lights will be spaced evenly with a maximum of 152 meters (500 feet) between lights. See Figures 7-12 and 7-13, for typical turnaround and taxiway edge light locations. Light spacing will be reduced to between 3 meters and 10.6 meters (10 feet and 35 feet) on curves and at corners or intersections. On curved sections, lights will be evenly spaced from point of tangency (PT) to PT, with the maximum spacing between lights equal to half the taxiway width. For all corners and all curves exceeding 30 degrees of arc, there will be a minimum of three lights. See UFC 3-535-01, Chapter 5, for additional edge light location details.

7-11.3.5 Overrun Edge Lights.

Overruns do not normally require edge lights; however, for overruns used as taxiways or turnarounds, edge lights may be installed using the location criteria stated in paragraph 7-11.3.4. In addition, the first pair of edge lights installed on overruns should not be more than 30.5 meters (100 feet) from the runway threshold.

7-11.4 Light Circuits and Controls.

Designers should investigate all required configurations of lighting (AMP-1, AMP-3 (Visual Spectrum), Infrared AMP-3, etc.) and develop a circuit and control system that can achieve all the required configurations.

7-11.4.1 Ferro-Resonant Regulators.

All new regulators used for LZ lighting systems will be ferro-resonant type.

7-11.4.2 Multi-Regulator Systems.

In this configuration, separate regulators will be needed to control lights for AMP-1, AMP-3 (Visual Spectrum), Infrared AMP-3, and taxiway circuits.

7-11.4.3 Single-Regulator Systems with Addressable Lights.

Systems are now available to have “assignable control” of individual lights via a carrier signal. For this type of configuration, all LZ runway lights could be powered by one regulator, with each configuration assigned to a different control setup.

7-11.5 Light Reflector Panels (Optional).

Light reflectors may be installed at the mid-point between LZ runway edge lights or taxiway edge lights. Contact the STT for information on obtaining light reflector panels.

Figure 7-9. Lighting Plans

Figure 7-9a – AMP-1 Lighting Plan

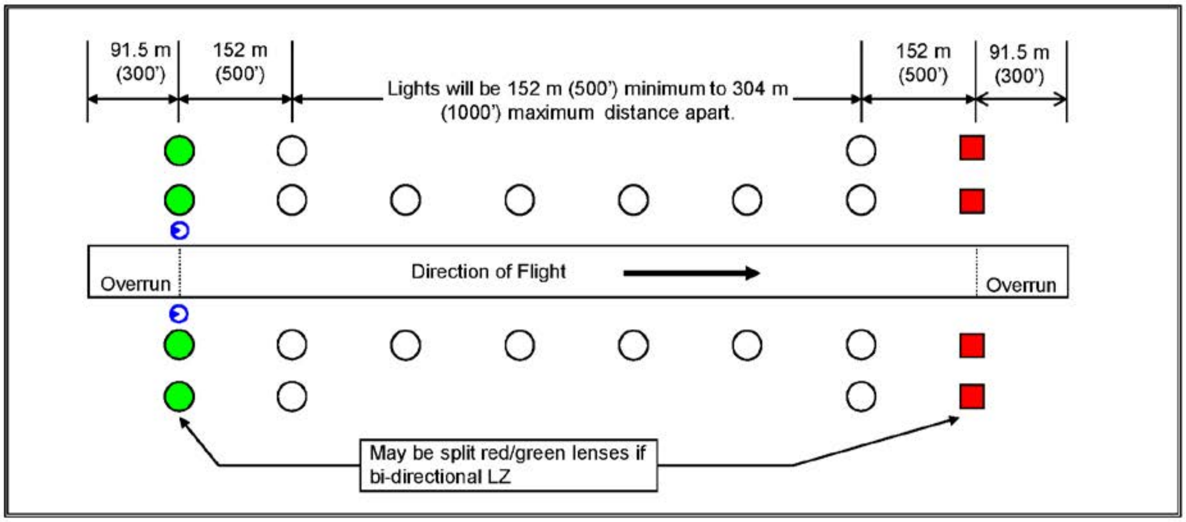


Figure 7-9b – AMP-2 Lighting Plan

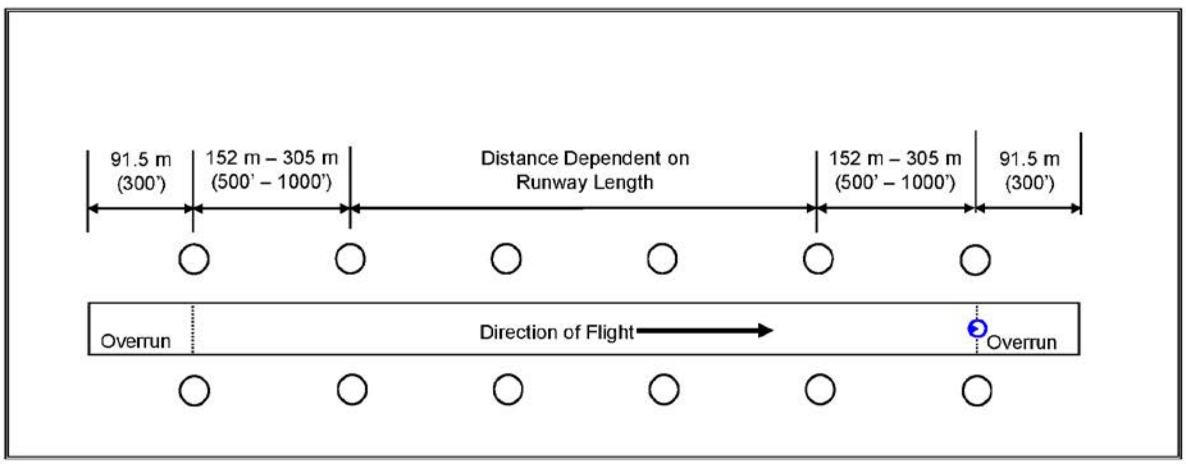
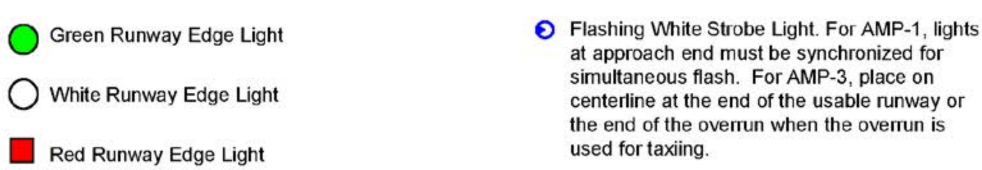
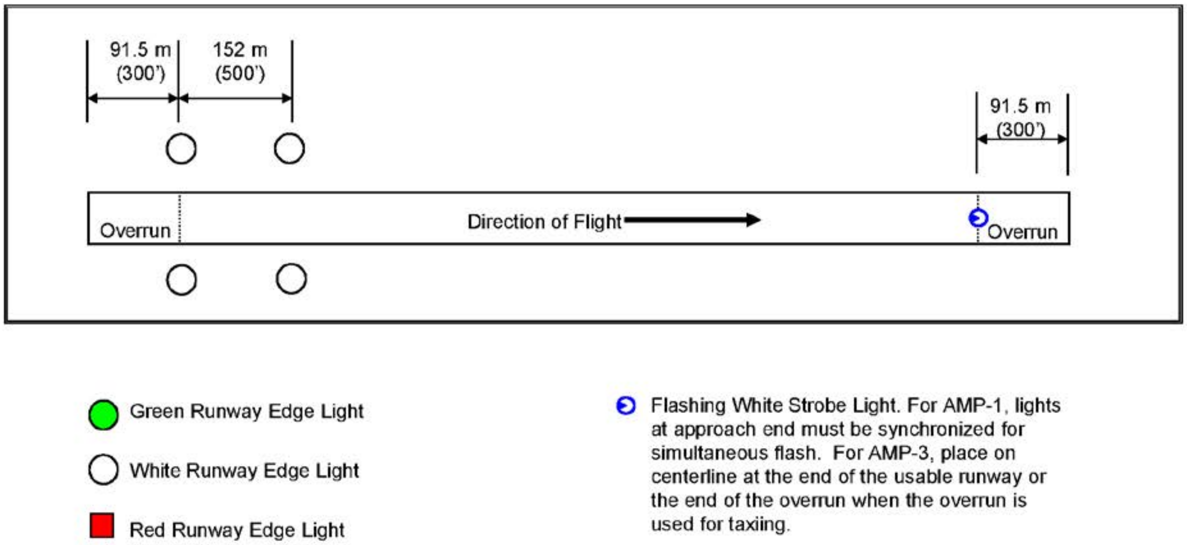




Notes:
1. See Figure 7-13 for additional light layout dimensional details.

Figure 7-9. Lighting Plans (continued)

Figure 7-9c – AMP-3 Lighting Plan



Notes:
1. See Figure 7-13 for additional light layout dimensional details.

7-11.6 AMP-3 (Visual Spectrum) LZ Lights Superimposed on Standard Operational Runways.

In some cases, it may be desirable to use a standard full-length runway for LZ training operations. Only the AMP-3 configuration should be installed in this situation. For this purpose, the LZ lighting scheme illustrated in Figures 7-15, 7-16 and 7-17, will be applied, subject to the following conditions. Service-specific airfield management approval is required before installation of AMP-2 configuration.

7-11.6.1 LZ Light Fixtures.

High-intensity light fixtures must be installed flush with the pavement surface to allow traffic to pass over them. Semi-flush lights will be FAA Type L-850A, Style 3, uni-directional, or an International Civil Aviation Organization (ICAO) equivalent. LZ light lens colors will be white. Five-step regulators will be installed on the LZ circuit(s) for light intensity control compatible with NVG operations (steps 1 through 3 are compatible with NVG operations).

7-11.6.2 LZ Location on the Runway.

When possible, the LZ threshold should be sited between 91 meters (300 feet) and 152 meters (500 feet) from the runway threshold. This will ensure aircraft loads are concentrated in the portion of the runway designed for heavier loads and avoid conflicts with runway pavement markings.

7-11.6.3 LZ Lighting Conflicts with Standard Runway Markings.

The LZ should be sited so the LZ light fixtures do not conflict with threshold markings, runway designation markings, touchdown zone markings, or fixed distance markings. An ideal location for the LZ threshold is 91 meters (300 feet) from the runway threshold. This will position the LZ light fixtures in the gaps between the standard runway markings. If LZ lights fall within a standard marking, the light fixture should be masked whenever repainting occurs.

7-11.6.4 LZ Lighting Conflicts with Approach Lights and Touchdown Zone (TDZ) Lights.

Runway approach lights and TDZ lights are spaced every 30 meters (100 feet) throughout the overrun and for the first 914 meters (3000 feet) of the runway. TDZ lights are installed in groups of three, starting 11 meters (36 feet) each side of the runway centerline and spaced over a 3-meter (10-foot) light bar. LZ lights for C-17s will not conflict with TDZ lights because LZ lights are 15 meters (50 feet) each side of the centerline. C-130 LZ lights are installed 10.5 meters (35 feet) each side of the centerline, so conflicts should not occur. If TDZ lights are installed on the runway, move the LZ lights closer to the LZ edge to position them inside the TDZ lights.

7-11.7 Infrared (IR) AMP-3 and AMP-2 Lights.

7-11.7.1 Installation.

At some locations, IR lights may be needed in addition to standard visual spectrum lights. IR lights can be installed in accordance with Figures 7-12, 7-13, 7-14 and 7-15.

7-11.7.2 IR Light Fixtures.

Procure and install FAA L-850A Style 3 fixtures, with infrared transmitting filter installed on the lens. Use only infrared transmitting filters will meet the specifications in Table 7-10 and the spectral transmittal limits required by the contracting officer. Use only infrared transmitting filters that are certified by an FAA-approved laboratory (currently Intertek Test Lab) to comply with the specifications in this paragraph and the required spectral transmittal limits. Submit to the contracting officer an FAA approved lab (currently Intertek Test Lab) report certifying compliance prior to installation.

Table 7-10. Infrared Transmitting Filter Specifications

Physical Properties	
Nominal thickness range	4–6 mm 0.17–0.23 in
Thermal linear expansion	$110x10^{-7}$/°C (30–300 °C) (86–572 °F)
Refractive index (n)	1.53
Density	2.67 g/cc
Strain temperature	492 °C (918 °F)
Transition temperature	510 °C (950 °F)
Anneal temperature	526 °C (979 °F)
Deformation temperature	563 °C (1045 °F)

7-11.8 Snowplow Rings.

Steel rings are used to protect semi-flush light fixtures in areas that are plowed for snow removal. See guidance on materials, configuration and installation procedures in FAA Engineering Brief No. 85, *Ductile Snowplow Protection Ring and Installation Procedures*.

7-12 PAVEMENT MARKINGS.

7-12.1 Minimum Requirements.

1\ The surface perimeter of non-contingency LZs, whether paved or semi-prepared, are required to be marked. For semi-prepared surfaces, the perimeter of landing surfaces, including the turn-around ends, will be marked with reflective markers referenced in AFTTP 3-32.13, *Airfield Marking and Striping After Major Attack*, or lighting options determined to be suitable for night operations in accordance with AFI 13-217. Stake chasers mentioned below are not suitable markings for night time operations. Reflective painted markings should be applied to paved surfaces where long-term use is intended. See Figures 7-11, 7-12, and 7-13 for illustrations of LZ pavement markings. /**1**/

7-12.2 Markings on Semi-Prepared LZs.

7-12.2.1 Paint.

It is generally not practical to apply paint to unpaved surfaces. However, markings are desirable to delineate the edge of operational surfaces, particularly turnaround areas. If the semi-prepared surfaces are stabilized, then painted markings may be feasible but will likely require frequent repainting.

7-12.2.2 Alternate Markings.

Alternatively, “stake chasers” can be installed along the edges of semi-prepared surfaces. Stake chasers are 150-millimeter (6-inch) flexible plastic bristles that attach to a 60-penny (60d) nail or a wooden stake. They are available in a variety of colors and can be purchased from survey supply stores. When used, the stake chasers should be installed at 7.6 to 15.2 meters ± 1.5 meters (25 to 50 feet ± 5 feet) intervals and driven into the ground so only 100 millimeters (4 inches) of the 150-millimeter (6-inch) whiskers are visible (exposed length may be dependent on soil conditions). This will help ensure the stakes are not dislodged by traffic or jet blast. When possible, install stake chasers with colors corresponding to the edge light (white = runway edge, blue = taxiway and turnaround edge). Stake chasers are illustrated in Figure 7-10.

Figure 7-10. Stake Chasers for Marking Edges of Semi-Prepared LZs, Taxiways and Turnarounds

7-12.3 Marking Requirements for Long-Term Use on Pavements.

7-12.3.1 Marking Material.

Use paint to apply markings to paved LZs, turnarounds, aprons, and taxiways. Paint should be applied at 0.305 to 0.356 millimeter (12 to 13 mils) wet film thickness for a desired dry film thickness of approximately 0.203 millimeter (8 mils). At this rate, coverage will be approximately 11 square meters (121 square feet) per gallon.

Normally, LZ markings should not be reflective to improve realism for operating on a semi-prepared LZ. However, for LZs that need additional reflectivity, glass beads (Type I or Type III) will be applied at a rate of approximately 3.6 to 4 kilograms (8 to 9 pounds) per gallon of paint.

7-12.3.2 Threshold Bar.

White threshold stripes may be marked at each end of the LZ runway to distinguish between the overrun and LZ runway surface. The marking will be 1.2 meters (4 feet) wide and extend from edge to edge of the LZ surface.

7-12.3.3 LZ Edge Stripes.

White side stripes should only be painted when there is no visual distinction between the LZ runway surface and the paved shoulder (e.g., both LZ runway and shoulder are asphalt). Edge stripes will be 0.3 meter (1 foot) wide and extend along the entire length of the LZ runway.

7-12.3.4 Taxiway Centerline.

If the LZ runway has connecting taxiways, the taxiway centerline turn radius will not be extended onto the LZ runway surface.

7-12.3.5 Taxiway, Apron, and Turnaround Edge Stripes.

If taxiways, aprons or turnarounds have paved shoulders and there is no visual distinction between the edge of load-bearing pavement and the shoulder, the edge of full-strength pavement will be marked with two 152-millimeter (6-inch) wide yellow stripes separated by a 152-millimeter (6-inch) wide gap.

7-12.3.6 Holding Position Markings.

The holding position is located a minimum of 30.5 meters (100 feet) from the near edge of the runway. This distance is measured perpendicular to the long axis of the LZ. For holding position marking dimensions, see Service-specific airfield marking guidance.

7-12.3.7 Touchdown Box Markings (Optional).

When desired by the airfield manager, touchdown box markings may be applied. These markings consist of 0.9-meter (3-foot) -wide white stripes that extend transversely across the entire width of the runway surface. The stripes are located 30.5 meters and 152 meters (100 feet and 500 feet) from the approach end threshold.

7-12.3.8 Runway Designation Markings.

Runway designation markings will not be used on LZ runways.

7-12.3.9 Runway Centerline (Optional).

When desired by the airfield manager, runway centerline stripes may be applied. Stripes are 0.5 meter to 0.9 meter (1.5 feet to 3 feet) wide and 30.5 meters (100 feet) long, with an 18.3-meter (60-foot) gap between stripes.

Figure 7-11. LZ Painted Marking Layout

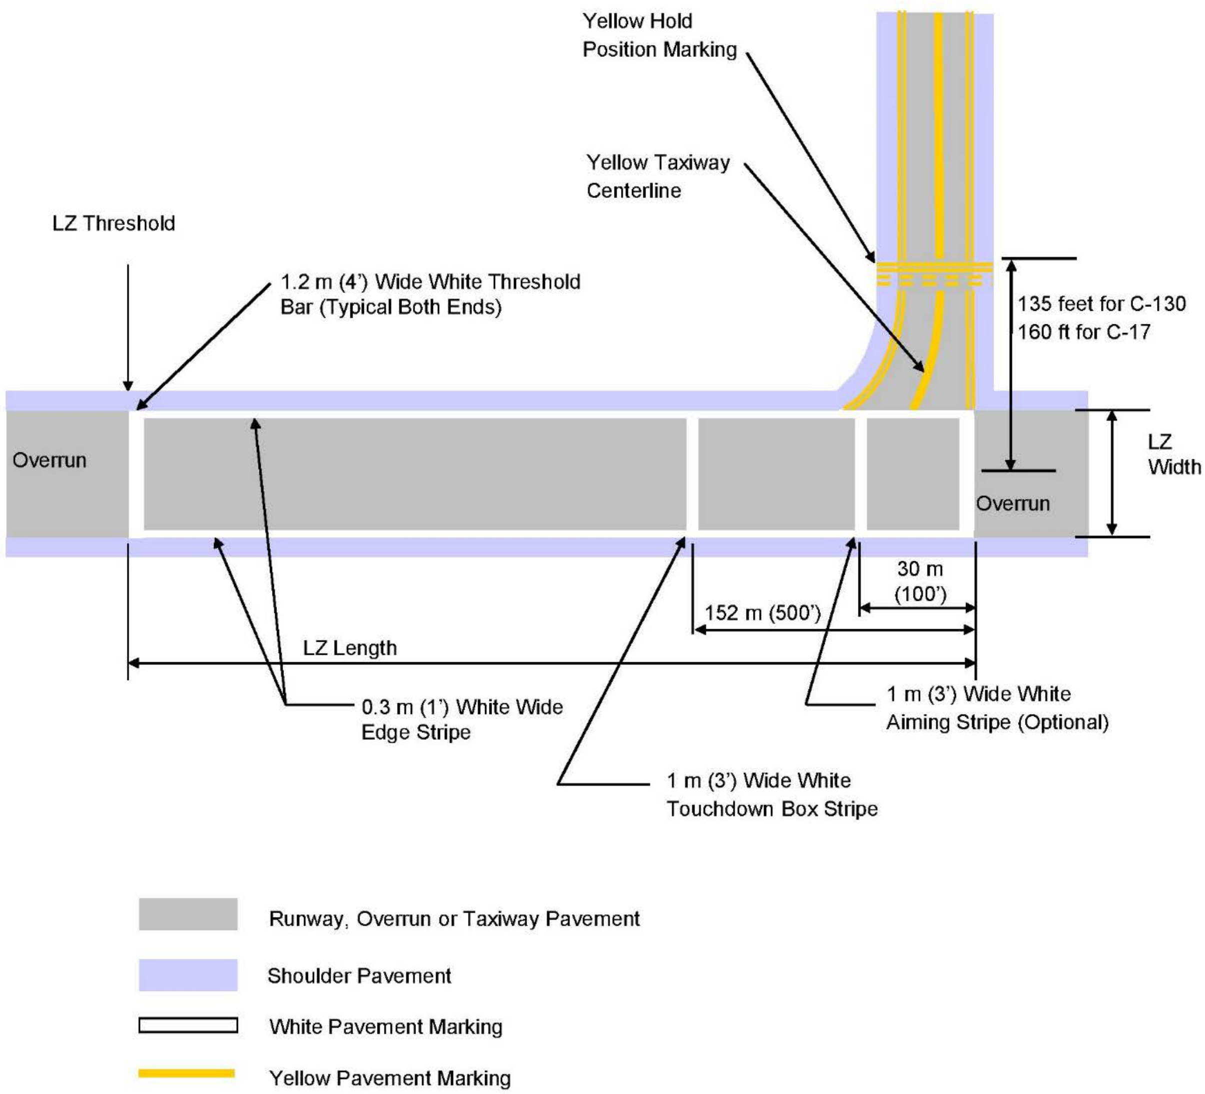


Figure 7-12. Typical Turnaround Marking and Lighting Plan

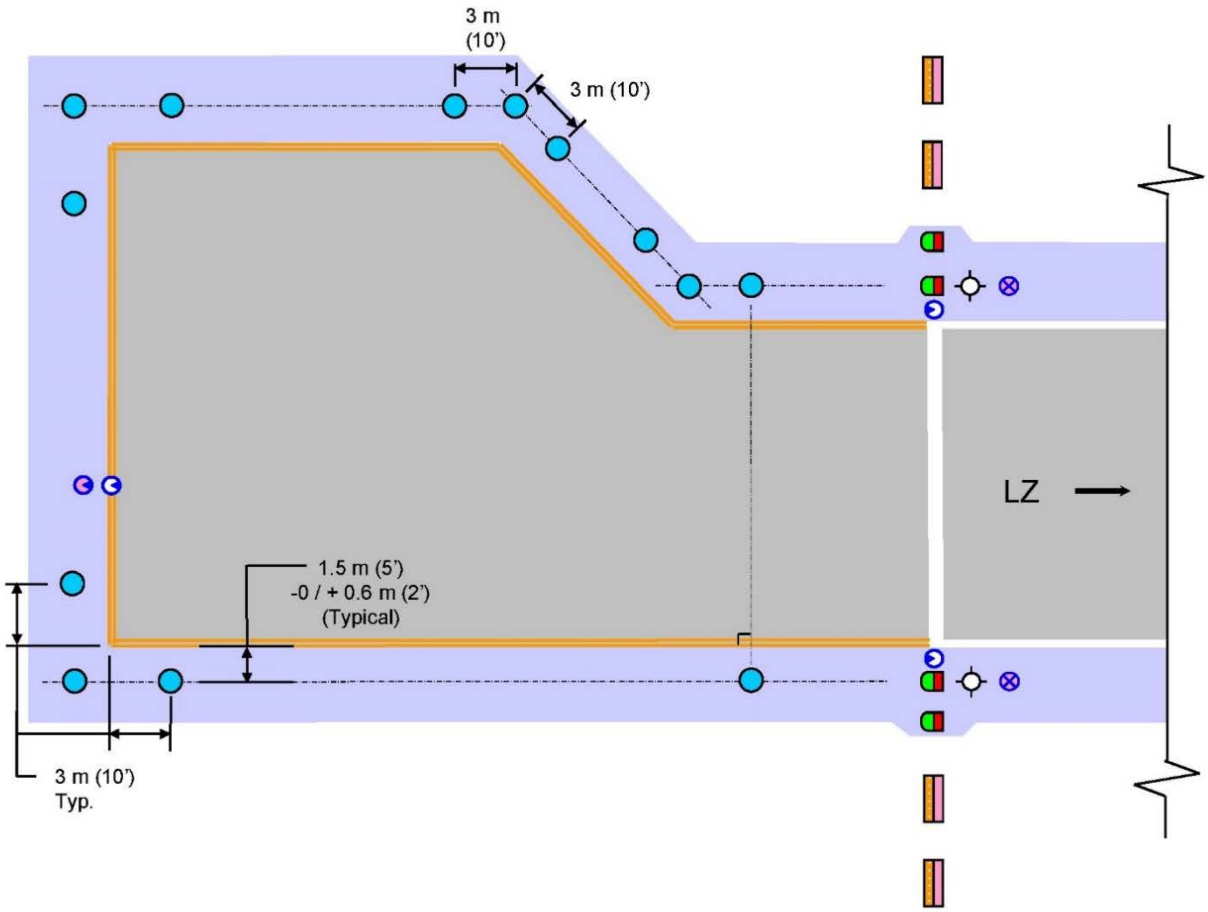


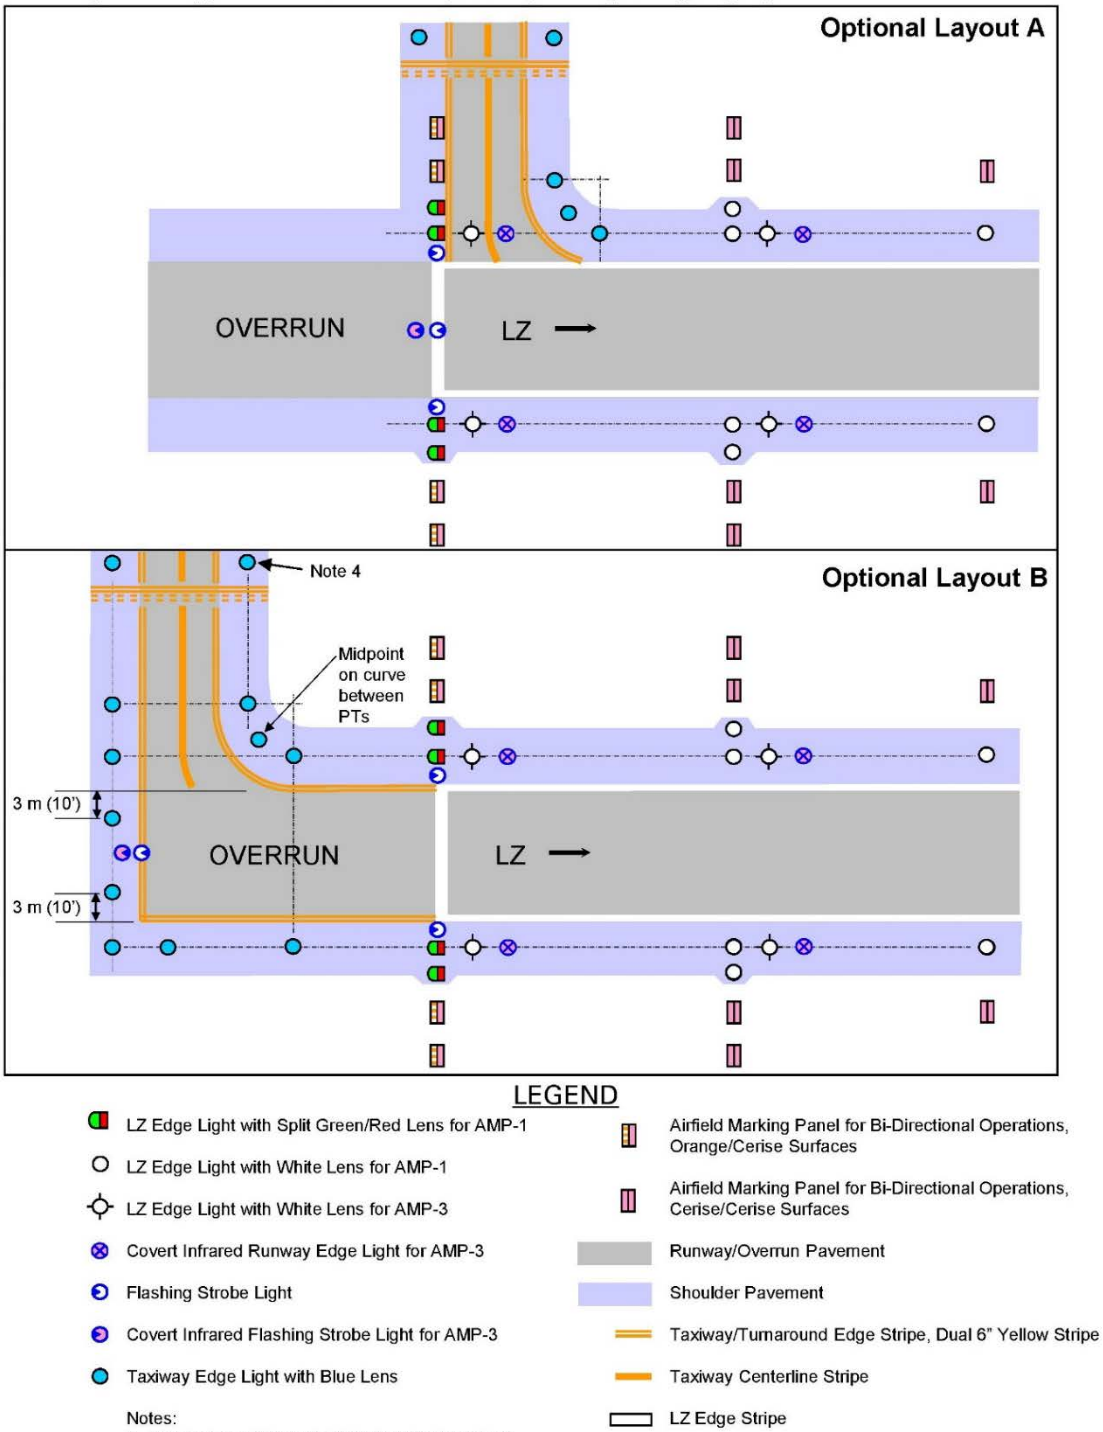
LEGEND

- LZ Edge Light with Split Green/Red Lens
- LZ Edge Light with White Lens for AMP-3
- Covert Infrared Runway Edge Light for AMP-3
- Flashing Strobe Light
- Covert Infrared Flashing Strobe Light for AMP-3
- Taxiway Edge Light, Blue Lens
- Airfield Marking Panel for Bi-Directional Operations, Orange/Cerise Surfaces
- Runway/Overrun Pavement
- Shoulder Pavement
- Taxiway/Turnaround Edge Stripe, Dual 6" Yellow Stripe
- LZ Edge or Threshold Stripe
- Layout Line
- 90-degree Layout Angle

Notes:

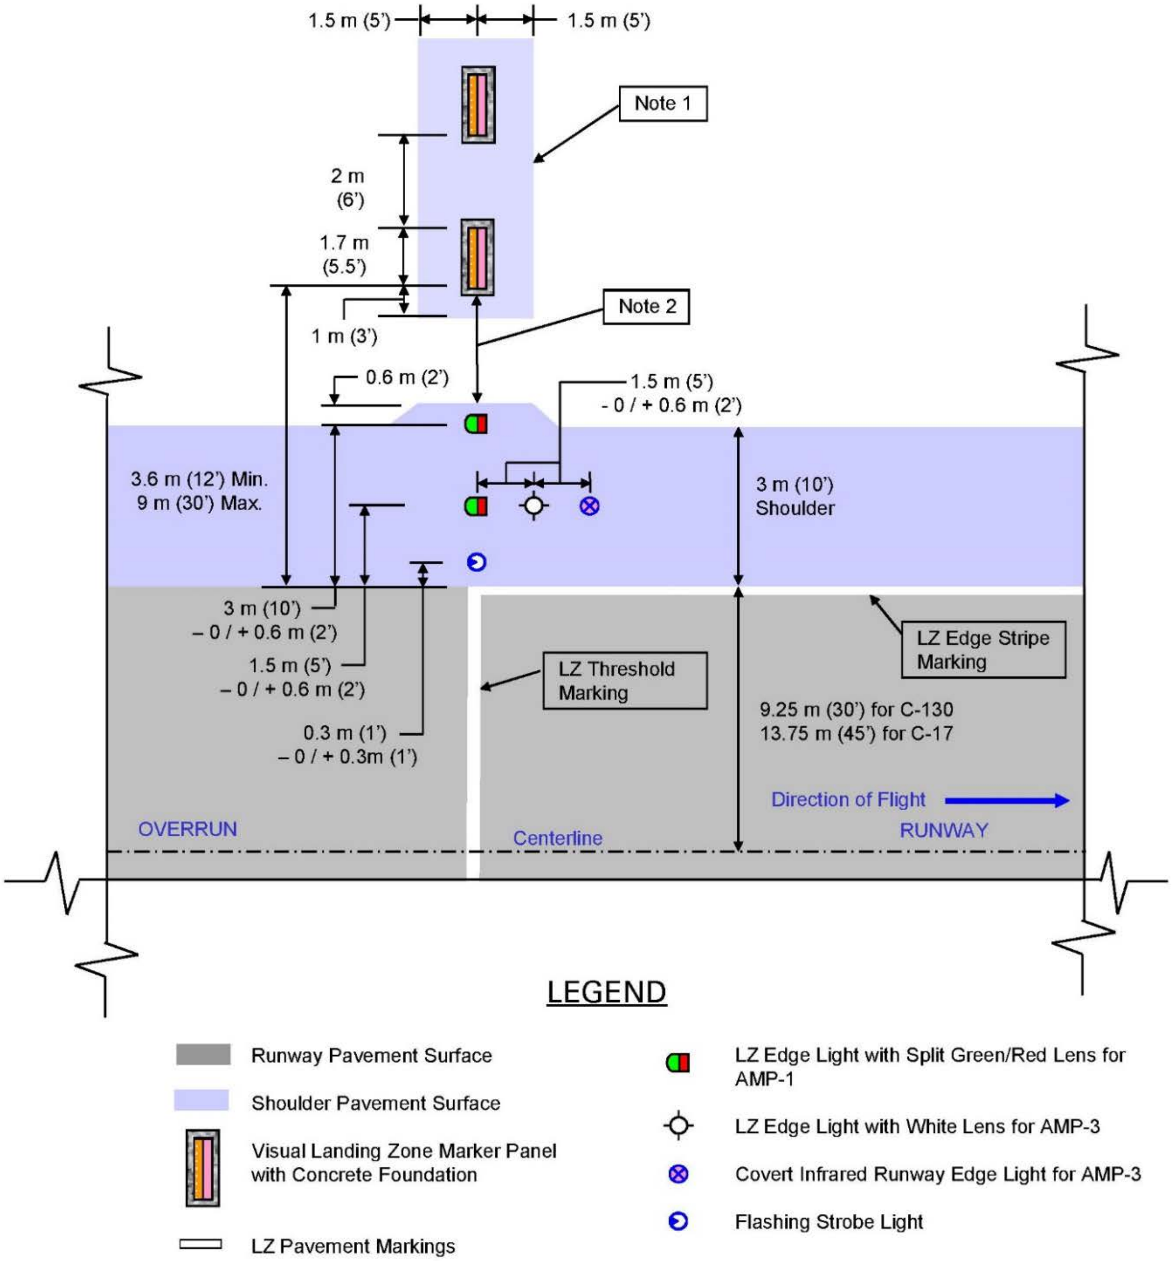
1. See text and Figure 7-14 for layout dimensions.
2. LZ is configured for bi-directional operations.
3. All taxiway lights shall be equidistant from taxiway/turnaround edge. Design tolerance is 1.5 m (5') – 0 / + 0.6 m (2').

Figure 7-13. Typical Bi-Directional Runway/Taxiway Marking and Lighting Layout



Notes:
1. See text and Figure 7-14 for layout dimensions.
2. LZ is marked and lighted for bi-directional operations.
3. All taxiway lights shall be equidistant from taxiway/turnaround edge. Design tolerance is 1.5 m (5') – 0 / + 0.6 m (2').
4. Locate taxiway lights behind the hold line according to UFC3-535-01, but no more than 60 m (200') from the point of tangency.

Figure 7-14. Light and Marker Panel Layout Detail on a Landing Zone with Combination AMP-1, AMP-3 (Visual Spectrum) and Infrared AMP-3



Notes:

1. Paved pad surrounding sign bases is recommended to eliminate need for mowing close to and between signs.
2. If gap between paved shoulder and sign foundation is less than 2.4 m (8'), pave entire gap.
3. LZ Edge lights must be on the same longitudinal alignment throughout the length of the LZ. Pairs of lights should be perpendicular and equidistant from the centerline.
4. All LZ lights should be located at least 0.6 m (2') from PCC pavement joints.
5. Minimum 1.2 m (4') spacing between Flashing Strobe and inboard Edge Light. Minimum 1.5 m (5') spacing between edge light pairs.

7-12.4 LZ Markings on Class A or B Runways.

In some cases, it may be desirable to use a standard full-length runway for LZ training operations. For this purpose, the LZ marking schemes illustrated in Figures 7-16 and 7-17 should be applied, subject to the following conditions.

7-12.4.1 LZ Marking Dimensions.

Non-reflective white markings, 3 meters (10 feet) by 1.7 meters (5.5 feet) are applied in the same pattern as VLZMP for the AMP-3 configuration.

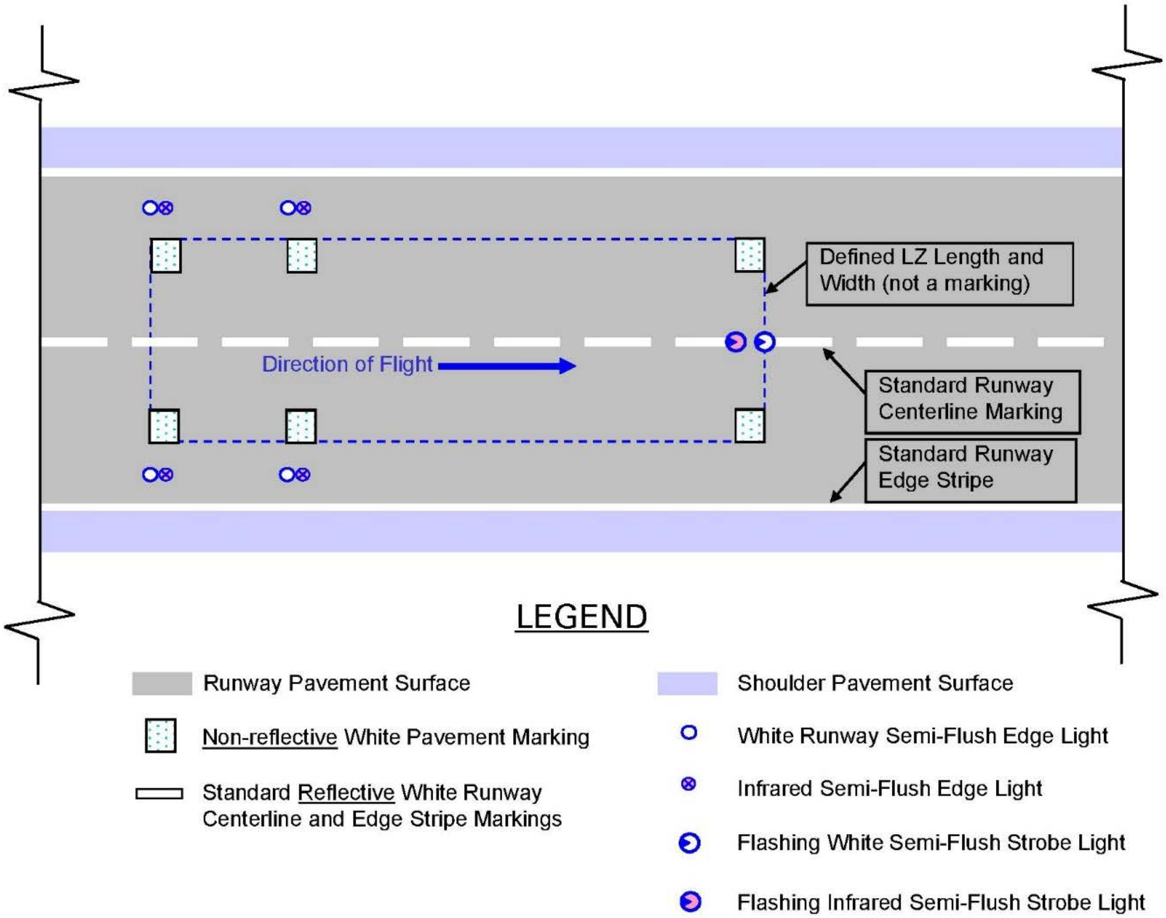
7-12.4.2 LZ Location on the Runway.

When possible, the LZ threshold should be sited so the LZ touchdown area is within the first 305 meters (1000 feet) of the runway pavement, and the 91-meter (300-foot) LZ overrun falls on the runway surface (not overrun). This will ensure that aircraft loads are concentrated on the portion of the runway designed for heavier loads. As described in paragraph 7-11.6.2, siting the LZ threshold 91 meters (300 feet) from the runway threshold will accomplish this objective.

7-12.4.3 LZ Marking Conflicts with Standard Runway Markings.

The LZ will be sited so the markings do not conflict with threshold markings, runway designation markings, touchdown zone markings, or fixed distance markings. An ideal location for the LZ threshold is 91 meters (300 feet) from the runway threshold. This will position the LZ markings in the gaps between the standard runway markings. See UFC 3-260-04 for standard airfield pavement marking criteria. When there is a conflict with Standard Runway Markings the Standard Runway Marking will take precedence. Any deviation from the standard runway marking requires a waiver to criteria.

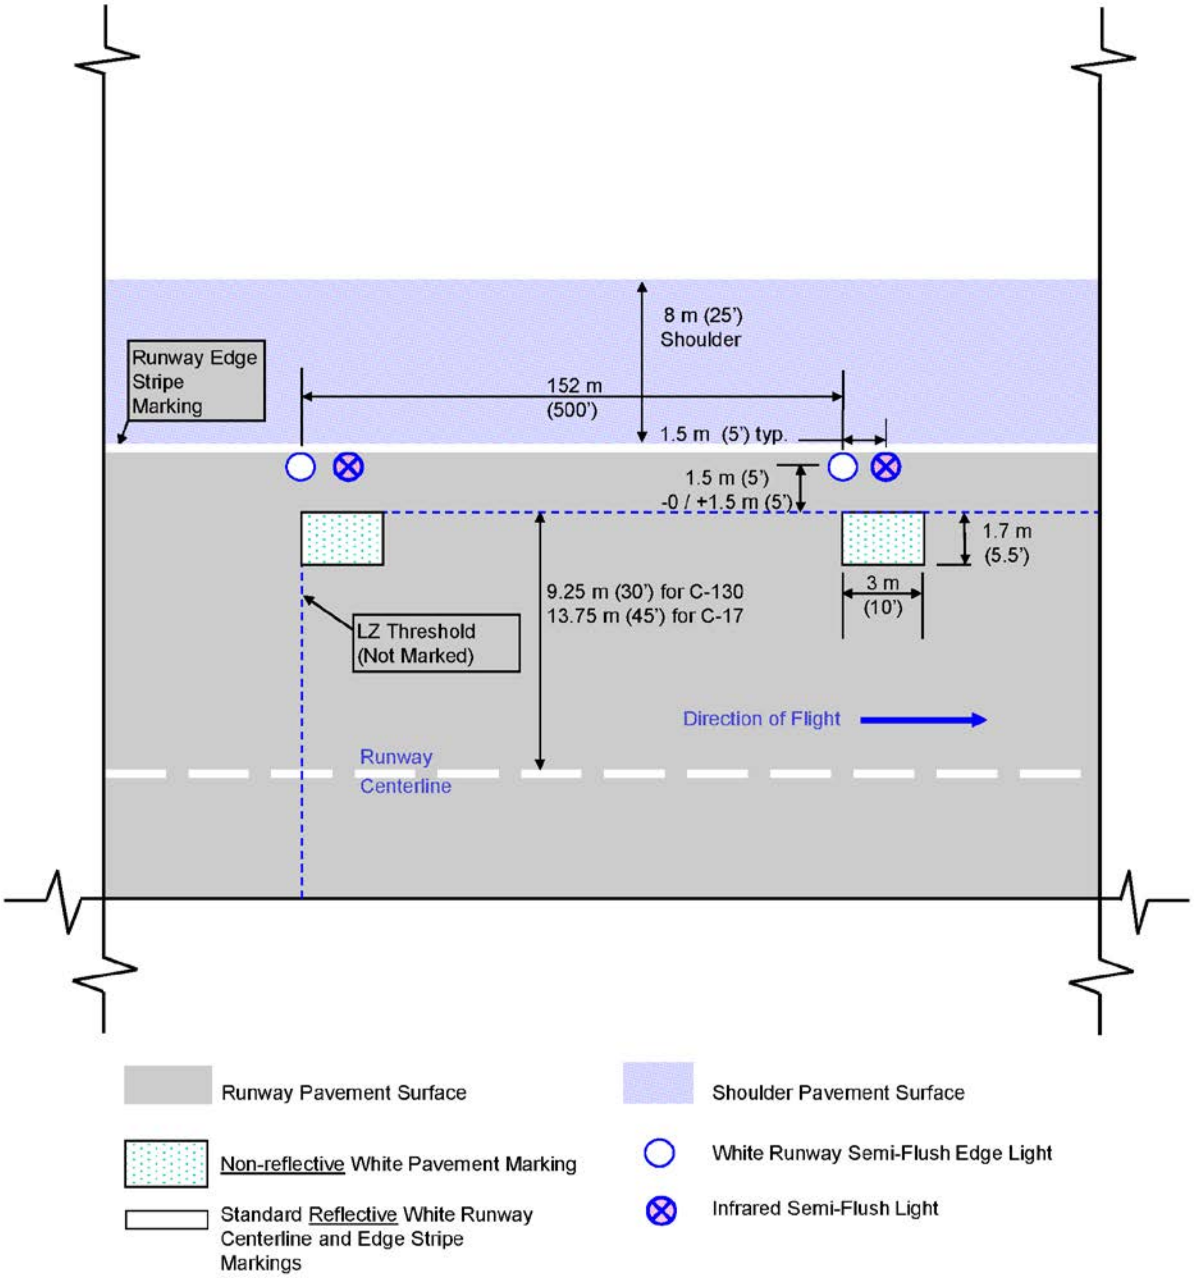
Figure 7-15. AMP-3 Lighting and Marking Scheme for LZ Superimposed on Class A or B Runway



Notes:

1. LZ Pavement Markings should be installed with the inside edge aligned with the edge of the LZ. The back edge should be aligned with the measurement from the threshold. Markings should be 3.0 m (10') long (parallel to runway centerline) and 1.7 m (5.5') wide.
2. If the flashing strobe light is not semi-flush, install at the end of the usable runway.
3. See Figure 7-16 and 7-17 for detailed layout of lights and markings.

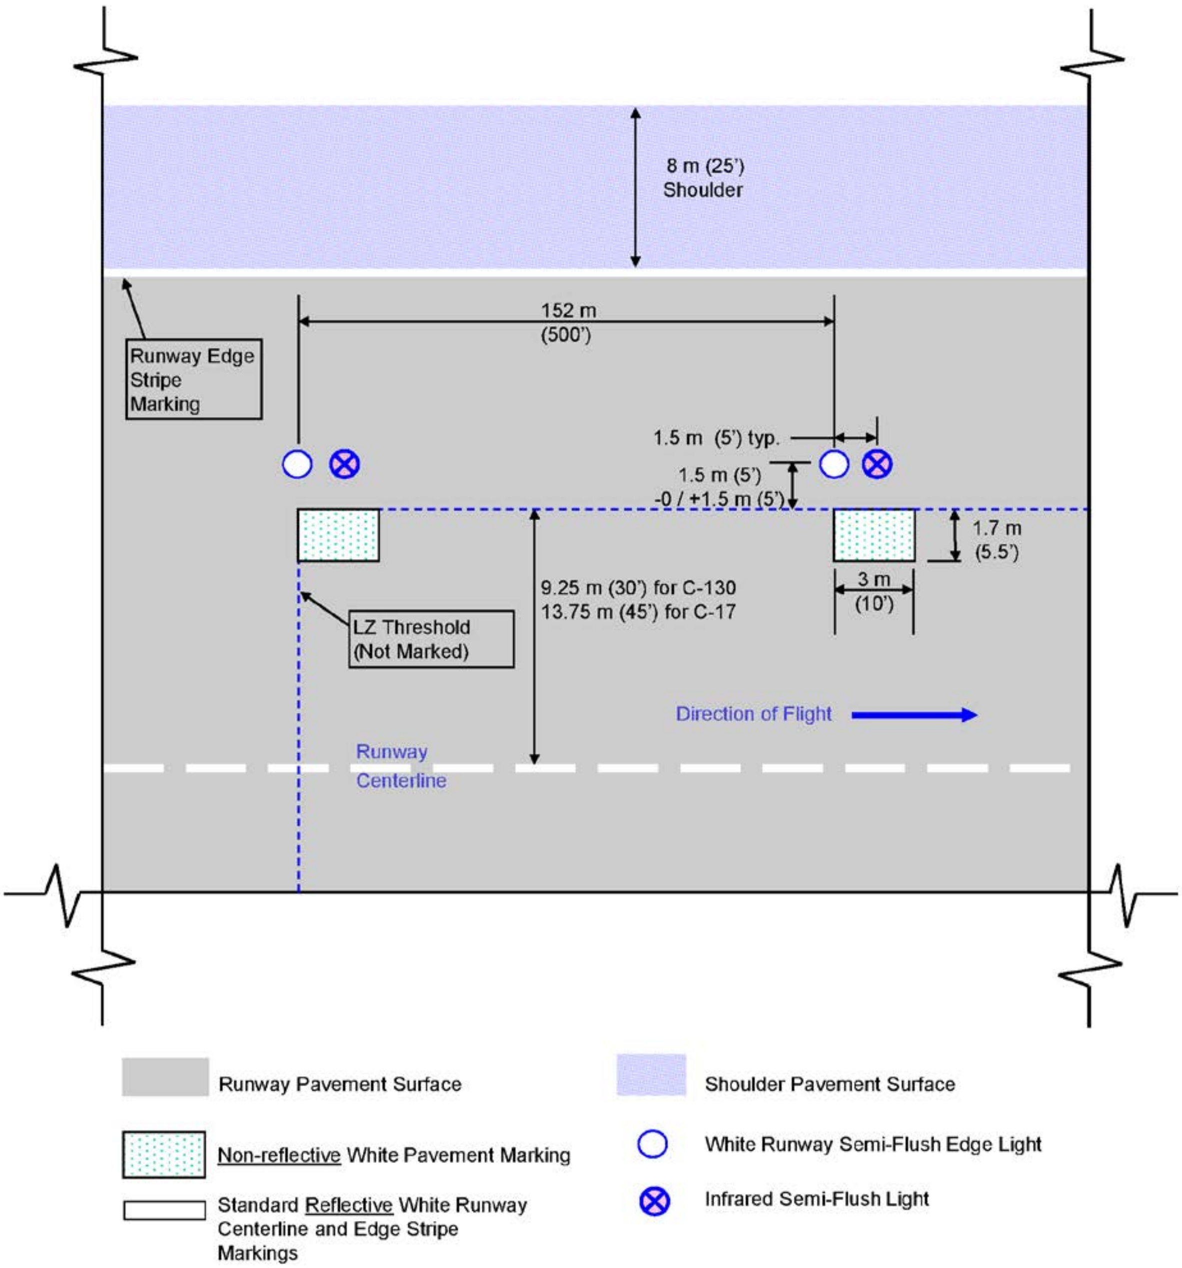
Figure 7-16. AMP-3 Visible and Infrared Lighting and Marking Layout Detail for LZ Superimposed on Class A Runway



Notes:

1. LZ threshold should be sited so that conflicts with standard lights and markings are avoided.
2. All LZ lights should be located at least 0.6 m (2') from PCC pavement joints.
3. See paragraphs 7-12.6 and 7-13.4 for additional details.
4. Ensure paint markings are not applied to LZ light fixtures.
5. Visible and Infrared light order may be reversed.

Figure 7-17. AMP-3 Visible and Infrared Lighting and Marking Layout Detail for LZ Superimposed on Class B Runway



Notes:

1. LZ threshold should be sited so that conflicts with standard lights and markings are avoided.
2. All LZ lights should be located at least 0.6 m (2') from PCC pavement joints.
3. See paragraphs 7-12.6 and 7-13.4 for additional details.
4. Ensure paint markings are not applied to LZ light fixtures.
5. Visible and Infrared light order may be reversed.

CHAPTER 8
FIXED-WING SHORT TAKEOFF AND VERTICAL LANDING (STOVL) FACILITIES

8-1 GENERAL INFORMATION.

This chapter discusses the airspace requirements, physical construction criteria, and general usage considerations for four types of STOVL facilities: LHD (amphibious assault ship) training facility, Vertical Landing (VL) pad, Forward Operating Base (FOB) facility, Tilt-Rotor Outlying Landing Field (OLF).

8-1.1 Chapter Organization.

Paragraphs 8-1, 8-2 and 8-3 provide general background information, definitions, and planning considerations that apply to all fixed-wing STOVL facilities. Paragraphs 8-4 through 8-7 provide specific requirements for designing the four types of STOVL facilities (LHD, VL Pad, FOB and OLF), including geometry, airspace, marking, lighting and pavement surface type.

8-1.2 Facility Concepts.

The STOVL facilities will support the training of F-35B and V-22 aircrew and ground personnel prior to ship-borne deployments and expeditionary operational environments. The smaller size of the amphibious assault ship (LHD) flight deck, as compared to the aircraft carrier (CVN) flight deck, and difference in landing type is significant enough to require its own dedicated training facility.

8-1.3 Basis of Design.

Criteria in this chapter were developed from the basis of design aircraft listed below; however, this is not intended to prohibit operations of other aircraft on these facilities. Each using aircraft, including the basis of design aircraft, must evaluate the facility for operational suitability.

Facility Type	Basis of Design Aircraft
LHD	F-35B and V-22 (LHD 5 ship deck)
FOB	F-35B
VL Pad	F-35B
Tilt-Rotor OLF	V-22

8-1.4 Background.

Due to the unique training requirements for F-35B and V-22 Flying Training Squadrons (FTSs) and the need for Operational Squadrons to train pilots for the rigors of ship and forward base deployments, those squadrons will need land-based STOVL specific facilities. This chapter addresses the criteria needed to design and construct land-based STOVL specific facilities and the imaginary surfaces necessary to support the STOVL facilities. The criteria presented in this document was developed from two main sources: Air Force ETL 14-4 "*Vertical Landing Zone (VLZ) and Other Airfield Pavement Design and Construction Using High Temperature Concrete*" dated 18 Aug 2014 and "F-35 Lightning II STOVL Airfield Facilities and Airspace Criteria Engineering Technical Letter (ETL), Document No: 2PSS00040, Rev 1" dated 30 July 2010. Criteria has been incorporated including changes, corrections, and other modifications resolving problems with original content. Non-applicable content has been omitted but may still be a useful reference to those seeking more background.

8-2 DEFINITIONS.

Only terms unique to this chapter are defined in this chapter. See the Glossary at the end of this UFC for general definitions.

8-2.1 Accident Potential Zone–STOVL (APZ-STOVL).

The land use control area beyond the clear zone of a STOVL that possesses a significant potential for accidents; therefore, land use is a concern.

8-2.2 Approach Clearance Surface.

An imaginary surface that is an inclined plane or combined incline and horizontal planes arranged symmetrically about the extended runway centerline covering the approach path for a directional STOVL facility. See Approach-Departure Clearance Surface for further detail.

8-2.3 Apron-STOVL.

A defined area on a STOVL facility intended to accommodate aircraft for loading or unloading passengers or cargo, refueling, parking, or maintenance. Aprons are sized to accommodate the mission.

8-2.4 Clear Zone-STOVL.

A surface on the ground or water, beginning at the runway threshold and symmetrical about the extended runway centerline, graded to protect aircraft operations and in which only properly sited NAVAIDs are allowed.

8-2.5 Departure Clearance Surface (DCS)-STOVL.

An imaginary surface that is an inclined plane or combined incline and horizontal planes arranged symmetrically about the extended runway centerline covering the departure path for a directional STOVL facility. See Approach-Departure Clearance Surface for further detail.

8-2.6 Forward Operating Base (FOB) STOVL Facility.

A FOB STOVL facility is one dedicated to short takeoff (STO) and rolling vertical landing (RVL) operations. These facilities have shorter and narrower runway dimensions than main airfields, and represent a mission oriented basing posture. The STO and RVL operations are performed to minimize ground roll and facility footprint.

8-2.7 Foul Line.

On an LHD STOVL Facility, a painted line that defines the edge of surface usable for takeoff and landing operations. The line is parallel to the centerline (tramline) and offset towards the LSO Tower. It consists of an alternating red and white stripe, with black outline.

8-2.8 High Temperature Concrete.

Portland cement concrete mixtures using expanded aggregates (also known as lightweight aggregates) or approved traprock sources are referred to as High Temperature Concrete (HTC). In this chapter, HTC only refers to high temperature concrete that meets the requirements of UFGS 32 13 13.43. HTC can be a specific formulation to support only V-22 aircraft, or V-22 and F-35B aircraft.

8-2.9 Imaginary Surfaces-STOVL.

Surfaces in space established around a STOVL Facility in relation to runways, helipads, or helicopter runways, and designed to define the protected airspace around the airfield. The imaginary surfaces for STOVL facilities are the primary surface, transitional surface, inner horizontal surface and ADCS.

8-2.10 LHD STOVL Facility.

A full size simulated land-based LHD ship flight deck used for field carrier landing practice (FCLP) consisting of short takeoff and vertical landing.

8-2.11 Primary Surface-STOVL.

An imaginary surface symmetrically centered on the STOVL Facility. The elevation of any point on the primary surface is the same as the elevation of the nearest point on the runway centerline or extended runway centerline.

8-2.12 Runway Centerline-STOVL.

The line extending the full length of the runway surface describing the center of the runway. For the LHD STOVL facility it is the tram line.

8-2.13 Safety Zones.

Safety zones are provided to prevent the erosion of graded surfaces by jet blast from aircraft transitioning to and from the STOVL facility.

8-2.14 STOVL Facility.

A STOVL facility is a takeoff and/or landing facility dedicated to short takeoff and vertical landing operations. For the purposes of this chapter there are four different types of STOVL facilities; LHD STOVL facility, Forward Operating Base (FOB) STOVL facility, Vertical Landing (VL) pad and Tilt-Rotor Outlying Landing Field (OLF).

8-2.15 STOVL Pavement Surface Types.

Several different surface types are required or recommended for STOVL Facilities because of the high temperature environment imposed by operations. For areas where F-35B vertical landings will occur, the surface will be constructed with High Temperature Concrete (HTC). See UFGS 32 13 13.43 and contact service-specific subject matter experts' guidance on HTC materials, mix design and construction techniques. Special considerations are needed for areas surrounding the landing surface and areas used for short takeoff operations. Four different types of pavement may be used on STOVL facilities.

- Continuously Reinforced High Temperature Concrete (CRHTC).
- Plain Jointed High Temperature Concrete (PJHTC)
- Plain Jointed Portland Cement Concrete (PJPCC)
- Hot Mix Asphalt (HMA)

8-2.16 Vertical Landing Pad (VL Pad.

Vertical landing pad is a paved surface of fixed dimension that affords a landing location for fixed-wing STOVL aircraft.

8-3 STOVL FACILITY PLANNING CONSIDERATIONS.

The landing and takeoff design considerations for a STOVL facilities will be directed to fulfill the requirements for the STOVL aircraft to include mission requirements, expected type and volume of air traffic, VFR and simulated IFR traffic patterns, runway (deck) length, runway orientation required by local wind conditions, local terrain, restrictions due to airspace obstacles or the surrounding community, noise impact, and aircraft accident potential. When planning to construct a new runway (deck) or reconstruct an existing runway (deck), in addition to local permitting requirements, file FAA Form 7480-1 in accordance with FAA Order 7400.2.

8-3.1 Site Conditions.

When planning the layout of a permanent STOVL, facility site conditions beyond safety of aircraft-related operations must be considered. These include land use compatibility with clear zones, primary surfaces, exclusion areas, impacts to existing instrument procedures and ADCS, and with existing and future use of the areas that surround the STOVL facility. In planning a STOVL facility, consider the use and zoning of surrounding land for compatibility with aircraft operations. The purpose is to protect the operational capability of the STOVL facility and prevent incompatible development, thus minimizing health and safety concerns in areas subject to high noise and accident potential resulting from frequent aircraft over-flights. The minimum criteria in this chapter establish standards for a safe environment for aircraft and ground operations. The goal is to provide a STOVL environment that provides the greatest margin of safety and compatibility for personnel, equipment, and facilities. Review the instructions and regulations for each Service and 32 CFR 989, *Environmental Impact Analysis Process (EIAP)* for guidance on the Environmental Impact Analysis Process.

8-3.2 Future Development (Land or Aircraft Technology).

Adequate land for future aviation growth must be considered when planning a STOVL facility. The facility should be compatible with the existing installation plan. Potential instrument flight rules (IFR) capability will require additional criteria considerations.

8-3.3 Prohibited Land Uses.

DoD and Service specific AICUZ directives govern land uses within the exclusion area, clear zone, and APZ. These restrictions are described in Tables 8-3, 8-6, 8-9 and 8-12.

8-3.4 APZs not on DoD Property.

APZs that are not on DoD property may require easements to control development and remove vegetation that may violate the ADCS. The need must be determined on a case-by-case basis.

8-3.5 SITING CONSIDERATIONS.

8-3.5.1 Site Considerations.

Site considerations include topography, vegetative cover, existing construction, weather elements, local wind conditions soil conditions, flood hazard, natural and man-made obstructions, adjacent land use, and availability of usable airspace, accessibility of roads and utilities, and potential for expansion capability. Applicable clearances, including separation distances, APZ, and imaginary surfaces must be. Siting approval must be obtained as part of planning and programming prior to any construction of new facilities or installation of equipment, including above ground infrastructure such as lights, pumps, etc. To minimize crosswinds, the strength, direction, and frequency of local winds must be considered when orienting a VL Pad. The potential for encroachment and effects of noise on the local community must also be considered.

8-3.5.2 Obstructions.

For training STOVL facilities, it is preferable to position the runway within an airfield environment to take advantage of existing runway and taxiway clearance areas. To maximize the training environment, the STOVL facility ADCS should be placed parallel to existing runway ADCS and with adequate separation to support parallel runway operations.

8-3.5.3 Orientation.

Runway orientation is the key to a safe, efficient, and usable aviation facility. Orientation is based on an analysis of wind data, terrain, local development, operational procedures, and other pertinent data. Procedures for analysis of wind data to determine wind orientation are discussed further in Appendix B, Section 4. Because an LHD runway is uni-directional, ensure the bow is oriented into the predominant wind direction.

8-3.5.4 Restricted Airspace.

Airspace through which aircraft operations are restricted, and possibly prohibited, is shown on sectional and local aeronautical charts. Runways should be oriented so that their approach and departure patterns do not encroach on restricted areas.

8-3.5.5 Noise Analysis.

The positioning of a STOVL facility must take into account noise levels on existing facilities, local communities, and noise-sensitive areas. Air Installations Compatible Use Zones (AICUZ) and Installation Compatible Use Zone (ICUZ) are programs initiated to implement Federal laws concerning land compatibility from the perspective of environmental noise impacts. The ICUZ program is the Army's extension of the AICUZ program, which was initiated by the DoD and undertaken primarily by Air Force and Navy aviation facilities. Studies under these programs establish noise abatement measures that help to eliminate or reduce the intensity of noise from its sources, and provide land use management measures for areas near the noise source.

8-3.5.5.1 Analysis.

Due to the widely varied aircraft, aircraft power plants, airfield traffic volume, and airfield traffic patterns, aviation noise at installations depends on both aircraft types and operational procedures. Aircraft noise studies should be prepared for aviation facilities to quantify noise levels and possible adverse environmental effects, ensure that noise reduction procedures are investigated, and plan land for uses that are compatible with higher levels of noise. While many areas of an aviation facility tolerate higher noise levels, many aviation landside facilities and adjoining properties do not. Noise contours developed under the AICUZ and ICUZ studies are used to graphically illustrate noise levels and provide a basis for land use management and impact mitigation. The primary means of noise assessment is mathematical modeling and computer simulation. Guidance regarding when to conduct noise studies is contained in the environmental directive for each Service.

8-3.5.6 Built-Up Areas.

Airfield sites and runway alignment will be selected and operational procedures adopted that will least impact local inhabitants. Additional guidance for facilities is found in DoDI 4165.57.

8-3.5.7 Clear Zones.

The purpose of the clear zone is to protect the safety of flight and safety of people on the ground. The entire clear zone area is a land use control area intended to protect people both flight safety and property on the ground. Land use for the clear zone area for STOVL facilities corresponds to the clear zone land use criteria for fixed-wing airfields as defined in DoD AICUZ and Service-specific standards and as discussed in Chapter 3.

8-3.5.8 Explosives.

8-3.5.8.1 General.

All explosives locations, including locations where aircraft loaded with explosives are parked must be sited in accordance with DoD Standard 6055.9 and applicable Service explosives safety regulations. Explosives site plans, approved through command channels to DoD, ensure that minimal acceptable risk exists between explosives and other airfield resources. To prevent inadvertent ignition of electro-explosive devices (EED), separation between sources of electromagnetic radiation is required. Separation distances must be according to safe separation distance criteria. Grounding requirements, lightning protection, and further considerations for explosives on aircraft are presented below. Where explosives or hazardous materials are handled at or near aircraft, safety and separation clearances are required. The clearances are based on quantity-distance criteria.

8-3.5.8.2 Separation Distance Requirements.

Minimum standards for separating explosives (explosion separation distances and quantity-distance [Q-D] relationships) -loaded aircraft from runways, taxiways, inhabited buildings, and other loaded aircraft are established in AR 385-10 for the Army; AFMAN 91-201 for the Air Force; and NAVSEA OP-5 and NAVAIR 16-1-529 for the Navy and Marine Corps. These documents also establish Q-D relationships for separating related and unrelated potential explosion site (PES) and explosive and non-explosive exposed sites.

8-3.5.8.3 Prohibited Zones.

Explosives, explosive facilities, and parked explosives-loaded aircraft (or those being loaded or unloaded) are prohibited from being located in Accident Potential Zones (APZ) I and II and clear zones as set forth in AR 385-10; DAPAM 385-64, Chapter 5; AFMAN 91-201; and AFI 32-7063.

8-3.6 FAA Requirements.

When a new STOVL facility is sited, in addition to local permitting requirements, file FAA Form 7480-1, *Notice of Landing Area Proposal*, in accordance with FAA Order 7400.2, *Procedures for Handling Airspace Matters*. Submit an FAA Form 7460-1, *Notice of Proposed Construction or Alteration*, for any above ground structures or modifications to existing airfields associated with the STOVL facilities.

8-3.7 Airspace Approval

Construction of new airfields, heliports, helipad or hoverpoints, or modifications to existing facilities affecting the use of airspace or changes in aircraft densities will be in conformance with JO 7400.2 (Procedures For Handling Airspace Matters).

8-3.8 Environmental.

Development of an aviation facility, including expansion of an existing aviation facility, requires compliance with a variety of laws, regulations, and policies. The National Environmental Policy Act (NEPA) requires all Federal agencies to consider the potential environmental impacts of certain proposed projects and activities, as directed by DoD Directive (DoDD) 6050.7. Implementation of these regulations is defined for each Service in these documents: Army: AR 200-1; Air Force: Title 32, Code of Federal Regulations, Part 989 (32 CFR 989); and Navy and Marine Corps: OPNAVINST 5090.1B (MCO 5090.2). Four broad categories of environmental review for a proposed action exist. The decision to conduct one study or another depends on the type of project and the potential consequences of a project to various environmental categories. Criteria for determining which type of study should be undertaken are defined in the environmental directives and regulations for each Service. Environmental studies should be prepared and reviewed locally. When additional assistance or guidance is necessary, this support may be obtained through various agencies such as the US Army Air Traffic Services Command (AFAT-ATC-CB), the US Army Corps of Engineers Transportation Systems Center (COE TSC), the US Army Corps of Engineers District Offices, NAVFAC Headquarters, and the Air Force Civil Engineer Center (HQ AFCEC).

8-3.9 Taxiway Connections.

Taxiways provide for ground movement of fixed- and rotary-wing aircraft. Taxiways connect the runways of the airfield with the parking and maintenance areas and provide access to hangars, parking aprons, and landing pads. Chapter 5 presents design standards and considerations for fixed- and rotary-wing taxiways.

8-3.9.1 Basic.

A basic taxiway layout provides low-volume access to single facility for a single purpose. For example, a single taxiway connecting a vertical landing pad to a main airfield parking apron or ramp supports the recovery of aircraft directly to the parking apron.

8-3.9.2 Parallel Taxiway.

A taxiway parallel for the length of the runway or STOVL facility, with connectors to the ends and the parking apron, provides multiple options for ground movement of aircraft.

8-3.9.3 Layout.

These considerations should be addressed when planning and locating taxiways to connect a STOVL facility to existing airfield infrastructure. Looking at our previous example, if the vertical landing pad is supported with a second taxiway departing and arriving traffic or multiple recovery aircraft can share the same STOVL facility.

8-3.9.3.1 Efficiency.

STOVL facility efficiency is enhanced by planning for multiple ground movement paths between the apron/fuel pits and the STOVL facility. Plans for aircraft movement in both directions should be included to support recovery of last landing aircraft and as the next evolution positions to begin their period of instruction.

8-3.9.3.2 Direct Access.

Taxiways should provide as direct an access as possible from the STOVL facility to the parking apron or fuel pits. The time spent taxiing the aircraft between training flights or STOVL training evolutions will directly affect the number of pilots trained during any given training period.

8-3.9.3.3 Simple Taxi Routes.

A sufficient number of taxiways should be provided to prevent complicated taxi routes or multiple hold points to give way to other aircraft. This consideration is magnified when flights of multiple aircraft are taxiing for departure or recovery. These flights sprawl and their taxi interval becomes extended complicating the movement of aircraft.

8-3.9.3.4 Delay Prevention.

A sufficient number of taxiways should be provided to prevent capacity delays that may result when one taxiway must service more than one STOVL Facility or multiple aircraft are planned to use the same STOVL facility. For example, if no parallel taxiway is available for aircraft using a FOB STOVL facility then only one aircraft at a time will be able to use the facility, because back taxiing on the runway will prohibit its use by a second aircraft.

8-3.9.4 Taxiway Shoulders.

Shoulders are provided along a taxiway to allow aircraft to recover if they leave the paved taxiway. Paved shoulders, also, prevent erosion caused by jet blast, support a potential aircraft that breaches the taxiway, support vehicular traffic, and reduce maintenance of unpaved shoulder areas. The shoulder for fixed-wing taxiways to support a STOVL facility should be paved to the maximum extent possible. Follow Table 5-1 for widths, slopes and grading requirements.

8-3.9.5 Aircraft Movement.

As can be seen from the description of the various factors going into taxiway design and layout, the potential exists to define the success or failure of a STOVL facility by the supporting taxiway structure. STOVL operations by definition involve a large number of takeoffs and landings as compared to normal T&R training events. This increased number of takeoffs and landings may or may not involve repositioning, ground loiter time, or a combination of both. Any delay between landing and subsequent takeoff will directly impact the number of aircraft the facility can support. Actions taken by planners and engineering to account for expected delays and provide movement options for aircraft on the ground will keep the STOVL facility deck clear of aircraft or other traffic and go a long way towards ensuring successful operations.

8-4 LHD STOVL FACILITIES.

8-4.1 LHD Concept.

STOVL carrier deployment training historically has incorporated the use of a full scale land-based LHD STOVL facility to include a Landing Signal Officer (LSO) tower, or V/STOL optical landing system (OLS), and Hover Position Indicator (HPI). The size and supporting structure of these facilities has afforded deploying forces the opportunity to train on the simulated LHD deck with significant flight deck realism. Training evolutions typically involve the pilots and LSOs, with a primary focus on practicing shipboard vertical landings followed by Short Take-Offs (STOs) under the supervision of a Launch Officer (LO). Additionally, these flight operations have included LSO under-training to train as launch officers, squadron personnel requiring flight deck familiarization, and the integration of ship’s personnel before actual operations afloat. The training benefits to the aircrew, LSO/LO and flight deck personnel are substantial, as they are taught to perceive the simulated flight deck as the actual deck. This realism affords them the opportunity to continue familiarization training beyond the simulator and builds on the training progression needed prior to deployment. VFR flight operations to and from the land-based facility will be assumed throughout this Chapter.

As stated in Paragraph 8-1.3, the basis of design shown in this UFC for an LHD facility is the LHD 5 ship deck. The dimensions, lights, and markings are typical for that ship, but new LHD or LHA ship configurations may change. Therefore, designers must determine current requirements at the time of design from:

Naval Air Warfare Center Aircraft Division (NAWCAD)
Route 547, Mail Stop 596-1
Joint Base MDL, NJ 08733-5000

Specific offices within NAWCAD are called out in later paragraphs for specific systems guidance.

8-4.2 LHD Standard Drawings.

NAVFAC Simulated LHD Shipdeck Standard drawings have been developed for this facility type. These include NAVFAC Drawing Numbers 14064429 through 14064452 and are available from the Whole Building Design Guide (http://www.wbdg.org/ffc/dod/unified-facilities-criteria-ufc/ufc-3-260-01), where this UFC is posted. Designer of Record must site-adapt, complete, and validate final design for construction. The original concept was developed for F-35B training; however, the design has been adapted to be compatible with V-22 operations also. These modifications include consideration of additional known F-35B operations, potential V-22 operations, lessons learned of pavement extents and materials. Existing facilities constructed prior to these modifications may need to be evaluated if such operational upgrades are desired.

8-4.3 LHD Background.

The LHD STOVL training facility will support the training of STOVL aircrew and ground personnel prior to ship-borne deployments. The smaller size of the LHD flight deck, as compared to the CVN flight deck, and difference in landing type is significant enough to require its own dedicated training facility.

STOVL carrier deployment training historically has incorporated the use of a full-scale land-based LHD STOVL facility to include a LSO tower, VSTOL optical landing system (OLS), and Hover Position Indicator (HPI). The size and supporting structure of these facilities has afforded deploying forces the opportunity to train on the simulated LHD deck with significant flight deck realism. Training evolutions typically involve the pilots and Landing Signal Officers (LSOs), with a primary focus on practicing ship-board vertical landings (VL) followed by Short Take-Offs (STOs) under the supervision of a Launch Officer (LO). Additionally, these flight operations have included LSO under-training to train as launch officers, squadron personnel requiring flight deck familiarization, and the integration of ship’s personnel before actual operations afloat. The training benefits to the aircrew, LSO/LO and flight deck personnel are substantial, as they are taught to perceive the simulated flight deck as the actual deck. This realism affords them the opportunity to continue familiarization training beyond the simulator and builds on the training progression needed prior to deployment. VFR flight operations to and from the land-based facility will be assumed throughout this Chapter. The pilot training requirements for field carrier landing practice (FCLP) have the pilots fly simulated instrument approaches until established on visual final for the STOVL deck.

However, these simulated carrier controlled approaches (CCAs) will be flown as self-contained VFR approaches or contact approach to the STOVL deck.

8-4.3.1 Assumptions.

- LHD criteria in this chapter is based on matching the dimensions, markings and lighting of an LHD 5 ship deck.
- The LHD STOVL facility is a unidirectional facility executing arrival and departures in the same direction.
- Airspace imaginary surfaces are defined for a standalone STOVL facility. When the LHD STOVL facility is collocated with an existing DoD airfield and their respective imaginary surfaces overlap, the most restrictive or lower surface will be utilized to ensure obstacle clearance.
- The imaginary surfaces for the LHD STOVL facility provide obstacle clearance for the F-35B day and night FCLP pattern. The day FCLP pattern altitude defines the inner horizontal surface and transitional area elevations. The night FCLP pattern defines the outer horizontal surface length and elevation, while the simulated IMC carrier controlled approach (CCA) profile defines the approach and departure path requirements. These surface dimensions are presented similar to the existing Class B runway criteria with the following exceptions; (1) the approach-departure paths were separated because the facility is not bi-directional, (2) the approach-departure slope is referenced to the LZ criteria because it provides clearance for the STO and vertical landing/rolling vertical landing (VL/RVL) profile, (3) the approach slope begins at the aft edge of the deck due to the VL approach profile, (4) the approach and departure horizontal distances terminate at the outer distance of the outer horizontal surface because this distance supports the simulated IFR CCA pattern, (5) inner surface radius corresponds with the approach-departure slope for the inner horizontal surface elevation, and (6) the width of the primary surface is reduced because all recoveries will be conducted under VMC and the close supervision of a Landing Signal Officer.
- The LHD STOVL facility is considered a directional facility with fixed approach and departure directions. These fixed approach and departure paths resulted in separate imaginary surface definition to minimize impact to surrounding environment and airfield infrastructure.
- A 300-foot primary surface width is used for LHD STOVL facilities because all recoveries will be conducted under Visual Meteorological Condition (VMC) and the close supervision of a Landing Signal Officer.
- Cross-axial approaches will not be conducted to the land based LHD STOVL facility.

8-4.4 LHD Geometry

8-4.4.1 Deck, Overrun and Safety Zone Descriptions.

Figures 8-1 through 8-13, and Table 8-1 provide dimensional criteria for layout and design of the LHD simulated ship flight deck, overruns, and safety zones. Safety zones are provided to prevent erosion of graded surfaces by jet blast from aircraft transitioning to and from the STOVL facility. Each zone or surface contains a brief description of its use and reference to where its specific dimension or graphic is located within the document.

8-4.4.2 Deck Length.

Table 8-1 provides the length of the overall simulated ship flight deck. Ideally the length varies slightly over the width of the simulated ship flight deck to reflect the actual outline of the deck it is designed to simulate.

8-4.4.3 Deck Width.

Table 8-1 provides the width of the simulated ship flight deck. Ideally the width varies slightly over the length of the simulated ship flight deck to reflect the actual outline of the deck it is designed to simulate.

8-4.4.4 Gradients of Operational Surfaces.

Gradient constraints are based upon sufficient slope to insure surface water runoff. A uniform slope is preferable to eliminate irregularities between landing gear at touchdown. For this reason the simulated deck surface can be crowned on the foul line or the entire deck surface sloped in one direction away from the LSO tower. Either sloping scheme will provide the pilot with a uniformly sloped surface for touchdown. See Table 8-1. After construction and prior to aircraft operations, each Landing Position will be surveyed on a 10' x 10' grid to determine elevations to the nearest 0.01'. This data will be analyzed using the procedures outlined in DM#315235 "Vertical Landing Pad Certification Requirements and Analysis" to verify the relative smoothness and certify the pads as "Authorized Level". If the pad does not meet the "Authorized Level" requirements, surface diamond grinding will be used to create a smooth surface with a consistent slope. The detailed requirements for conducting a pad levelness survey can be provided by the F-35 JPO. The purpose of the survey is to obtain measurements for analysis to verify that landing spot levelness and flatness complies with F-35B Flight Series Data (FSD). Post construction landing spot survey data should be sent to Lightning.Support.Team@jsf.mil for analysis. Analysis results will be provided to the requestor. Additionally, data, analysis, and results for all landing spots analyzed by the Lightning Support Team (LST) will be retained and archived for future reference; they may be found at DM#315485. Contact the F-35 JPO and Naval Air Surface Warfare Center Aircraft Division (NAWCAD) AR-6.7.8.2 NAVAIR Aviation Shore Facility Integration Branch for additional information on this subject.

8-4.4.5 Forward Safety Zone Length.

Table 8-1 provides the length of the overrun or forward safety zone. This length is dependent on the short takeoff (STO) profile and the distance from the simulated deck bow where the profile reaches a minimum altitude of 150 ft AGL.

8-4.4.6 Forward Safety Zone Width.

Table 8-1 provides the width of the overrun or forward safety zone. This width, at a minimum, reflects the width of the simulated flight deck plus a minimum shoulder width of 10 ft on each side (20 ft total). The width of the overrun may neck down or narrow by 50% if desired, however this narrowing of the overrun will be centered on the extended runway centerline or tram line for the simulated flight deck.

8-4.4.7 Shoulder Length.

Table 8-1 provides the length of the shoulder. This length is dependent on the length of the simulated ship deck and tied into the forward and aft safety zones for one continuous surface.

8-4.4.8 Shoulder Width.

Table 8-1 provides the width of the left and right shoulders. This width is designed to prevent soil erosion from decelerating aircraft alongside of the simulated flight deck before the aircraft crosses to the assigned landing spot.

8-4.4.9 Approach Safety Zone Length.

Table 8-1 provides the length of the approach safety zone. This length is dependent on the Field Carrier Landing Practice (FCLP) pattern and corresponds to distance from the aft deck edge where the profile reaches a minimum altitude of 150 ft AGL.

8-4.4.10 Approach Safety Zone Width

Table 8-1 provides the width of the approach safety zone. This width, at a minimum, reflects the width of the simulated flight deck plus the Left Shoulder or Abeam Safety Zone.

8-4.4.11 Supporting Facilities.

Several different types of supporting facilities may be adjacent to or connected to the LHD facility, depending on mission requirements. Generally, facilities should be connected on the right (starboard) side of the LHD. Use the appropriate criteria (such as Chapter 5 or 6 for connecting taxiways and aprons) in this UFC or other documents to design supporting facilities, such as:

Connecting Taxiway
Parking Apron
Refueling Systems

Bathroom
Airfield Lighting Vault

8-4.5 LHD Separation Distances.

Table 8-1 provides the minimum separation distances between permanent runways/helipads and the LHD STOVL facility for simultaneous operations. Table 8-1 also provides the minimum separation distances between permanent Class A or Class B Runways and LHD STOVL facility for non-simultaneous operations.

8-4.6 LHD Clear Zones, Imaginary Surfaces, and APZs.

Applicable clearances and grade controls must be established to provide a reasonable level of safety. Their description and layout are similar to other airfield types and are not unique to the LHD STOVL facility. Each zone or surface contains a brief description of their use and reference to where their specific dimension or graphic is located within the document.

8-4.6.1 Clear Zones.

Runway clear zones are areas on the ground, located at the ends of each runway. They possess a high potential for accidents, and their use is restricted to be compatible with aircraft operations. Runway clear zones are required for the runway and should be owned or protected under a long-term lease. See Table 8-3.

8-4.6.2 Imaginary Surfaces.

Surfaces in space established around a STOVL facility in relation to the simulated LHD deck, and designed to define the protected airspace around the facility. The imaginary surfaces for the LHD STOVL facilities are the primary surface, transitional surface, inner horizontal surface, conical surface, outer surface and approach-departure path surfaces. These surfaces provide obstacle clearance for the F-35B day and night FCLP pattern. The day FCLP pattern altitude defines the inner horizontal surface and transitional area elevations. The night FCLP pattern defines the outer horizontal surface length and elevation, while the simulated IMC carrier controlled approach (CCA) profile defines the approach and departure path requirements. See Table 8-2. Note: the imaginary surfaces described in this chapter were developed only for F-35B operations. Airspace for other aircraft using the LHD facility must be evaluated separately.

8-4.6.3 Accident Potential Zones.

A land use control area beyond the clear zone of a STOVL facility that possesses a significant potential for accidents. Land use within the APZ is restricted in accordance with DoDI 4165.57. The dimensions and layout are listed in Table 8-3. Navy planners will use OPNAVINST 11010.36C/MCO 11010.16 (or latest version) to determine specific AICUZ requirements. For the Air Force, land use guidelines within the clear zone (beyond the graded area) and APZ I and APZ II are provided in AFI 32-7063 and AFH 32-7084.

8-4.7 LHD Pavement Marking.

Apply markings to LHD pavements using airfield marking paint with reflective beads (except LHD tram line, aircraft elevator outlines and clear zone markings outside deck outline without beads), following the general scheme shown in Figures 8-14 and 8-15. See NAVFAC Simulated LHD Shipdeck Standard Drawings for specific layout and detailed dimensions. For new construction or modifications, ensure current marking requirements are obtained from NAWCAD 4.8.2.3. Taxiways and aprons connected to the LHD Facility will be marked according to UFC 3-260-04.

8-4.8 LHD Lighting.

Install airfield lights on the LHD deck following the general scheme shown in Figures 8-16 through 8-19. See NAVFAC Simulated LHD Shipdeck Standard Drawings for specific layout and detailed dimensions. For new construction or modifications, ensure current lighting requirements are obtained from NAWCAD 4.8.2.3. Shipboard lighting equipment will be certified annually by NAWCAD 4.8.7.5.

Special features of the lighting system include:

- Crows foot lighting for each landing spot should be on its own circuit so that the landing spot lights can be controlled individually.
- Airfield Lighting Power Supply may be from an airfield lighting vault adjacent to the LSO Tower within the island outline, or lighting systems may be powered from a nearby airfield lighting vault.
- LHD airfield lighting circuits do not require backup power.
- The following airfield lighting components should be placed on separate circuits:

  Tramline Lights
  STO Rotation Light (Pencil Line Light)
  Landing Spot Lights
  Landing Area Edge Light
  Athwartship Lights
  Nozzle Rotation Light

- Lighting systems and controls must be compatible with Night Vision Devices/Systems by stepped regulators or dimming.
- Taxiways and aprons connected to the LHD will be lit according to UFC 3-535-01.

8-4.8.1 LSO Tower on LHD STOVL Facility.

An LSO Tower will be included in all LHD STOVL facilities to provide lighting and control capabilities. Figure 8-20 shows key components and dimensions for the LSO Tower.

See NAVFAC Simulated LHD Shipdeck Standard Drawings for specific layout and detailed dimensions. Other design considerations are listed in the following paragraphs.

8-4.8.1.1 LSO Tower Structural Features.

The tower structure will be designed to support all components (tower cab, lighting systems, stairs, catwalk, etc.) and withstand live loads (wind, seismic, etc.) per local design requirements. Jet exhaust and/or propeller wash from using aircraft will also be considered. Tower structure may be open metal framework or solid wall concrete or masonry, depending on local design requirements or preferences. Tower shall be designed to minimize movement (vibration) of OLS and HPI systems due to wind, jet blast or propeller wash.

8-4.8.1.2 LSO Tower Cab Features.

The LSO Tower Cab is designed to match the dimensions and layout of a LHD 5 cab, with the same controls and components found on a ship. The cab will include windows providing a clear view in all directions and angled out to allow observation directly down to the deck. Windows will include tinted screens to reduce sun glare within the cab. A backlit deck lighting control panel will be installed, with control systems to match the same shipboard components. Inside lighting shall be compatible with Night Vision devices/systems. See UFGS 08 88 58, *Air Traffic Control Tower Glass*, for additional guidance on tower cab windows.

8-4.8.1.3 LSO Tower Lighting Features.

Several lighting systems are mounted directly on the LSO Tower Cab. The navigational lighting systems must match the shipboard systems type and location and must be mounted in the same locations relative to the landing spots as found on an LHD 5 ship. Non-navigational lighting systems (floodlights, obstruction lights) shall be placed as needed for function. Lighting systems on the LSO Tower include:

Visual Landing Aid (VLA) Systems
Optical Landing System (OLS)
Hover Point Indicator (HPI)
Wave-off and Cut Lights
Obstruction Lights
Overhead Floodlights (Forward, Amidships, Aft)

8-4.8.1.4 LSO Tower Communications Systems.

The LSO Tower will include the following systems for communications with the base:

Network data cable (for computer connection)
Airfield Radio (minimum two frequencies) for communications with Air Traffic Control Tower, aircraft, and ground support.
Telephone

8-4.8.1.5 LSO Tower HVAC Systems.

The LSO Tower Cab will be an air-conditioned space, designed to provide a comfortable temperature and humidity for occupants according to local design requirements, and considering heat loads from electronic components within the cab. Design indoor space to the same conditions as described in UFC 4-133-01, Para 3-4.1. The airfield lighting vault building associated with the LHD facility shall be designed to keep the vault interior within the acceptable operating conditions for the contained power and control equipment.

8-4.8.1.6 LSO Tower Weather Systems.

Basic weather measurement systems (at a minimum, temperature, wind speed and direction) will be installed on or near the LSO Tower with data displayed inside the LSO Tower Cab.

8-4.9 LHD Pavement Surface Types.

Figures 8-21 and 8-22 show the pavement types needed for LHD Facilities. Pavements in Landing Spots 7 and 9 as well as the short takeoff lane must be constructed with CRHTC. PJHTC must be used in the areas indicated to support landings and/or hover operations where pavements will be exposed to high exhaust temperatures and high pressures. Shoulder and Safety Zone pavements may be constructed with PJPCC or HMA, but life cycle cost analysis should be used to evaluate the best choice. The paved safety zone pavement thickness will be designed in accordance with UFC 3-260-02, as Traffic Area B, for 2,500 passes of an F-35B aircraft loaded at 61,500 pounds. Paved surfaces under and surrounding Landing Spots have been expanded beyond the deck edge to support landing, hover, and takeoff operations by MV-22 and rotary-wing aircraft. Paved shoulders surrounding these landing spots must also be provided, as indicated. Adjust pavement type dimensions as needed to provide minimum 0.75 m (2.5 ft) between center of in-pavement lights and nearest rigid pavement joint. Use neoprene joint sealant for jointed PJHTC pavements within parking positions. Use silicone sealant for PJHTC pavements outside the LHD deck surface.

Table 8-1. LHD STOVL Facility Deck Criteria

Item		Requirement	Remarks
No.	**Description**		
1	Simulated Deck Length	257.3 m (844 ft)	Simulated LHD Deck
2	Simulated Deck Width	36.6 m (120 ft)	Simulated LHD Deck
3	Left Paved Shoulder	Length: 257.3 m (844 ft) Width: 45.7 m (150 ft)	Left shoulder serves as a safety zone abeam the simulated L-class deck for approach and wave-off to prevent erosion of graded surfaces by jet blast from aircraft transition to and from the STOVL facility. See Paragraph 8-4.9 for pavement type in shoulder areas. Exceeds Air Force, Navy and Marine Corps airfields criteria.
4	Right Paved Shoulder	Length: 257.3 m (844 ft) Width: 7.6 m (25 ft)	Right shoulder serves as a safety zone abeam the simulated L-class deck to prevent erosion of graded surfaces by jet blast from aircraft transition to and from the STOVL facility. Consideration should be given to expanding the shoulder width directly abeam the primary landing spots to provide added protection against erosion. See Note 1. Meets Air Force criteria and exceeds Navy and Marine Corps airfields criteria.
5	Forward Safety Zone	Length: 152.4 m (500 ft) Width: 51.8 m (170 ft)	Forward safety zone serves as an overrun off the bow of the simulated L-class deck. Safety zones are provided to prevent erosion of graded surfaces by jet blast from aircraft departing from the STOVL facility. See Note 1.
6	Approach Safety Zone	Length: Min 457.2 m (1,500 ft) Width: Min 82.3 m (270 ft)	Approach safety zone is provided to prevent erosion of graded surfaces by jet blast from aircraft landing at the STOVL facility. See Note 1. The length of the approach safety zone will be dependent on the length of the STOVL facility plus any approach path length where the aircraft will be below 150 ft AGL. (For example: 1500 ft approach @ 3 deg. = 80 ft, plus 70 ft hover abeam spot = 150 ft AGL).
7	Longitudinal grades of runway and shoulders	0% min 0.87% max	Grades may be both positive and negative but must not exceed the limit specified. Maximum composite grade is 1.5%. Grade restrictions are exclusive of other pavements and shoulders. Where other pavements tie into runways, comply with grading requirements for towways, taxiways, or aprons as applicable, but hold grade changes to the minimum practicable to facilitate drainage.

Table 8-1. LHD STOVL Facility Deck Criteria			
Item		Requirement	Remarks
No.	Description		
8	Longitudinal runway grade change	No grade change is to occur	Where economically feasible, the runway will have a constant centerline gradient from end to end. Exception: Where HTC is built 2” higher than the surrounding pavement, transition down to the surrounding pavement elevation over a 15-ft length. As future HTC surface grinding occurs, the slope of the transition pavement will decrease.
9	Longitudinal safety zone grade	0% min 3% max	Grades may be both positive and negative but must not exceed the limit specified. Grade restrictions are exclusive of other pavements and shoulders. Where other pavements tie into runways, comply with grading requirements for towways, taxiways, or aprons as applicable, but hold grade changes to the minimum practicable to facilitate drainage. Slope pavement downwards from the foul line for simulated ship decks, which runs roughly down the center of the deck, or centerline for runways. The selected transverse grade is to remain constant for the length and width of the simulated L-class ship deck, except at or adjacent to intersections where the pavement surfaces must be warped to match abutting pavements.
10	Transverse grade of runway	Min 0.5% Max 0.87%	New STOVL training facility pavements will be foul line crowned or sloped decks. Maximum composite grade is 1.5%. A uniform slope is preferable to eliminate irregularities between landing gear during touchdown. The simulated deck surface will be foul line crowned with uniform slope in opposing directions to the edges of the simulated deck, or the entire deck slope to insure surface water drainage and runoff. Existing STOVL facility and runway pavements with insufficient transverse gradients for rapid drainage should provide increasing gradients when overlaid or reconstructed. Exception: Where HTC is built 2” higher than the surrounding pavement, transition down to the surrounding pavement elevation over a 15-ft length. As future HTC surface grinding occurs, the slope of the transition pavement will decrease.

Table 8-1. LHD STOVL Facility Deck Criteria

Item No.	Item Description	Requirement	Remarks
11	Transverse grade of paved shoulder	0.5% min 3% max	Paved portion of shoulder should slope downward from deck pavement. Reversals are not allowed. Ideally, 2% Min. for first 25 ft, then 0.5% Min. farther away from runway.
12	Transverse grade of safety zone	0.5% min 3% max	Slope pavement downwards from the simulated ship deck with no reversals to insure adequate drainage and surface water runoff. Exception is at or adjacent to intersections where the pavement surfaces must be warped to match abutting pavements.
13	Runway Lateral Clearance Zone (corresponds to half the width of primary surface)	Width: 45.72 m (150 ft)	Supports VFR operations. Width measured perpendicularly from the port deck edge of the simulated LHD surface. This area is to be clear of fixed and mobile obstacles. In addition to the lateral clearance criterion, the vertical height restriction on structures and parked aircraft as a result of the transitional slope must be taken into account. Fixed obstacles include man-made or natural features constituting possible hazards to moving aircraft. <u>Exception or Permissible Deviation (Air Force)</u>: LSO tower.
14	Longitudinal grades within Runway Lateral Clearance Zone	Max 10.0%	Does not apply to paved shoulders, safety zones, and cover over drainage structures. Slopes are to be as gradual as practicable. Avoid abrupt changes or sudden reversals. Rough grade to the extent necessary to minimize damage to aircraft.
15	Distance from Centerline of Fixed-Wing Runway to the Centerline of a parallel STOVL runway	Min 304.80 m (1,000 ft)	Simultaneous VFR operations for Class B runway for Air Force, Navy and Marine Corps.
		Min 213.36m (700 ft)	Non-simultaneous VFR and IFR operations. Distance may be reduced to 60.96m (200ft); however, waiver must be based on wake-turbulence and jet blast.
			NOTE: LSO Tower and other aboveground structure siting must be based on runway obstacle evaluation and must not be an obstruction to the adjacent runway(s) imaginary surfaces.
16	Width of Graded Area Each Side of LHD	45.72 m (150 ft)	Extends outward each side of Left and Right Paved Shoulders.
17	Length of Graded Area Each End of LHD	304.80 m (1,000 ft)	Extends outward from the Forward and Approach Safety Zones.

Table 8-1. LHD STOVL Facility Deck Criteria			
Item		Requirement	Remarks
No.	Description		
18	Longitudinal or Transverse Grade in Graded Area	Max. 10.0%	Preferred slope downward, but may include upward slopes provided graded elevation does not exceed Primary Surface elevation.

Table 8-2. LHD STOVL Facility Airspace Imaginary Surfaces

Table 8-2. LHD STOVL Facility Airspace Imaginary Surface				
Item		Legend	Requirement	Remarks
No.	Description			
1	Primary surface width	A	91.44 m (300 ft)	Centered on port deck edge of the Simulated LHD Deck. At US Navy and Marine Corps VTSOL facilities where the lateral clearance was established according to previous criterion, that distance may remain.
2	Primary surface length	A	Deck length + 60.96 m (200 ft) at departure end	Primary surface extends 60.96 m (200 ft) beyond the departure end of the simulated LHD Deck. The primary surface ends at the approach end or fantail of the simulated deck.
3	Primary surface elevation	A		The elevation of any point on the primary surface is the same as the elevation of the nearest point on the deck centerline
4	Clear zone surface (graded area)	B	Length: 304.8 m (1,000 ft) Width: 91.44 m (300 ft)	See LHD STOVL Deck Facility Criteria, Table 8-1, Item 14
5	Start of approach-departure surface	C	Approach: 0 m (0 ft) Departure: 60.96 m (200 ft)	Measured from the corresponding deck edge of the simulated LHD deck. The facility is not bi-directional so the requirements for the approach and departure surfaces reflect planned aircraft profile.
6	Length of sloped portion of approach-departure surface	C	5,334.0 m (17,500 ft)	Measured horizontally. This distance reflects the horizontal distance that corresponds with an increase in elevation to meet the outer surface elevation.
7	Slope of approach-departure surface	C	35:1	Slope ratio is horizontal: vertical. Example: 35:1 is 35 m (ft) horizontal to 1 m (ft) vertical.

Table 8-2. LHD STOVL Facility Airspace Imaginary Surface				
Item		**Legend**	**Requirement**	**Remarks**
No.	**Description**			
8	Width of approach-departure surface at start of sloped portion	C	91.44 m (300 ft)	Centered on the port deck edge of the simulated LHD surface and this width represent the same rate of change in width as a Class-A VFR runway. - At US Navy and Marine Corps STOVL facilities where the lateral clearance was established according to previous criterion, that distance may remain.
9	Width of approach-departure surface at end of sloped portion	C	891.50 m (2,925 ft)	Centered on the port deck edge of the simulated LHD surface and this width represent the same rate of change in width as a Class-A VFR runway. - The 1000:75 width ratio is horizontal length: horizontal width. This ratio is consistent with Class-A VFR runway requirements. - At US Navy and Marine Corps STOVL facilities where the lateral clearance was established according to previous criterion, that distance may remain.
10	Elevation of approach-departure surface at start of sloped portion	C	0 m (0 ft)	Same as the simulated ship deck centerline at the threshold
11	Elevation of approach-departure surface at end of sloped portion	C	152.4 m (500 ft)	Above the established simulated ship deck elevation
12	Start of horizontal portion of approach-departure surface	D	NA	Approach-departure horizontal surface not required
13	Length of horizontal portion of approach-departure surface	D	NA	Approach-departure horizontal surface not required

Table 8-2. LHD STOVL Facility Airspace Imaginary Surface				
Item		**Legend**	**Requirement**	**Remarks**
No.	**Description**			
14	Width of approach-departure surface at start of horizontal portion	D	NA	Approach-departure horizontal surface not required
15	Width of approach-departure surface at end of horizontal portion	D	NA	Approach-departure horizontal surface not required
16	Elevation of horizontal portion of approach-departure surface	D	NA	Approach-departure horizontal surface not required
17	Radius of inner horizontal surface	E	1,600 m (5,250 ft)	An imaginary surface constructed by scribing an arc with a radius of 1600 m (5250 ft) about the centerline at each end of the simulated ship deck and interconnecting these arcs with tangents. This radius (distance) corresponds to the increase in elevation for the sloped approach-departure surfaces.
18	Width between outer edges of inner horizontal surface	E	3,200 m (10,500 ft)	
19	Elevation of inner horizontal surface	E	45.72 m (150 ft)	Above the established simulated ship deck elevation. Exception: When the LHD is adjacent to an airfield, the inner horizontal surface is established to match the adjacent airfield's inner horizontal surface.
20	Horizontal width of conical surface	F	2,133.6 m (7,000 ft)	Extends horizontally outward from the outer boundary of the inner horizontal surface.
21	Slope of conical surface	F	20:1	Slope ratio is horizontal: vertical. Example: 20:1 is 20 m (ft) horizontal to 1 m (ft) vertical.

Table 8-2. LHD STOVL Facility Airspace Imaginary Surface				
Item		Legend	Requirement	Remarks
No.	Description			
22	Elevation of conical surface at the start of slope	F	45.72 m (150 ft)	Above the established simulated ship deck elevation.
23	Elevation of conical surface at the end of slope	F	152.4 m (500 ft)	Above the established simulated ship deck elevation.
24	Distance to outer edge of conical surface	G	3,733.6 m (12,250 ft)	
25	Width of outer horizontal surface	G	9144 m (30,000 ft)	Extending horizontally outward from the outer periphery of the conical surface.
26	Elevation of outer horizontal surface	G	152.4 m (500 ft)	Above the established simulated ship deck elevation.
27	Distance to outer edge of outer horizontal surface	G	12,877.0 m (42,250 ft)	An imaginary surface constructed by scribing an arc with a radius of 12,877.0 m (42,250 ft) about the centerline at each end of the simulated ship deck and interconnecting these arcs with tangents.
28	Start of transitional surface	H	45.72 m (150 ft)	Measured perpendicularly from the port deck edge of the simulated LHD surface.
29	End of transitional surface	H	Various	The transitional surface ends at the inner horizontal surface, conical surface, or at an elevation of 45.72 m (150 ft). See NOTE 1

Table 8-2. LHD STOVL Facility Airspace Imaginary Surface				
Item		Legend	Requirement	Remarks
No.	Description			
30	Slope of transitional surfaces	H	2:1	Slope ratio is horizontal: vertical. 2:1 is 2 m (ft) horizontal to 1 m (ft) vertical. Vertical height of vegetation and other fixed or mobile obstacles and/or structures will not penetrate the transitional surface. Taxiing aircraft are exempt from this requirement. For Navy and Marine Corps airfields, taxiway pavements are exempt from this requirement. For the USAF, the air traffic control tower is exempt from this requirement if the height will not affect TERPS criteria.

NOTES:

1. When the LHD STOVL facility is located within the boundaries of an existing DoD airfield and the imaginary surfaces of the two facilities overlap, the LHD transitional surface elevation will extend to meet the existing inner horizontal surface elevation of the DoD airfield. The LHD imaginary surface requirements may be waived provided the existing DoD airfield imaginary surfaces meet or exceed the obstacle clearance requirements defined by the imaginary surfaces in Table 8-2.
2. When the LHD STOVL facility is located parallel with an existing DoD runway use of the runway approach/departure surface may suffice for the LHD approach/departure surface provided a visual transition between the path and the LHD STOVL facility can be conducted while under VMC conditions.

Table 8-3. LHD STOVL Facility Clear Zone and APZs

Table 8-3. LHD STOVL Facility Clear Zone and Accident Potential Zone (APZ)				
Item		Legend	Requirement	Remarks
No.	Description			
1	Clear Zone	B	Departure Clear Zone Length: 304.80m (1,000 ft) Width: 91.44m (300 ft)	Length measured along the extended tram line beginning at the end of the primary surface. Width measured perpendicular to the extended tram line and is centered on the port deck edge of the simulated LHD surface.
			Approach Clear Zone Length: 914.40m (3,000 ft) Width: 91.44m (300 ft)	Length measured along the extended tram line beginning at the end of the primary surface. Width measured perpendicular to the extended tram line and is centered on the port deck edge of the simulated LHD surface.
2	APZ I	J	Departure Length: 762.00m (2,500 ft)	APZ I starts at the end of the clear zone, and is centered on the port deck edge of the simulated LHD surface.

			Width: 152.40m (500 ft)	
			Approach Length: 762.00m (2,500 ft) Width: 228.60m (750 ft)	APZ I starts at the end of the clear zone, and is centered on the port deck edge of the simulated LHD surface.
3	APZ II	J	Length: 2,133.60m (2,500 ft) Width: 304.80m (1,000 ft)	APZ II starts at the end of the APZ I and is centered on the port deck edge of the simulated LHD surface.

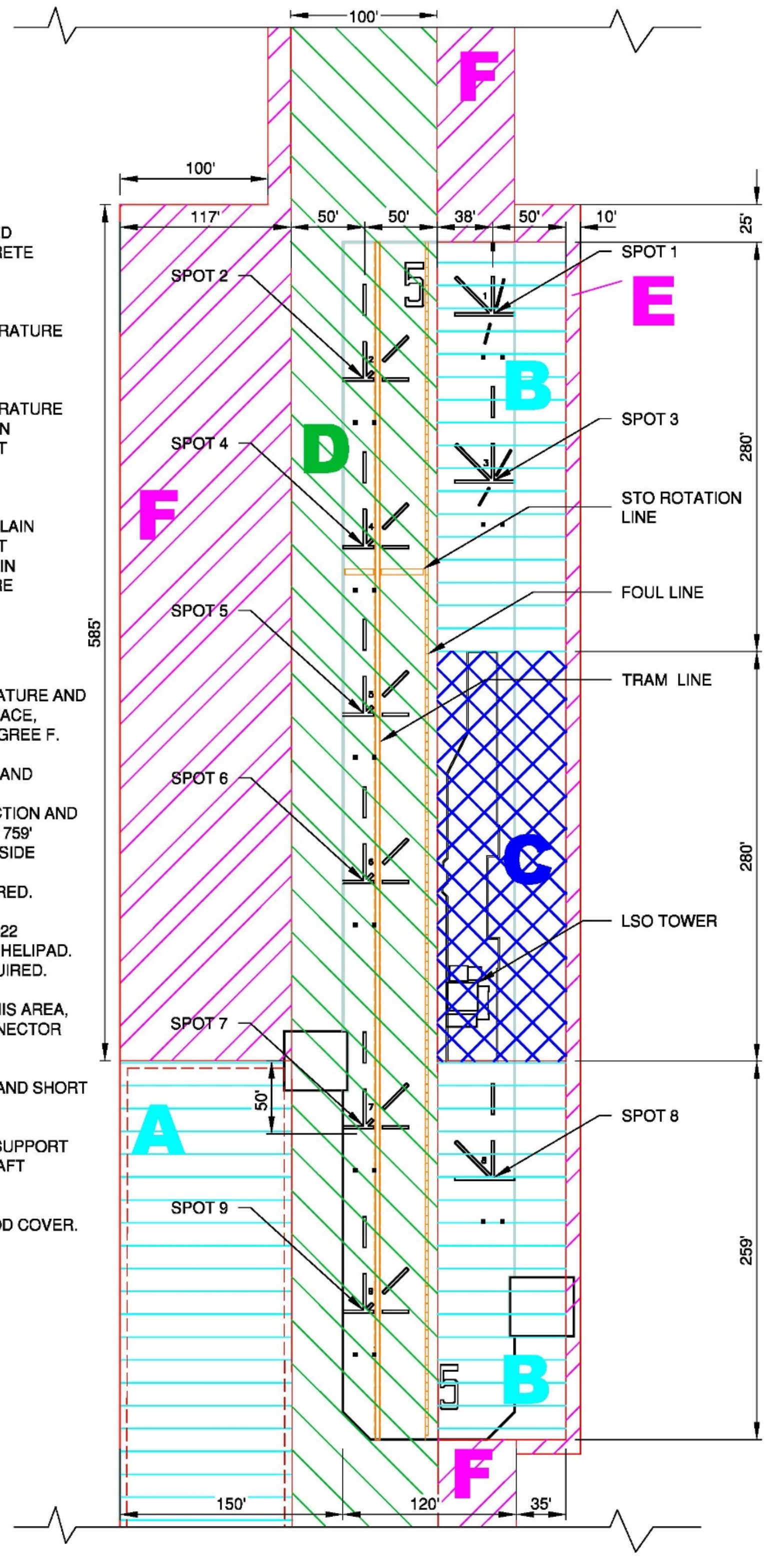
ASPHALT CONCRETE (AC), PLAIN JOINTED PORTLAND CEMENT CONCRETE (PJPCC), <u>OR</u> PLAIN JOINTED HIGH TEMPERATURE CONCRETE (PJHTC)



NOTES

AREA A: HTC REQUIRED DUE TO TEMPERATURE AND PRESSURE. AT 100' ABOVE SURFACE, HOVER TEMPERATURE IS 100 DEGREE F. AT 35' ABOVE SURFACE, HOVER TEMPERATURE IS 500 DEGREE F AND PRESSURE IS 25 PSI. ALL JOINTS DOWELED (CONTRACTION AND CONSTRUCTION) REQUIRED FOR 759' CLOSEST TO LANDING SPOTS (INSIDE DASHED RED LINE). SILICONE JOINT SEALANT REQUIRED.

AREA B: HTC REQUIRED TO SUPPORT MV-22 AIRCRAFT AND SIZED TO MATCH HELIPAD. NEOPRENE JOINT SEALANT REQUIRED.

AREA C: NO AIRCRAFT ANTICIPATED IN THIS AREA, EXCEPT WHERE USED AS A CONNECTOR TAXIWAY.

AREA D: CRHTC FOR VERTICAL LANDING AND SHORT TAKE-OFF OPERATIONS.

AREA E: PAVED SURFACE REQUIRED TO SUPPORT MV-22 AND ROTARY WING AIRCRAFT (HELIPAD SHOULDER).

AREA F: PAVED SURFACE TO PROVIDE FOD COVER.

8-5 F-35B VERTICAL LANDING (VL) PADS.

8-5.1 VL Pad Concept.

The vertical landing pads are located at main air base facilities or forward operating bases. They are positioned at these facilities to provide proficiency training and flexibility for degraded aircraft system recovery. Though not prohibited, the STOVL design of the F-35B aircraft was not intended for routine vertical takeoffs from VL pads. Instead the follow-on takeoff from an airfield with a VL pad will be a conventional or short takeoff based on the facilities available. For this reason, the approach surfaces will be the focus of obstacle clearance considerations for the VL pad. Departure surfaces are not considered because vertical takeoffs are not performed. When the VL pad is collocated with an existing DoD airfield or FOB STOVL training facility and their respective imaginary surfaces overlap, the most restrictive or lower surface will be utilized to ensure obstacle clearance.

8-5.2 VL Pad Standard Drawings.

NAVFAC Vertical Landing Pad (VLP) Standard Drawings have been developed for this facility type. These include NAVFAC Drawing Numbers 14064454 through 14064465 and are available from (http://www.wbdg.org/ffc/dod/unified-facilities-criteria-ufc/ufc-3-260-01), where this UFC is posted. Designer of Record must site-adapt, complete, and validate final design for construction. The original concept was developed for F-35B training; however, the design has been adapted to be compatible with rotary-wing aircraft operations also. These modifications include adjusting the approach surface to match the helipad criteria. Existing facilities constructed prior to these modifications may need to be evaluated if such operational upgrades are desired.

8-5.3 VL Pad Background.

Vertical landing pads are located at main air base facilities or forward operating bases. They are positioned at these facilities to provide proficiency training and flexibility for degraded aircraft system recovery. Though not prohibited, the STOVL design of the F-35B aircraft was not intended for routine vertical takeoffs from VL pads. Instead the follow-on takeoff from a VL pad equipped facility will be a conventional or short takeoff based on the facilities available. For this reason, the approach surfaces will be the focus of obstacle clearance considerations for the VL pad. When the VL pad is collocated with an existing DoD airfield or FOB STOVL training facility and their respective imaginary surfaces overlap, the most restrictive or lower surface will be utilized to ensure obstacle clearance.

8-5.3.1 Assumptions.

- Airspace imaginary surfaces are defined for a standalone facility. When the VL pad is collocated with an existing DoD airfield or FOB STOVL facility and their respective imaginary surfaces overlap, the most restrictive or lower surface will be utilized to ensure obstacle clearance.

- The imaginary surfaces for the VL pad provide obstacle clearance for the F-35B to approach the VL pad for a day or night landing under VMC. The supporting landing pattern altitude defines the inner horizontal surface and transitional area elevations. An overhead entry or straight-in visual approach will be the entry maneuver for the VL pad visual pattern, and the obstacle clearance needed for these maneuvers define the approach surface requirements.
- The VL pad is considered a directional facility with a fixed approach direction. When departures are planned from the VL pad the vertical takeoff altitude will exceed the inner horizontal surface elevation before the start of the departure transition ensuring obstacle clearance requirements are met.
- VFR operations under visual meteorological conditions will be assumed at the vertical landing pad for training and simulated mission profiles.
- A 300-foot primary surface width is used for the VL pad because all recoveries (landings) will be conducted under VMC, with slow approach speeds, and the terminal phase resulting in a hover. This primary surface width is consistent with rotary-wing criteria conducting similar approach profiles.

8-5.4 VL Pad Geometry.

8-5.4.1 Pad and Safety Zone Descriptions.

Figures 8-23 through 8-27 and Table 8-4 provide dimensional criteria for layout and design of the VL pad and safety zones. The VL pad and safety zones are provided to prevent erosion of graded surfaces by jet blast from aircraft transition to/from the pad and surface water runoff. Each zone or surface contains a brief description of their use and reference to where their specific dimension or graphic is located within the document.

8-5.4.2 Size.

Table 8-4 provides the overall size of the vertical landing pad. In general terms and dimension the vertical landing pad will be constructed as a single square surface to the dimensions presented here.

8-5.4.3 Shoulder Width.

Table 8-4 provides the width of the paved shoulder that surrounds the vertical landing pad. This dimension reflects the width required to maintain a visual transition from approach to stabilized hover over the pad. The shoulder width provides safety buffer against approach altitude deviations creating FOD debris on the intended point of landing, and protection against erosion of the graded unpaved surface surrounding the VL pad.

8-5.4.4 Grading.

Table 8-4 provides the grade constraints to insure surface water runoff. A uniform surface is required to eliminate irregularities between landing gear at touchdown. For this reason, the vertical landing pad will be sloped in one direction. **1**\ During the construction phase and prior to contract completion, each VL Pad must be constructed to tolerances and surveyed by an independent surveyor for smoothness and flatness. Construction tolerances and survey requirements are noted on the VL Pad Standard Drawings to facilitate the F-35 JPO survey process, which is separate. The F-35 JPO will conduct its own survey and certify the VL pad as "Authorized Level" prior to aircraft operations. /**1**/ If the pad does not meet the "Authorized Level" requirements, surface diamond grinding will be used to create a smooth surface with a consistent slope. **1**\ The F-35 JPO retains requirements for conducting its own pad levelness survey in DM#315235, "Vertical Landing Pad Certification Requirements and Analysis." /**1**/ The purpose of the survey is to obtain measurements for analysis to verify that pad levelness and flatness complies with F-35B Flight Series Data (FSD). Post construction VL pad survey data should be sent to Lightning.Support.Team@jsf.mil for analysis. Analysis results will be provided to the requestor. Additionally, data, analysis, and results for all pads analyzed by the Lightning Support Team (LST) will be retained and archived for future reference; they may be found at DM#315485. Contact the F-35 JPO and Naval Air Surface Warfare Center Aircraft Division (NAWCAD) AR-6.7.8.2 NAVAIR Aviation Shore Facility Integration Branch for additional information on this subject.

- **Raised Elevation.** To ensure an elevation that will allow future grinding of the HTC surface, the VL pad and safety zone must be constructed together such that up to 51 millimeters (2 inches) of material may be diamond-ground from the landing pad surface and still maintain the maximum and minimum grades to eliminate ponding. This higher elevation of the VL pad must be transitioned to the safety zone on all sides, using slopes as indicated in Table 8-4.
- **Primary Surface Elevation.** The primary surface elevation is the highest point on a VL pad. The designer will verify that the primary surface of a VL pad does not interfere with the primary surface and other clearances of adjacent runways, aprons, or taxiways.
- **Grades Within Primary Surface.** Exclusive of pavement and shoulders, grades within the primary surface must be at least two percent to a maximum of five percent, prior to drainage channelization; however, the channel bottom may be flat. The balance of the area is to be clear of obstructions and rough-graded to the extent necessary to minimize damage to aircraft in the event of an emergency landing. For VLZs, the grade requirements apply to the entire primary surface.

8-5.5 VL Pad Separation Distances.

VL pads may be constructed as stand-alone facilities. If co-located at a Class A or Class B airfield, plan for taxiways that provide VL pad access. Table 8-4 provides the minimum separation distances between permanent fixed-wing runways and vertical landing pads for simultaneous VFR operations. Table 8-4 provides the minimum separation distances between permanent fixed-wing runways and vertical landing pads for non-simultaneous VFR operations. Vertical landing pads, paved safety zones, paved shoulders, and unpaved shoulders will be located outside all taxiway clearance distances.

8-5.6 VL Pad Clear Zones, Imaginary Surfaces, and APZs.

Figures 8-25 and 8-26, and Tables 8-5 and 8-6 provide applicable clearances and grade controls for a reasonable level of safety. Their description and layout are similar to other STOVL facility and airfield types and are not unique to the vertical landing pad. Each zone or surface contains a brief description of their use and reference to where their specific dimension or graphic is located within the document. VL Pad Clear Zones and Imaginary Surfaces on the approach-departure path are compatible with rotary-wing (helipad) surfaces defined in Chapter 4. For only F-35B operations, the 2:1 Transitional Surface may be applied on all sides of the VL Pad and the ADCS will start at the edge of the Transitional Surface. See Figure 8-27 for an illustration of this configuration.

8-5.6.1 Clear Zones.

Clear zones are areas on the ground, located at the ends of the primary surface, along the approach-departure path of the VL pad. They possess a high potential for accidents and their use is restricted to be compatible with aircraft operations. VL pad clear zones are required and should be government owned or protected under long term lease. The clear zone will be cleared, graded and free of aboveground objects. See Table 8-9.

8-5.6.2 Imaginary Surfaces.

Surfaces in space established around a vertical landing pad that are designed to protect the airspace around the pad from encroachment and insure obstacle clearance. The imaginary surfaces for the vertical landing pad are the primary surface, transitional surface, inner horizontal surface, and approach-departure path surfaces. The lower approach-departure clearance surface (ADCS) will begin at edge of the primary surface. The upper ADCS will begin at the top of the lower ADCS. Both ADCS surfaces extend outward along the centerline of the approach or departure path. See Table 8-8.

8-5.6.3 Accident Potential Zones.

A land use control area beyond the clear zone of a vertical landing pad that possesses a significant potential for accidents, and their use is restricted in accordance with DoDI 4165.57. Their dimensions and layout are listed in Table 8-9. Navy planners will use OPNAVINST 11010.36C/MCO 11010.16 (or latest version) to determine specific AICUZ requirements. For the Air Force, land use guidelines within the clear zone (beyond the graded area) and APZ I and APZ II are provided in AFI 32-7063 and AFH 32-7084.

8-5.7 VL Pad Pavement Marking.

Apply markings to VL Pads using reflective airfield marking paint, following the general scheme shown in Figure 8-28. See NAVFAC Vertical Landing Pad (VLP) Standard Drawings for specific layout and detailed dimensions.

8-5.7.1 Diagonal Line-up Cue Markings.

Paved pads 1.5m x 1.5m (5 ft x 5 ft) will be constructed on the diagonals at 30m (100 ft) from the corners of the VL Pad Safety Zone to provide additional visual cues for pilots to line up over the VL Pads prior to descending. Pads will be at the same elevation as the surrounding turf and painted orange, as shown in Figure 8-28.

8-5.8 VL Pad Lighting.

Install edge lights on the VL Pad and the connector taxiway, following the general scheme shown in Figure 8-29. See NAVFAC Vertical Landing Pad (VLP) Standard Drawings for detailed light layout and installation details.

8-5.9 VL Pad Pavement Surface Types.

Figure 8-30 shows the pavement types needed for VL Pads. The vertical landing pad will be constructed using CRHTC. The surrounding Paved Safety Zone will be constructed with PJHTC. The taxiway within 50-ft adjacent to the VL Pad will be constructed with PJHTC. The taxiway connecting to adjacent runway or taxiway may be constructed with PJPCC or Hot Mix Asphalt. The paved shoulders will be constructed with PJPCC or HMA. Regardless of construction material or method, the vertical landing surface will have a smooth transition to surrounding safety zones, shoulders, and taxiways. The paved safety zone pavement thickness will be designed in accordance with UFC 3-260-02, as Traffic Area B, for 2,500 passes of an F-35B aircraft loaded at 61,500 pounds. **\1** Seal joints in PJHTC with silicone sealant. **/1/**

Table 8-4. Vertical Landing (VL) Pad Criteria

Table 8-4. Vertical Landing (VL) Pad Criteria			
Item		**Requirement**	**Remarks**
No.	**Description**		
1	Size	**\1** 30.48 m x 30.48 m **/1/** (100 ft x 100 ft)	Same as a Standard VFR and IFR Helipad
2	Paved Safety Zone	\1\ 15.24 m /1/ (50 ft)	- Safety zones are provided to prevent erosion of graded surfaces by jet blast from aircraft transitioning to and from the VL facility. - The VL pad will be centered on the safety zone making the outside dimensions of the safety zone 61m x 61m (200 ft x 200 ft).
3	Paved Shoulder	**\1** 3.05 m **/1/** (10 ft)	
4	VL Pad Grade	Min. 0.5% Max. 0.87%	A uniform slope is required to eliminate irregularities between landing gear during touchdown. -Uniformly sloped in one direction in both the longitudinal and transverse directions. - The resultant effective grade will not exceed 1.5%. - Crowning or peaking of these paved areas will not be allowed. - The pavement design engineer will verify that all areas of vertical landing pads, paved safety zones, connecting taxiways, and paved and unpaved shoulders, effectively drain surface water.
5	Safety Zone Grade	Min 0.5% Max 1.0%	Uniformly slope in one direction in both the longitudinal and transverse direction.
6	Shoulder Grade	Min 2.0% Max 4.0%	Uniformly slope in one direction in both the longitudinal and transverse direction.
7	Vertical landing pad lateral clearance zone (corresponds to half the width of primary surface)	46.7 m (150 ft)	Supports VFR operations - Measured perpendicularly from centerline of vertical landing pad. This area is to be clear of fixed and mobile obstacles. In addition to the lateral clearance criterion, the vertical height restriction on structures and parked aircraft as a result of the transitional slope must be taken into account. - Fixed obstacles include man-made or natural features constituting possible hazards to moving aircraft.
8	Grades within runway lateral clearance zone (Primary Surface)	Min 2.0% Max 5.0%	Does not apply to paved VL Pad, Safety Zone or Shoulder. - Grades within the primary surface must be at least two percent to a maximum of five percent, prior to drainage channelization; however, the channel bottom may be flat. Avoid abrupt changes or sudden reversals. - The balance of the area is to be clear of obstructions and rough-graded to the extent necessary to minimize damage to aircraft in the event of an emergency landing. Grade requirements apply to the entire primary surface.
9	Distance from centerline of	Min 213.36 m (700 ft)	Simultaneous VFR operations for Class A runway for Air Force, Navy and Marine Corps.

Table 8-4. Vertical Landing (VL) Pad Criteria

Item		Requirement	Remarks
No.	Description		
	fixed-wing runway to the centerline of the vertical landing pad	Min 304.8 m (1,000 ft)	Simultaneous VFR operations for Class B runway for Air Force, Navy and Marine Corps.
		Min 60.96 m (200 ft)	For non-simultaneous VFR and IFR operations. - Distance may be reduced to 60.96 m (200 ft); however, waiver must be based on wake-turbulence and jet blast. - Operations for Class B runway for Air Force, Navy and Marine Corps, vertical landing pads may be sited within the runway primary surface, but must remain a distance from the runway edge equal to the distance the runway hold position markings are located.
		Min. 762.00 m (2,500 ft)	IFR using simultaneous operations (depart-depart) (depart-approach).
		Min. 1,310.64 m (4,300 ft)	IFR using simultaneous approaches.
10	Connecting Taxiway Width	**\1** 22.86 m **/1/** (75 ft)	The connecting taxiway must be long enough so that after an aircraft has landed and is on the VL pad, it does not interfere with aircraft operations on the runway, taxiway or apron to which the VLZ is connected.
11	Connecting Taxiway Total Width of shoulders (paved and unpaved)	15 m (50 ft)	
12	Connecting Taxiway Paved Shoulder Width	**\1** 3.05 m **/1/** (10 ft)	
13	Connecting Taxiway Grades	See Table 5-1.	

Table 8-5. Vertical Landing (VL) Pad Airspace Imaginary Surfaces

Table 8-5. Vertical Landing Pad Airspace Imaginary Surfaces				
Item		Legend	Requirement	Remarks
No.	Description			
1	Primary surface width	A	93.5 m (300 ft)	Centered on vertical landing pad. - At US Navy and Marine Corps STOVL facilities where the lateral clearance was established according to previous criterion, that distance may remain.
2	Primary surface length	A	93.5 m (300 ft)	Centered on vertical landing pad. At US Navy and Marine Corps STOVL facilities where the lateral clearance was established according to previous criterion, that distance may remain.
3	Primary surface elevation	A	Elevation of VL pad.	The primary surface elevation is the highest point on a VL pad. The VL Pad primary surface must be at the same elevation or above the primary surface of adjacent runways. The designer will verify that the primary surface of a VL pad does not interfere with the primary surface and other clearances of adjacent runways, aprons, or taxiways.
4	Grade of Clear Zone in any direction	B	5.0% Max.	The clear zone starts at the end of the primary surface and has the same width as the primary surface (93.5 m [300 ft]), with a length of 400 ft. - Clear zones are areas on the ground, located at the ends of the primary surface, centered on the primary approach path to the VL pad. - Areas to be free of obstructions. Rough grade and turf when required. Positive drainage to avoid standing water.
5	Start of Lower approach-departure Surface	C	45.72 m (150 ft)	Measured from the center of the VL Pad along the primary approach path.
6	Length of sloped Lower approach-departure surface	C	365.7 m (1,200 ft)	Measured horizontally along the extended approach path. - This approach length reflects obstacle clearance requirements for STOVL or rotary aircraft to make a straight decelerating transition to the intended point of landing.
7	Slope of Lower approach-departure surface	C	8:1	Slope ratio is horizontal: vertical. Example: 8:1 is 8 m (ft) horizontal to 1 m (ft) vertical.

Table 8-5. Vertical Landing Pad Airspace Imaginary Surfaces

Item No.	Item Description	Legend	Requirement	Remarks
8	Width of Lower approach-departure surface at start of sloped portion	C	91.44 m (300 ft)	- Centered on the extended centerline of the approach path and at the primary surface. - At US Navy and Marine Corps VTSOL facilities where the lateral clearance was established according to previous criterion, that distance may remain.
9	Width of Lower approach-departure surface at end of sloped portion	C	274.3 m (900 ft)	- Perpendicular to the extended centerline of the approach path. - At US Navy and Marine Corps VTSOL facilities where the lateral clearance was established according to previous criterion, that distance may remain.
10	Elevation of Lower approach-departure surface at start of sloped portion	C	Elevation of VL Pad	
11	Elevation of Lower approach-departure surface at end of sloped portion	C	45.7 m (150 ft)	Measured up from the primary surface.
12	Start of Upper approach-departure Surface	D	365.7 m (1,200 ft)	Measured from the center of the VL Pad along the primary approach path. It starts at the top of the Lower Approach Surface.
13	Length of sloped Upper approach-departure surface	D	4,267 m (14,000 ft)	Measured horizontally along the extended approach path. - This approach length reflects obstacle clearance requirements for the STOVL aircraft to make a straight decelerating transition to the intended point of landing. - This is the horizontal distance required to extend from the top of the Lower Approach Surface to 500 ft AGL.

Table 8-5. Vertical Landing Pad Airspace Imaginary Surfaces				
Item		**Legend**	**Requirement**	**Remarks**
No.	**Description**			
14	Slope of Upper approach-departure surface	D	40:1	Slope ratio is horizontal: vertical. Example: 40:1 is 40 m (ft) horizontal to 1 m (ft) vertical.
15	Width of Upper approach-departure surface at start of sloped portion	D	274.3 m (900 ft)	- Centered on the extended centerline of the approach path and starts at the top of the 2:1 transitional slope. This distance spans the full width along the top of the transition surface. - At US Navy and Marine Corps VTSOL facilities where the lateral clearance was established according to previous criterion, that distance may remain.
16	Width of Upper approach-departure surface at end of sloped portion	D	914.4 m (3,000 ft)	- Perpendicular to the extended centerline of the approach path. - The 1000:75 width ratio is horizontal length: horizontal width. This ratio is consistent with class-A VFR runway requirements. - At US Navy and Marine Corps VTSOL facilities where the lateral clearance was established according to previous criterion, that distance may remain.
17	Elevation of Upper approach-departure surface at start of sloped portion	D	45.7 m (150 ft)	- Measured up from the primary surface elevation to the top of the 8:1 approach surface. - This start elevation reflects the requirement for the STOVL aircraft to remain above 150 ft AGL until over the intended point of landing.
18	Elevation of Upper approach-departure surface at end of sloped portion	D	152.4 m (500 ft)	Measured from the edge of VL pad on approach centerline.
19	Radius of inner horizontal surface	E	1,869 m (6,000 ft)	An imaginary surface constructed by scribing a 180-degree (or more for multiple approaches) arc with a radius of 1,869 m (6,000 ft) from the center of the VL pad. -This imaginary surface covers the VFR landing pattern obstacle clearance requirements.

Table 8-5. Vertical Landing Pad Airspace Imaginary Surfaces				
Item		Legend	Requirement	Remarks
No.	Description			
20	Width between outer edges of inner horizontal surface	E	3,738 m (12,000 ft)	
21	Elevation of inner horizontal surface	E	45.72 m (150 ft)	Measured up from the elevation of the VL Pad Primary Surface. Exception: When the VL Pad is adjacent to an airfield, the inner horizontal surface is established to match the adjacent airfield's inner horizontal surface.
22	Start of transitional surface	H	45.72 m (150 ft)	Measured perpendicularly from centerline of the approach path and extended centerline of Vertical Landing pad (coincident with edge of Primary Surface).
23	End of transitional surface	H	Various	The transitional surface ends at the inner horizontal surface, at an elevation of 45.72 m (150 ft). See NOTE 1.
24	Slope of transitional surfaces	H	2:1	Slope ratio is horizontal: vertical. 2:1 is 2 m (ft) horizontal to 1 m (ft) vertical. Vertical height of vegetation and other fixed or mobile obstacles and/or structures will not penetrate the transitional surface. - For Navy and Marine Corps airfields, taxiway pavements are exempt from this requirement. - For the USAF, the air traffic control tower is exempt from this requirement if the height will not affect TERPS criteria.

NOTES:

1. When the vertical landing pad is located within the boundaries of an existing DoD airfield and the imaginary surfaces of the two facilities overlap, the vertical landing pad transitional surface elevation will extend to meet the existing inner horizontal surface elevation of the DoD airfield. The vertical landing pad imaginary surface requirements may be waived provided the existing DoD airfield imaginary surfaces meet or exceed the obstacle clearance requirements defined by the imaginary surfaces in Table 8-8.
2. When the vertical landing pad is located within the primary surface of the existing DoD runway, use of the runway approach/departure surface may suffice for the vertical landing pad approach surface provided a visual transition between the path and the vertical landing pad can be conducted while under VMC conditions.

Table 8-6. Vertical Landing (VL) Pad Clear Zone and APZs

Item No.	Item Description	Legend	Requirement	Remarks
1	Clear Zone	B	Length: 121.90m (400 ft) Width: 91.44m (300 ft)	Length measured along the extended primary approach path. Width measured perpendicular to the primary approach path.
2	APZ I	J	Length: 243.83m (800 ft) Width: 91.44m (300 ft)	APZ I starts at the end of the clear zone, and is centered on the primary approach path. Width measured perpendicular to the primary approach path.

8-6 FORWARD OPERATING BASE (FOB) STOVL FACILITY.

8-6.1 FOB Concept.

At some locations, STOVL Forward Operating Base training has incorporated the use of secondary roads or taxiways to support FOB mission Training and Readiness qualification requirements. The size and structure of these facilities varies slightly from location to location; however, in general terms the facility would be narrower and shorter than a standard Class A or B runway. The primary focus of these training evolutions is the training objectives for the pilots and Landing Site Supervisors (LSSs). The primary landing at a FOB in support of those objectives is a precision Rolling Vertical Landing (RVL) with a typical approach speed of 60 knots. The acceptable tolerances for a precision RVL are significantly tighter than the typical RVL flown to a Class B runway. To afford the proper visual cuing and reinforcement of the established tolerances for the FOB training facility the criteria for the C-130 landing zone (60 ft x 3000 ft runway) and similar obstacle clearances are used. The use of these criteria is applicable because the FOB operations will be conducted under Visual Flight Rules and while under the control of a LSS. Use of these accepted criterions has real world applications were FOBs are set up as ground loiter points based on mission necessity and not the availability of host nation airfields. These mission-critical ground loiter points may or may not meet typical obstacle clearance criteria; however, they are robust enough to insure the aviation commander sufficient margin for safe and efficient aircraft operations.

8-6.2 FOB Standard Drawings.

No standard drawings have been developed for FOB facilities. The criteria provided in this chapter must be site-adapted to the proposed location.

8-6.3 FOB Background.

STOVL Forward Operating Base training varies slightly from location to location; however, in general terms the facility would be narrower and shorter than a standard Class A or B runway. The primary focus of these training evolutions is the training objectives for the pilots and Landing Site Supervisors (LSSs). The primary landing at a FOB in support of those objectives is a precision Rolling Vertical Landing (RVL) with a typical approach speed of 150 knots, landing at approximately 60 knots. The acceptable tolerances for a precision RVL are significantly tighter than the typical RVL flown to a Class B runway. To afford the proper visual cuing and reinforcement of the established tolerances for the FOB training facility the criteria for the C-130 landing zone (60 ft x 3000 ft runway) and similar obstacle clearances are used. The use of these criteria is applicable because the FOB operations will be conducted under Visual Meteorological Conditions and while under the control of a landing site supervisor. Use of these accepted criterions has real world applications were FOBs are set up as ground loiter points based on mission necessity and not the availability of host nation airfields. These mission-critical ground loiter points may or may not meet typical obstacle clearance criteria, however are robust enough to insure the aviation commander sufficient margin for safe and efficient aircraft operations.

8-6.3.1 Assumptions.

- Airspace imaginary surfaces are defined for a standalone training facility. When the FOB STOVL facility is collocated with an existing DoD airfield and their respective imaginary surfaces overlap, the most restrictive or lower surface will be utilized to ensure obstacle clearance.
- The imaginary surfaces for the FOB STOVL facility provide obstacle clearance for the F-35B day/night visual pattern. The FOB visual landing pattern altitude defines the inner horizontal surface and transitional area elevations. An overhead entry or straight-in visual approach will be the entry maneuver for the FOB visual pattern, and the obstacle clearance needed for these maneuvers define the approach and departure path requirements. These definitions are presented similar to the existing Class B runway criteria.
- A 300-foot primary surface width is used for the FOB STOVL facility because all recoveries will be conducted under VMC and the close supervision of a Landing Site Supervisor.
- Airspace imaginary surfaces extend 1.5 nm abeam and 3.3 nm approach-departure path to support obstacle clearance for aircraft within the landing pattern or maneuvering to a 3 nm initial.

8-6.4 FOB Geometry.

8-6.4.1 Runway, Overrun, and Safety Zone Descriptions.

Figures 8-31 through 8-41, and Table 8-7 provide dimensional criteria for the layout and design of the FOB runway, overruns, and safety zones. The FOB runway should be considered bi-directional unless specifically limited to a single approach and departure path. Overruns and shoulders are provided as safety zones to prevent erosion of graded surfaces by jet blast from aircraft and surface water runoff, and to provide a smooth transition from paved to unpaved surface. Runway shoulders are not required in cases where the runway width meets or exceeds the combined total widths for the runway and shoulders defined in this document. Each zone or surface contains a brief description of their use and reference to where their specific dimension or graphic is located within the document.

8-6.4.2 Runway Length.

Table 8-7 provides the minimum length for the FOB runway. Training and operational facilities will be of various lengths based on facilities available, elevation, and supported mission.

8-6.4.3 Runway Width.

Table 8-7 provides the minimum width for the FOB runway. Training and operational facilities will be of various widths based on facilities available and supported mission.

8-6.4.4 Gradients of Operational Surfaces.

Gradient constraints are based upon sufficient slope to insure surface water runoff. A uniform transverse slope is preferable to eliminate irregularities between landing gear at touchdown. For this reason, the FOB runway should be centerline crowned or the entire runway sloped in one direction. Either sloping scheme will provide the pilot with a consistent uniform surface adequate for touchdown. See Table 8-7.

8-6.4.5 Overrun Length.

Table 8-7 provides the length of the overrun for both the approach and departure ends. This length is dependent on the STO profile and the distance from the FOB runway where the profile reaches a minimum altitude of 150 ft AGL.

8-6.4.6 Overrun Width.

Table 8-7 provides the width of the overrun. This width, at a minimum, reflects the width of the FOB runway plus any shoulder width and will be centered on the extended runway centerline.

8-6.4.7 Shoulder Length.

Table 8-7 provides the length of the shoulder. This length is dependent on the length of the FOB runway and ties into the overrun on both ends of the FOB runway for one continuous surface.

8-6.4.8 Shoulder Width.

Table 8-7 provides the width of the shoulder. This width is designed to prevent soil erosion from jet blast or surface water runoff and provide a smooth transition to the graded unpaved shoulder areas.

8-6.5 FOB Separation Distances.

Table 8-7 provides the minimum separation distances between permanent runways/helipads and the FOB runway for simultaneous operations. Table 8-7 provides the minimum separation distances between permanent Class A or Class B Runways and FOB runway for non-simultaneous operations.

8-6.6 FOB Clear Zones, Imaginary Surfaces, and APZs.

Figures 8-35 through 8-39 and Tables 8-8 and 8-9 provide applicable clearances and grade controls for a reasonable level of safety. Their description and layout are similar to other airfield types and are not unique to the FOB runway or facility. Each zone or surface contains a brief description of their use and reference to where their specific dimension or graphic is located within the document.

8-6.6.1 Clear Zones.

Runway clear zones are areas on the ground, located at the ends of each runway. The FOB runway should be considered bi-directional unless specifically limited to a single approach and departure path. They possess a high potential for accidents, and their use is restricted to be compatible with aircraft operations. Runway clear zones are required for the runway and should be owned or protected under a long-term lease. See Table 8-9.

8-6.6.2 Imaginary Surfaces.

Surfaces in space established around a STOVL facility in relation to the FOB runway and designed to define the protected airspace around the STOVL facility. The imaginary surfaces for the FOB STOVL facilities are the primary surface, transitional surface, inner horizontal surface, conical surface, outer surface and approach-departure path surfaces. See Table 8-8.

8-6.7 Accident Potential Zones.

Accident Potential Zones of a STOVL facility that possesses a significant potential for accidents, and their use is restricted in accordance with DoDI 4165.57. Their dimensions and layout are listed in Table 8-9. Navy planners will use OPNAVINST 11010.36C/MCO 11010.16 (or latest version) to determine specific AICUZ requirements. For the Air Force, land use guidelines within the clear zone (beyond the graded area) and APZ I and APZ II are provided in AFI 32-7063 and AFH 32-7084.

8-6.8 FOB Pavement Markings.

No pavement markings are <u>required</u> for FOB STOVL Facilities; however, at locations where FOB STOVL facilities will be used for training or long-term operations, it is desirable to apply painted markings to the pavement surface to enhance safety. When needed, apply markings to FOB pavements using reflective airfield marking paint, following the general scheme shown in Figure 8-40.

8-6.8.1 Threshold Bar.

White threshold stripes may be marked at each end of the FOB runway to distinguish between the overrun and the FOB runway surface. The marking will be 1.2 meters (4 feet) wide and extend from edge to edge of the FOB runway surface.

8-6.8.2 Edge Stripes.

White side stripes should be painted when there is no visual distinction between the FOB runway surface and the paved shoulder (e.g. both FOB runway and shoulder are asphalt). Edge stripes will be 0.3 meter (1 foot) wide and extend along the entire length of the FOB runway.

8-6.8.3 Taxiway Centerline.

If the FOB runway has connecting taxiways, the taxiway centerline turn radius will not be extended onto the FOB runway surface.

8-6.8.4 Taxiway, Apron and Turnaround Edge Stripes.

If FOB STOVL facility taxiways, aprons or turnarounds have paved shoulders and there is no visual distinction between the edge of load-bearing pavement and the shoulder, the edge of full-strength pavement will be marked with two 152-millimeter (6-inch) wide yellow stripes separated by a 152-millimeter (6-inch) wide gap.

8-6.8.5 Holding Position Marking.

The holding position is located a minimum of 30.5 meters (100 feet) from the near edge of the FOB runway. This distance is measured perpendicular to the long axis of the runway. For holding position marking dimensions, see Service-specific airfield marking guidance.

8-6.8.6 Touchdown Box Markings (Optional).

When desired by the airfield manager, touchdown box markings may be applied. These markings consist of 0.9-meter (3-foot) -wide white stripes that extend transversely across the entire width of the runway surface. The stripes are located 30.5 meters and 152 meters (100 feet and 500 feet) from the approach end threshold.

8-6.8.7 Runway Designation Markings.

Runway designation markings will not be used on FOB runways.

8-6.8.8 Runway Centerline (Optional).

When desired by the airfield manager, runway centerline stripes may be applied. Stripes are 0.5 meter to 0.9 meter (1.5 feet to 3 feet) wide and 30.5 meters (100 feet) long, with an 18.3-meter (60-foot) gap between stripes.

8-6.9 FOB Lighting.

No airfield lighting is <u>required</u> for FOB STOVL Facilities; however, at locations where FOB STOVL facilities will be used for training or long-term operations, it is desirable to install edge light systems to enhance safety. When needed, install edge lights on the FOB STOVL Facility following the general scheme shown in Figure 8-41. See UFC 3-535-01 for lighting component details. Lighting layout generally follows the Chapter 7 AMP-1 Lighting Layout.

8-6.10 FOB Pavement Surface Types.

Figure 8-42 shows the pavement types needed for FOB Runway Facilities. Pavements on the FOB Runway must be constructed with PJPCC. Life-cycle cost considerations should be used to determine the whether CRPCC is cost effective to reduce the number of pavement joints subjected to high pressures during takeoff operations and thereby reduce future maintenance demands. Shoulder pavements may be constructed with PJPCC or HMA. Overruns will be designed to match the runway pavement. Special design consideration may be needed if the overrun is used as a taxiway or turnaround area.

Table 8-7. Forward Operating Base (FOB) STOVL Runway Criteria

Table 8-7. Forward Operating Base (FOB) STOVL Facility Runway Criteria			
Item		Requirement	Remarks
No.	Description		
1	Length	914 m (3,000 ft)	
2	Width	Min. 10m (32ft)	Typical width is 18.5m (60 ft).
3	Width of shoulders	Min. 3 m (10 ft)	Navy and Marine Corps airfields
4	Paved shoulder width	3 m (10 ft)	Navy and Marine Corps airfields
5	Paved Overrun length	Min 91.44 m (300 ft)	The length of the overrun may be dependent on the approach path length where the aircraft will be below 25 ft AGL.
6	Paved Overrun width	Min.15.85m (52 ft)	The width of the Overrun will match the total width of the runway plus shoulders. Typical width is 24.5m (80 ft).
7	Graded Clear Zone Length	Min. 60.96 m (500 ft)	Measured from the runway threshold. Corresponds to the Clear Zone Area.
8	Graded Clear Zone Width	Min. 91.44 m (300 ft)	Centered on the runway centerline. Corresponds to the Clear Zone area.
9	Longitudinal grades of runway and shoulders	Max 3.0%	Grades may be both positive and negative but must not exceed the limit specified. - Grade restrictions are exclusive of other pavements and shoulders. - Where other pavements tie into runways, comply with grading requirements for towways, taxiways, or aprons as applicable, but hold grade changes to the minimum practicable to facilitate drainage.
10	Longitudinal runway grade change	Max 1.5% per 61m (200 ft)	Where economically feasible, the runway will have a constant centerline gradient from end to end.

Table 8-7. Forward Operating Base (FOB) STOVL Facility Runway Criteria			
Item		Requirement	Remarks
No.	Description		
11	Longitudinal Overrun grade	Max 3.0%	Grades may be both positive and negative but must not exceed the limit specified. Grade restrictions are exclusive of other pavements and shoulders. - Where other pavements tie into runways, comply with grading requirements for towways, taxiways, or aprons as applicable, but hold grade changes to the minimum practicable to facilitate drainage.
12	Graded Clear Zone slope	Max. 10.0%	Does not apply to overrun paved surfaces. Grades may be both positive and negative but must not exceed the limit specified. Applies to both longitudinal and transverse directions.
13	Transverse grade of runway	Min 0.5% Max 3.0%	- New STOVL training facility pavements will be centerline crowned to insure adequate drainage of surface water. - Existing STOVL facility and runway pavements with insufficient transverse gradients for rapid drainage should provide increasing gradients when overlaid or reconstructed.
14	Transverse grade of paved shoulder	Min 1.5% Max 5.0%	Paved portion of shoulder Slope downward from runway pavement. Reversals are not allowed.
15	Transverse grade of Overrun	Min 0.5% Max 3.0%	Slope pavement downwards from the runway with no reversals to insure adequate drainage of surface water. Exception is at or adjacent to intersections where the pavement surfaces must be warped to match abutting pavements.
16	Runway Lateral Clearance Zone (corresponds to half the width of primary surface)	45.72 m (150 ft)	Supports VFR operations - Measured perpendicularly from centerline of STOVL facility. This area is to be clear of fixed and mobile obstacles. - In addition to the lateral clearance criterion, the vertical height restriction on structures and parked aircraft as a result of the transitional slope must be taken into account. - Fixed obstacles include man-made or natural features constituting possible hazards to moving aircraft.
17	Transverse grades within Runway Lateral Clearance Zone	Max 10.0%	- Exclusive of pavement, shoulders, and cover over drainage structures. - Slopes are to be as gradual as practicable. Avoid abrupt changes or sudden reversals. Rough grade to the extent necessary to minimize damage to aircraft.
18	Distance from centerline of fixed-wing runway to the centerline of a parallel	Min 213.36m (700 ft)	Simultaneous VFR operations for Class A runway
		Min 304.80 m (1,000 ft)	Simultaneous VFR operations for Class B runway.

Table 8-7. Forward Operating Base (FOB) STOVL Facility Runway Criteria			
Item		Requirement	Remarks
No.	Description		
	FOB runway	Min 213.36m (700 ft)	Non- simultaneous VFR operations. Distance may be reduced to 60.96m (200ft); however, waiver must be based on wake-turbulence and jet blast. FOB may be sited within the adjacent runway primary surface but must be positioned outside the adjacent runway hold position markings.

Table 8-8. Forward Operating Base (FOB) STOVL Airspace Imaginary Surfaces

Table 8-8. FOB STOVL Airspace Imaginary Surfaces				
Item		Legend	Requirement	Remarks
No.	Description			
1	Primary surface width	A	91.44 m (300 ft)	Centered on FOB runway.
2	Primary surface length	A	Runway length + 60.96 m (200 ft) at each end	Primary surface extends 60.96 m (200 ft) beyond each end of the FOB runway
3	Primary surface elevation	A	See Remarks	The elevation of the primary surface is the same as the elevation of the nearest point on the FOB runway centerline
4	Clear Zone longitudinal and transverse grade of surface	B	Max 10.0%	See Table 8-4, Safety Zone Grades
5	Start of approach-departure Surface	C	60.96 m (200 ft)	Measured from the end of the FOB runway.
6	Length of sloped portion of approach-departure surface	C	Min 5334 m (17,500 ft)	Measured horizontally
7	Slope of approach-departure surface	C	35:1	Slope ratio is horizontal: vertical. Example: 35:1 is 35 m (ft) horizontal to 1 m (ft) vertical.
8	Width of approach-departure surface at start of sloped portion	C	91.44 m (300 ft)	Centered on the extended FOB runway centerline and is the same width as the primary surface.

Table 8-8. FOB STOVL Airspace Imaginary Surfaces				
Item		Legend	Requirement	Remarks
No.	Description			
9	Width of approach-departure surface at end of sloped portion	C	891.5 m (2,925 ft)	- Centered on the extended FOB runway centerline. - The 1000:75 width ratio is horizontal length: horizontal width. This ratio is consistent with class-A VFR runway requirements. - At US Navy and Marine Corps VTSOL facilities where the lateral clearance was established according to previous criterion, that distance may remain.
10	Elevation of approach-departure surface at start of sloped portion	C	0 m (0 ft)	Same as the FOB runway centerline at the threshold.
11	Elevation of approach-departure surface at end of sloped portion	C	152.4 m (500 ft)	Above the established FOB runway elevation.
12	Start of horizontal portion of approach-departure surface	D	Min 5334 m (17,500 ft)	Measured from the end of the primary surface. The end of the primary surface (start of the approach-departure surface) is 60.96 m (200 ft) from the end of the FOB runway.
13	Length of horizontal portion of approach-departure surface	D	Min 4419 m (14,500 ft)	Measured horizontally along the ground. Total approach path length is the same total length as the LZ approach path 9,753 m (32,000 ft).
14	Width of approach-departure surface at start of horizontal portion	D	891.5 m (2,925 ft)	Centered along the FOB runway extended centerline.
15	Width of app-dep surface at end of horizontal portion	D	1,555 m (5,100 ft)	- Centered along the FOB runway extended centerline. - The 1000:75 width ratio is horizontal length: horizontal width. This ratio is consistent with class-A VFR runway requirements.
16	Elevation of horizontal portion of approach-departure surface	D	152.4 m (500 ft)	Above the established FOB runway elevation
17	Radius of inner horizontal surface	E	1,600 m (5,250 ft)	Imaginary surface constructed by scribing an arc with a radius of 1,600m (5,250 ft) about the centerline at each end of the FOB runway and interconnecting these arcs with tangents.

Table 8-8. FOB STOVL Airspace Imaginary Surfaces				
Item		Legend	Requirement	Remarks
No.	Description			
18	Width between outer edges of inner horizontal surface	E	3,200 m (10,500 ft)	
19	Elevation of inner horizontal surface	E	45.72 m (150 ft)	Above the established FOB runway elevation. Exception: When the FOB is adjacent to an airfield, the inner horizontal surface is established to match the adjacent airfield's inner horizontal surface.
20	Horizontal width of conical surface	F	NA	Conical surface not required
21	Slope of conical surface	F	NA	Conical surface not required
22	Elevation of conical surface at start of slope	F	NA	Conical surface not required
23	Elevation of conical surface at the end of slope	F	NA	Conical surface not required
24	Distance to outer edge of conical surface	G	NA	Outer horizontal surface not required
25	Width of outer horizontal surface	G	NA	Outer horizontal surface not required
26	Elevation of outer horizontal surface	G	NA	Outer horizontal surface not required
27	Distance to outer edge of outer horizontal surface	G	NA	Outer horizontal surface not required
28	Start of transitional surface	H	45.72 m (150 ft)	Measured perpendicularly from FOB runway centerline.
29	End of transitional surface	H	Various	The transitional surface ends at the inner horizontal surface, conical surface, or at an elevation of 45.72 m (150 ft). See NOTE 1.

Table 8-8. FOB STOVL Airspace Imaginary Surfaces				
Item		Legend	Requirement	Remarks
No.	Description			
30	Slope of transitional surfaces	H	2:1	- Slope ratio is horizontal: vertical. 2:1 is 2 m (ft) horizontal to 1 m (ft) vertical. - Vertical height of vegetation and other fixed or mobile obstacles and/or structures will not penetrate the transitional surface. Taxiing aircraft are exempt from this requirement. - For Navy and Marine Corps airfields, taxiway pavements are exempt from this requirement. - For the USAF, the air traffic control tower is exempt from this requirement if the height will not affect TERPS criteria.

NOTES:

1. When the FOB STOVL facility is located within the boundaries of an existing DoD airfield and the imaginary surfaces of the two facilities overlap, the FOB STOVL facility transitional surface elevation will extend to meet the existing inner horizontal surface elevation of the DoD airfield. The FOB STOVL facility imaginary surface requirements may be waived provided the existing DoD airfield imaginary surfaces meet or exceed the obstacle clearance requirements defined by the imaginary surfaces in Table 8-8.
2. When the FOB STOVL facility is located parallel with an existing DoD runway use of the runway approach/departure surface may suffice for the FOB STOVL facility approach/departure surface provided a visual transition between the path and the FOB STOVL facility can be conducted while under VMC conditions.

Table 8-9. Forward Operating Base (FOB) STOVL Facility Clear Zone and APZs

Item No.	Item Description	Legend	Requirement	Remarks
1	Clear Zone	B	Length: 152.40m (500 ft) Width: 91.44m (300 ft)	Length measured along the extended runway centerline beginning at the end of the runway. Width measured perpendicular to the extended runway centerline.
2	APZ I	J	Length: 762.00m (2,500 ft) Width: 152.40m (500 ft)	APZ I starts at the end of the clear zone, and is centered and measured on the extended runway centerline. Modification (reduction) from class-A runway requirement is made because all STOVL facility operations will be VMC, and all landings and departures will be under the supervision of a Landing Site Supervisor (LSS).
3	APZ II	J	Length: 762.00m (2,500 ft) Width: 304.80m (1,000 ft)	APZ II starts at the end of the APZ I and is centered and measured on the extended runway centerline. Class A runway criteria are used because all STOVL facility operations will under VMC, and all landings and departures will be under the supervision of a Landing Site Supervisor (LSS).

8-7 V-22 TILT-ROTOR OUTLYING LANDING FIELD (OLF) FACILITY FOR TRAINING.

8-7.1 OLF Concept.

OLFs are auxiliary airfields generally located near and associated with a Naval or Marine Corps Air Station. OLF's have no based units or aircraft and only minimal facilities. They are usually positioned in an area with low aircraft traffic to provide proficiency training and flexibility for degraded aircraft system recovery.

8-7.2 OLF Standard Drawings.

No standard drawings have been developed for OLF facilities. The criteria provided in this chapter must be site-adapted to the proposed location.

8-7.3 OLF Background.

OLF training varies slightly from location to location; however, in general terms the facility would be narrower and shorter than a standard Class A or B runway. OLFs are auxiliary airfields, generally located near and associated with a Naval or Marine Corps Air Station. In most cases, OLF's have no based units or aircraft and only minimal facilities. They are usually positioned in an area with low aircraft traffic for flight training, with reduced risks and distractions of other aircraft traffic.

8-7.3.1 Assumptions.

- Airspace imaginary surfaces are defined for a standalone training facility.
- The imaginary surfaces for the OLF facility provide obstacle clearance for the V-22 visual landing pattern. The OLF visual landing pattern altitude defines the inner horizontal surface and transitional area elevations. An overhead entry or straight-in visual approach will be the entry maneuver for the OLF visual pattern, and the obstacle clearance needed for these maneuvers define the approach and departure surface requirements. These definitions are presented similar to the existing Class B runway criteria.
- A 300 m (1,000-ft) primary surface width is used for the OLF facility.

8-7.4 OLF Geometry.

8-7.4.1 OLF Runway, Overrun, and Safety Zone Descriptions.

Figures 8-43 through 8-46 and Table 8-10 provide dimensional criteria for the layout and design of the OLF runway, overruns, and safety zones. The OLF runway should be considered bi-directional unless specifically limited to a single approach and departure path. Overruns and shoulders are provided as safety zones to prevent erosion of graded surfaces by jet blast from aircraft and surface water runoff, and to provide a smooth transition from paved to unpaved surface. Runway shoulders are not required in cases where the runway width meets or exceeds the combined total widths for the runway and shoulders defined in this document. Each zone or surface contains a brief description of their use and reference to where their specific dimension or graphic is located within the document.

8-7.4.2 Runway Length.

Table 8-10 provides the minimum length for the OLF runway. Training and operational facilities will be of various lengths based on facilities available, elevation, and supported mission.

8-7.4.3 Runway Width.

Table 8-10 provides the minimum width for the OLF runway. Training and operational facilities will be of various widths based on facilities available and supported mission.

8-7.4.4 Gradients of Operational Surfaces.

Gradient constraints are based upon sufficient slope to insure surface water runoff. A uniform transverse slope is preferable to eliminate irregularities between landing gear at touchdown. For this reason, the OLF runway should be centerline crowned or the entire runway sloped in one direction. Either sloping scheme will provide the pilot with a consistent uniform surface adequate for touchdown. See Table 8-10 and Figures 8-45 and 8-46.

8-7.4.5 Overrun Length.

Table 8-10 provides the length of the overrun for both the approach and departure ends.

8-7.4.6 Overrun Width.

Table 8-10 provides the width of the overrun. This width, at a minimum, reflects the width of the OLF runway plus any shoulder width and will be centered on the extended runway centerline.

8-7.4.7 Shoulder Length.

Table 8-10 provides the length of the shoulder. This length is dependent on the length of the OLF runway and ties into the overrun on both ends of the OLF runway for one continuous surface.

8-7.4.8 Shoulder Width.

Table 8-10 provides the width of the shoulder. This width is designed to prevent soil erosion from jet blast or surface water runoff and provide a smooth transition to the graded unpaved shoulder areas.

8-7.5 OLF Separation Distances.

Table 8-10 provides the minimum separation distances between permanent runways/helipads and the OLF runway for simultaneous operations. Table 8-10 provides the minimum separation distances between permanent Class A or Class B Runways and OLF runway for non-simultaneous operations.

8-7.6 OLF Clear Zones, Imaginary Surfaces, and APZs.

Figures 8-47 through 8-50 and Tables 8-11 and 8-12 provide applicable clearances and grade controls for a reasonable level of safety. Their description and layout are similar to other airfield types and are not unique to the OLF runway or facility. Each zone or surface contains a brief description of their use and reference to where their specific dimension or graphic is located within the document.

8-7.6.1 Clear Zones.

Runway clear zones are areas on the ground, located at the ends of each runway. The OLF runway should be considered bi-directional unless specifically limited to a single approach and departure path. They possess a high potential for accidents, and their use is restricted to be compatible with aircraft operations. Runway clear zones are required for the runway and should be owned or protected under a long-term lease and must be cleared and graded. See Table 8-12.

8-7.6.2 Imaginary Surfaces.

Surfaces in space established around a STOVL facility in relation to the OLF runway and designed to define the protected airspace around the STOVL facility. The imaginary surfaces for the OLF facilities are the primary surface, transitional surface, inner horizontal surface and approach-departure path surfaces. See Table 8-11.

8-7.6.3 Accident Potential Zones.

A land use control area beyond the clear zone of a STOVL facility that possesses a significant potential for accidents, and their use is restricted in accordance with DoDI 4165.57. Their dimensions and layout are listed in Table 8-12. Navy planners will use OPNAVINST 11010.36C/MCO 11010.16 (or latest version) to determine specific AICUZ requirements. For the Air Force, land use guidelines within the clear zone (beyond the graded area) and APZ I and APZ II are provided in AFI 32-7063 and AFH 32-7084.

8-7.7 OLF Pavement Markings.

No pavement markings are required for OLF facilities.

8-7.8 OLF Lighting.

No airfield lighting is required for OLF facilities.

8-7.9 OLF Pavement Surface Types.

Figure 8-51 shows the pavement types needed for Tilt-Rotor OLF. The paved operations surfaces used for these facilities will be constructed with HMA or PJPCC. Life-cycle cost considerations should be used to determine whether PJHTC is cost effective to improve the durability of the pavement and reduce future pavement demands, particularly for the first and last 150 m (500 ft). Seal joints in rigid pavement with neoprene.

Table 8-10. Tilt-Rotor Outlying Landing Field (OLF) Facility Criteria

Table 8-10. Tilt-Rotor Outlying Landing Field (OLF) Facility Criteria			
Item		Requirement	Remarks
No.	Description		
1	Runway Length	Min. 490 m (1,600 ft)	Basic length to be corrected for elevation and temperature. Increase 10% for each 300 m (1,000 ft) in elevation above 600 m (2,000 ft) MSL and add 4.0% for each 5 degree Celsius (10 degree Fahrenheit), above 15 degree Celsius (59 degree Fahrenheit) for the average daily maximum temperature for the hottest month. (1) Additional runway length will be provided based on operational and training requirements. Justification will be provided on a case-by-case basis. (2) For special mission or proficiency training such as autorotation operations, the length may be increased up to 300 m (1,000 ft) with no additive corrections.
2	Runway Width	Min. 30m (100ft)	
3	Total Width of shoulders (paved and unpaved) adjacent to all operational pavements	Min. 7.5 m (25 ft)	Minimum of 3.75m (12.5 ft) of shoulder width will be paved o provide a minimum width of 37.5 m (125 ft) of paved surface (30 m + 3.75m + 3.75 m (100 ft + 12.5 ft + 12.5 ft)).
4	Paved shoulder width	3.75 m (12.5 ft)	
5	Overrun length (unpaved)	Min 120 m (400 ft)	
6	Overrun width	Min. 37.5 m (125 ft)	The width of the Overrun will match the total width of the runway plus paved shoulders.
7	Longitudinal grades of OLF Runways, Overruns and Shoulders	Max 1.0%	Grades may be both positive and negative but must not exceed the limit specified. - Grade restrictions are exclusive of other pavements and shoulders. - Where other pavements tie into runways, comply with grading requirements for towways, taxiways, or aprons as applicable, but hold grade changes to the minimum practicable to facilitate drainage.

Table 8-10. Tilt-Rotor Outlying Landing Field (OLF) Facility Criteria			
Item		Requirement	Remarks
No.	Description		
8	Longitudinal grade change on OLF Runways, Overruns and Shoulders	Max 0.167% per 30m (100 ft)	Where economically feasible, the runway will have a constant centerline gradient from end to end. Exceptions: 0.4% per 30 m (100 ft) for edge of runways at runway intersections.
9	Transverse grade of runway	Min 1.0% Max 1.5%	OLF Runway may be centerline crowned or single cross-slope to insure adequate drainage of surface water.
10	Transverse grade of paved shoulder	Min 2.0% Max 4.0%	Slope downward from runway pavement. Reversals are not allowed.
11	Transverse grade of unpaved shoulder (adjacent to paved shoulder)	(a) 40 mm (1.5 inches) drop off at edge of paved shoulder (b) 5% slope first 3 m (10 ft) (c) Primary Surface criteria apply beyond this point	Slope downward from edge of shoulder. See Item 14.
12	Transverse grade of Overrun	Min 2.0% Max 3.0%	Slope pavement downwards from the runway with no reversals to insure adequate drainage of surface water. Exception is at or adjacent to intersections where the pavement surfaces must be warped to match abutting pavements.
13	Runway Lateral Clearance Zone (corresponds to half the width of primary surface)	150 m (500 ft)	Measured perpendicularly from centerline of OLF runway. This area is to be clear of fixed and mobile obstacles. In addition to the lateral clearance criterion, the vertical height restriction on structures and parked aircraft as a result of the transitional slope must be taken into account. (1) Fixed obstacles include man-made or natural features constituting possible hazards to moving aircraft. See Note 1. (2) Mobile obstacles include parked aircraft, parked and moving vehicles, railroad cars and similar equipment. (3) Taxiing aircraft are exempt from this restriction. However, parallel taxiways (exclusive of shoulder width) must be located in excess of the lateral clearance distance.
14	Grades within the Primary Surface (in any direction)	Max 5.0%	- Exclusive of pavement, shoulders, and cover over drainage structures. - Slopes are to be as gradual as practicable. Avoid abrupt changes or sudden reversals. Rough grade to the extent necessary to minimize damage to aircraft.

Table 8-11. Tilt-Rotor Outlying Landing Field (OLF) Airspace Imaginary Surfaces

Table 8-11. Tilt-Rotor OLF Airspace Imaginary Surfaces				
Item		**Legend**	**Requirement**	**Remarks**
No.	**Description**			
1	Primary surface width	A	300 m (1,000 ft)	Centered on OLF runway centerline.
2	Primary surface length	A	Runway length + 61 m (200 ft) at each end	Primary surface extends 61 m (200 ft) beyond each end of the OLF runway
3	Primary surface elevation	A	See Remarks	The elevation of the primary surface is the same as the elevation of the nearest point on the OLF runway centerline
4	Grade of Clear Zone in any direction	B	5.0% Max.	The clear zone starts at the end of the primary surface and has the same width as the primary surface (93.5 m [300 ft]), with a length of 400 ft. - Clear zones are areas on the ground, located at the ends of the primary surface, centered on the primary approach path to the VL pad. - Areas to be free of obstructions. Rough grade and turf when required. Positive drainage to avoid standing water.
5	Start of OLF Approach-Departure Surface	C	61 m (200 ft)	Measured from the end of the OLF runway.
6	Length of sloped portion of OLF Approach-Departure Surface	C	Min 2,400 m (8,000 ft)	Measured horizontally
7	Slope of OLF Approach-Departure Surface	C	20:1	Slope ratio is horizontal: vertical. Example: 20:1 is 20 m (ft) horizontal to 1 m (ft) vertical. For clearances over highway and railroads, see Table 3-8, Imaginary Surfaces Minimum Clearances over Highway, Railroad, Waterway and Trees.
8	Width of OLF Approach-Departure Surface at start of sloped portion	C	300 m (1,000 ft)	Centered on the extended OLF runway centerline, and is the same width as the primary surface.

Table 8-11. Tilt-Rotor OLF Airspace Imaginary Surfaces				
Item		Legend	Requirement	Remarks
No.	Description			
9	Width of OLF Approach-Departure Surface at end of sloped portion	C	1,030 m (3,400 ft)	Centered on the extended OLF runway centerline.
10	Elevation of Approach-Departure Surface at start of sloped portion	C	0 m (0 ft)	Same as the OLF runway centerline at the threshold.
11	Elevation of OLF Approach-Departure Surface at end of sloped portion	C	120 m (400 ft)	Above the established OLF runway elevation.
12	Transitional Surface Slope	—	2:1	Slope ratio is horizontal:vertical. 2:1 is 2 m (ft) horizontal to 1 m (ft) vertical. (1) The transitional surface starts at the lateral edges of the Primary Surface and the Approach-Departure Surface. It continues outward and upward at the prescribed slope to an elevation of 45 m (150 ft) above the established airfield elevation.
13	Inner Horizontal Surface Radius	E	1,400 m (4,600 ft)	An Imaginary surface constructed by scribing an arc with a radius of 1,400 m (4,600 ft) about the centerline at each end of the OLF runway and interconnecting these arcs with tangents.
14	Elevation of Inner Horizontal Surface	E	45 m (150 ft)	Above the established OLF runway elevation. Exception: When the OLF is adjacent to an airfield, the inner horizontal surface is established to match the adjacent airfield's inner horizontal surface.

Table 8-12. Tilt-Rotor Outlying Landing Field (OLF) Clear Zone and APZs

Item No.	Item Description	Legend	Requirement	Remarks
1	Clear Zone	B	Length: 120 m (400 ft) Width: 300 m (1,000 ft)	Length measured along the extended runway centerline beginning at the end of the primary surface. Width of Clear Zone is centered on and measured perpendicular to the extended runway centerline.
2	Clear Zone Grades (any direction)		Min 2.0% Max. 5.0%	Clear Zone only. Area to be free of obstructions. Rough grade and turf when required.
3	APZ I	J	Length: 240 m (800 ft) Width: 300m (1,000 ft)	APZ I starts at the end of the clear zone, and is centered and measured on the extended runway centerline.

CHAPTER 9
UNMANNED AIRCRAFT SYSTEMS (UAS)

9-1 CONTENTS.

This chapter presents guidance and criteria for planning and designing runway and ancillary movement areas that support operations of US Army (USA)/US Air Force (USAF)/US Navy wheeled/skid Unmanned Aircraft Systems (UAS).

9-2 REQUIREMENTS. LAND USE AND AIRSPACE APPROVAL.

Public Aircraft Operations are limited by federal statue to certain government operations within U.S. airspace per Federal Aviation Administration (FAA) proposed rules.

9-3 RUNWAY.

Runway location and orientation are paramount to airfield safety for UAS aircraft. Wind direction and velocity is a major consideration for siting runways. With respect to UAS operations, prevailing winds and velocities may actually prevent operations if the runway cannot be aligned with them. To be functional, efficient, and safe, the runway should be oriented in alignment with the prevailing winds, to the greatest extent practical, to provide favorable wind coverage. Wind data, obtained from local sources, for a period of not less than five years, should be used as a basis for developing the wind rose to be shown on the airfield general site plan. Appendix B, Section 4, provides guidance for the research, assessment, and application of wind data. NOTE: For RQ-7Bv2, the term “runway” in this chapter shall be synonymous with “launch/recovery strip” and the term “hangar” shall be synonymous with “shelter.”

9-4 AIRCRAFT COVERED IN THIS CHAPTER.

- MQ-9A Reaper
- MQ-1B Predator
- MQ-1C Gray Eagle
- RQ-4A/B Global Hawk
- MQ-4C Triton
- RQ-7Bv2 Shadow (or earlier versions)
- MQ-8B/C Fire Scout

9-5 AIRCRAFT CHARACTERISTICS.

For aircraft characteristics see USACE Technical Report TSC 13- 2.

9-6 AIRFIELD DIMENSIONAL CRITERIA.

The dimensions for airfield facilities, airfield lateral safety clearances, and airspace imaginary surfaces are provided in this document. Typical layout, sections and profiles for UAS runways and the associated airspace surfaces are shown in Figures 9-1 through 9-6.

9-6.1 Airfields/Heliports Used by Both Manned and Unmanned Aircraft.

Airfields/Heliports, Air Force Bases, Naval Air Stations and Marine Corps Air Stations used by both manned and unmanned aircraft (dual use facilities) will use the geometric criteria contained in this UFC. The most critical criteria **(manned versus unmanned aircraft criteria)** will apply based on the segment use, it may even be a combination of UAS Criteria, i.e. the taxiway to the UAS apron will be designed based on this UFC. The RQ-4A/B and MQ-4 require a Class B runway. New pavements for UAS aircraft at manned aircraft facilities shall be designed in accordance with the requirements in UFC 3-260-02. Chapter 1 of UFC 3-260-02 details which pavements must be rigid pavements and which pavements can be either rigid or flexible pavements. The traffic mix utilized for the installation shall be used for these new UAS pavements (installation traffic mixes are spelled out in UFC 3-260-02 Chapter 2 for Army Class I, II, III, IV and in Chapter 3 for USAF medium, light, heavy, etc.).

9-6.2 Permissible Deviations from Design Criteria.

See paragraph B13-2.16 for deviations from criteria.

9-6.3 UAS Runway Co-located with an Active Army Airfield, Army Heliport, Air Force, Navy or Marine Corps Runway.

9-6.3.1 Separation Criteria.

Table 9-1 lists the separation criteria between manned and unmanned runways. If the UAS facility is planned for dual use, the requirements of this UFC, UFC 3-535-01 and appropriate service marking directives apply.

9-6.3.2 New Pavements.

New pavements for UAS aircraft at collocated facilities shall be designed in accordance with the requirements in UFC 3-260-02. Chapter 1 of UFC 3-260-02 details which pavements must be rigid pavements and which pavements can be either rigid or flexible pavements. The traffic mix used for UAS only pavements shall be, as a minimum, the same as the traffic used for an Army Class II Helipad (20,000 passes of a 22,680kg [50,000lb] CH-47 Aircraft). If other support vehicles (i.e. crash fire trucks, support trucks, forklifts, etc.) utilize these areas that require a thicker pavement design then the thickened design for those vehicles shall govern.

Table 9-1. Separation Distance Between Runways

Table 9-1. Separation Distance Between Runways	
Min. 213.4m [700 ft]	Non-simultaneous Visual Flight Rules (VFR) operations.
Min. 304.8m [1000 ft]	Simultaneous VFR operations
Min. 762m [2500 ft]	Instrument Flight Rules (IFR)/VFR using simultaneous operations (depart-depart) (depart-approach).
Concurrent UAS Ops	The separation distance between multiple runways that are going to be used for UAS aircraft operations will need to be coordinated with the UAS Program Managers (operating multiple TALS in close proximity to each other may create radar signature interferences or conflicts for approaching UAS aircraft).

9-6.4 UAS-only Facilities.

This section presents design considerations for UAS only facilities. See TC 25-8 *Training Ranges* for additional RQ-7Bv2 Shadow facility design criteria, especially expeditionary training and/or semi-improved training facilities.

9-6.4.1 New Pavements.

New pavements for UAS aircraft at these facilities shall be designed in accordance with the requirements in UFC 3-260-02. Chapter 1 of UFC 3-260-02 details which pavements must be rigid pavements and which pavements can be either rigid or flexible pavements. The traffic mix used for UAS only pavements shall be, as a minimum, the same as the traffic used for an Army Class II Helipad (20,000 passes of a 22,680kg [50,000lb] CH-47 Aircraft). If other support vehicles (i.e. crash fire trucks, support trucks, forklifts, etc.) utilize these areas that require a thicker pavement design then the thickened design for those vehicles shall govern.

9-6.4.2 Runway Designation.

For runway designation see UFC 3-260-04. These runways are not built structurally to support standard fixed wing or rotary aircraft operations.

9-6.4.3 Tactical Shadow Facility.

Down range tactical facilities are rudimentary in nature to enable launch/recovery and provide basic shelter to support training operations. These facilities are permanent sites that are constructed on installation range complexes to enable launch and recovery under the veil of installation restricted airspace. Tactical facilities must be configured IAW Operators Manual requirements for tactical use. Building structures should be sited to comply with Table 9-6.

Table 9-2. UAS Runways

Table 9-2. UAS Runways					
	Item	Criteria			Remarks
No.	Description	MQ-1	RQ-7Bv2	MQ-9	
1	Length (min)	1524m [5000']	243.84m [800']	2286m [7500']	MQ-1C: 1371.6m [4500'], at 2743.2m [9000'] elevation runway length is 1676.4m [5500']. For USAF required length shall be determine by the A2, but not less than stated except for lengths in Appendix B. For RQ-7, length of runway will depend on the number of TALs touch down points. 243.84m [800'] is only adequate for one touch point. Increase runway length to 304.8m [1,000'] for two or more platoons.
2	Width	22.86m [75']	15.24m [50']	22.86m [75']	MQ-1C 30.48m [100']
3	Width of shoulder	3.05m [10']	1.52m [5']	3.05m [10']	Shoulder may be paved or unpaved.
4	Longitudinal grades of runway and shoulders	Grades may be both positive and negative but must not exceed the limit specified in this UFC. Shadow can operate on a max grade of 1.7%. Grade restrictions are exclusive of other pavements and shoulders. Where other pavements tie into runways, comply with grading requirements for towways, taxiways, or aprons as applicable, but hold grade changes to the minimum practicable to facilitate drainage.			
5	Longitudinal runway grade changes	No grade change is to occur less than 304.8m [1,000'] from the runway end	No grade change is to occur less than 30.48m [100'] from the runway end	No grade change is to occur less than 304.8m [1,000'] from the runway end	Where economically feasible, the runway will have a constant centerline gradient from end to end. Where terrain dictates the need for centerline grade changes, the distance between two successive points of intersection (PI) will be not less than 304.8m [1,000'] (MQ-1 and MQ-9), 30.48m [100'] (RQ-7A/B) and two successive distances between PIs will not be the same.
6	Rate of longitudinal runway grade changes	Maximum rate of longitudinal grade change is produced by vertical curves having 180-m [600-ft] lengths for each percent of algebraic difference between the two grades.			
7	Longitudinal sight distance	Any two points 2.44m [8'] above the pavement must be mutually visible (visible by each other) for 1524m [5000']. Proportionally reduce height above runway for runways shorter than 1524m [5,000'].			
8	Transverse grade of runway	Min 1.0% Max 1.5%	Max 0.5%	Min 1.0% Max 1.5%	Runway pavements will be centerline crowned. Slope pavement downwards

Table 9-2. UAS Runways

	Item	Criteria			Remarks
No.	Description	MQ-1	RQ-7Bv2	MQ-9	
					from centerline of runway. 1.5% slope is optimum transverse grade of runway.
9	Transverse grade of paved shoulder	Slope downward from runway pavement. Reversals are not allowed.			
10	Runway lateral clearance zone width (from centerline)	76.2m [250']	18.29m [60']	76.2m [250']	The runway lateral clearance limits coincide with the limits of the primary surface. The ends of the lateral clearance zone coincide with the runway ends plus overruns. The ground surface within this area must be clear of fixed or mobile objects, and graded to the requirements in Table 3-2, items 13 and 14, Chapter 3. The zone width is measured perpendicularly from the centerline of the runway and begins at the runway centerline. (1) Fixed obstacles include man-made or natural features such as buildings, trees, rocks, terrain irregularities and any other features constituting possible hazards to moving aircraft. (2) Mobile obstacles include parked aircraft, parked and moving vehicles, railroad cars, and similar equipment. Taxiing aircraft, emergency vehicles, and authorized maintenance vehicles are exempt. (3) Parallel taxiway (exclusive of shoulder width) will be located in excess of the lateral clearance distances (primary surface). (4) Above ground drainage structures, including headwall, are not permitted within 45.72m [150'] (24.38m [80'] for RQ-7) of the runway centerline.
11	Longitudinal grades within runway lateral clearance zone	Exclusive of pavement, shoulders, and cover over drainage structures. Slopes are to be as gradual as practicable. Avoid abrupt changes or sudden reversals. Rough grade to the extent necessary to minimize damage to aircraft.			

Table 9-2. UAS Runways					
	Item	Criteria			Remarks
No.	Description	MQ-1	RQ-7Bv2	MQ-9	
12	Transverse grades within runway lateral clearance zone (in direction of surface drainage)	Exclusive of pavement, shoulders, and cover over drainage structures. Slopes are to be as gradual as practicable. Avoid abrupt changes or sudden reversals. Rough grade to the extent necessary to minimize damage to aircraft. Grades may need to be adjusted as necessary to accommodate siting of RQ-7 TALS, but shall be done in accordance with these requirements.			
13	Width of mandatory frangibility zone (MFZ)	91.44m [300']	NA*	91.44m [300']	Centered on the runway centerline. All items sited within this area must be frangible. (See Appendix B, Section 13.).
14	Length of MFZ	Extends the entire length of the runway plus clear zone. Items that must be sited there due to their function must be made frangible to the maximum extent possible.(See Appendix B, Section 13)*			

***** For the RQ-7 runways no objects except for the arresting system and barrier net may be placed within the primary surface.

B - CLEAR ZONE SURFACE.
C - APPROACH-DEPARTURE CLEARANCE SURFACE (40H:1V FOR MQ-1/9 & 20H:1V FOR RQ-7).
H - TRANSITIONAL SURFACE (4H:1V SLOPE RATIO).

NOTES:

1. DATUM ELEVATION FOR SURFACE C IS THE RUNWAY CENTERLINE ELEVATION AT THE THRESHOLD. SURFACE H VARIES AT EACH POINT.

9-6.5 Runway Overruns.

Runway overruns keep the probability of serious damage to an aircraft to a minimum in the event that the aircraft runs off the runway end during a takeoff or landing, or lands short during a landing. Overruns are required for the landing and takeoff area.

Table 9-3. UAS Overruns

Table 9-3. Overruns					
Item		MQ-1	RQ-7Bv2	MQ-9	Remarks
No.	Description	Requirement			
1	Length	60.96m [200']	30.48m [100']	60.96m [200'	
2	Paved Length	60.96m [200']	30.48m [100']	60.96m [200']	If runway is paved, overrun will be paved.
3	Total width of overrun (paved and unpaved)	Sum of runway and shoulders			The outside edges of the overrun, equal in width to the runway shoulder, are graded but not paved.
4	Paved overrun width	Same as width of runway			Center on runway centerline extended.
5	Longitudinal centerline grade	Same as last 304.8m [1,000'] of runway	Same as last 30.48m [100'] of runway	Same as last 304.8m [1,000'] of runway	To avoid abrupt changes in grade between the first 91.44m [300'] and remainder of overrun the maximum change of grade is 2.0% (1.7% for RQ-7) per 30.48 linear meter [100 linear ft.]
6	Transverse grade	Min 2.0% Max 3.0% (1.7% max for RQ-7) 1.5 in drop-off at edge of paved overrun +/- 0.5 in			From centerline of overrun. Transition from the runway and runway shoulder grades to the overrun grades to be made within the first 15.24m [50'] of overrun.

9-6.6 Runway Clear Zones.

Runway clear zones are areas on the ground, located at the ends of each runway. They possess a high potential for accidents, and their use is restricted to be compatible with aircraft operations. Hence, they are treated as “exclusion zones” and not merely restricted access. Runway clear zones are required for the runway and should be owned or protected under a long-term lease.

9-6.6.1 Treatment of Clear Zones.

The purpose of the clear zone is to protect the safety of flight and safety of people on the ground. The entire clear zone area is a land use control area intended to protect people both flight safety and property on the ground. Land use for the clear zone area for UAS facilities corresponds to the clear zone land use criteria for fixed-wing airfields as defined for DoD AICUZ and Service-specific standard and as discussed in Chapter 3.

9-6.6.2 Clear Zone Mandatory Frangibility Zone (MFZ).

The MFZ extends through the graded area. Items that must be sited there due to their function must be made frangible to the maximum extent possible (Appendix B, Section 13).

9-6.6.3 Prohibited Land Uses.

Criteria prohibits certain land uses within the clear zone and APZs (APZ I and APZ II). These land uses include storage and handling of munitions and hazardous materials, and live fire weapons ranges (See DoDI 4165.57 and individual service component directives and DA PAM 385-63 for more information on compatible land use).

Table 9-4. UAS Clear Zones

Table 9-4. UAS Clear Zones					
Item No.	Description	MQ-1	RQ-7Bv2	MQ-9	Remarks
		Requirement			
1	Length	304.8m [1000’]	30.48m [100’]	304.8m [1000’]	Measured along the extended runway centerline beginning at the runway end. For grading requirements, see items 4 and 5.
2	Width at start of clear zone (adjacent to the runway)	152.4m [500’]	36.58m [120’]	152.4m [500’]	Centered on the runway center line extended.
3	Length of Graded Clear zone surface (graded area)	152.4m [500’]	30.48m [100’]	152.4m [500’]	Graded area only. For land use outside the graded area of the clear zone, apply AICUZ standards.
4	Width at end of clear zone	152.4m [500’]	36.58m [120’]	152.4m [500’]	Centered on the runway center line extended.
5	Longitudinal grade of area to be graded	Max 10.0%	Max 1.7%	Max 10.0%	The area to be graded is 152.4m [500’] (MQ-1, MQ-9), and 30.48m [100’] (RQ-7) in length by the established width of the primary surface. Grades are exclusive of the overrun, but are to be shaped into the overrun grade. The maximum longitudinal grade change cannot exceed + 2.0% per 30.48m [100’]. Grade restrictions are also exclusive of other pavements and shoulders. Where other pavements cross the graded area, comply with grading requirements for the specific pavement design (towways, taxiways, or aprons as applicable), but hold grade changes to the minimum practicable to facilitate drainage. The graded area is to be cleared and grubbed of stumps and free of abrupt surface irregularities, ditches, and ponding

Table 9-4. UAS Clear Zones					
Item No.	Description	MQ-1	RQ-7Bv2	MQ-9	Remarks
		Requirement			
					areas. No aboveground structures, objects, or roadways (except air traffic control controlled service roads to arresting gear are permitted in the area to be graded, but gentle swales, subsurface drainage, covered culverts and underground structures are permissible. The transition from the graded area to the remainder of the clear zone is to be as gradual as feasible. For policy regarding permissible facilities, geographical features, and land use in the remainder of the clear zone, refer to guidance furnished by the DoD AICUZ guidelines for clear zones and accident potential zones. (See Appendix B, Section 3.).
6	Transverse grade of area to be graded (in direction of surface drain-age prior to channelization)	Min 2.0% Max 10.0%			For RQ-7 Max 1.7%
7	Width of MFZ	91.44m [300']	NA	91.44m [300']	Centered on the extended runway centerline. All items sited within the MFZ in the graded area of the clear zone must be frangible. Items located beyond the Graded Area of the clear zone but within the MFZ must be constructed to be frangible, low impact resistant structures, or semi-frangible (see Appendix B, Section 13).
8	Length of MFZ	152.4m [500']	NA	152.4m [500']	Extends the full length of the runway plus the clear zone.

Table 9-5. UAS Accident Potential Zones

Table 9-5. UAS Accident Potential Zones					
Item		MQ-1	RQ-7Bv2	MQ-9	Remarks
No.	Description	Requirement			
1	APZ I length	457.2m [1500']			APZ I starts at the end of the clear zone, and is centered and measured on the extended centerline. Modifications will be considered if: - The runway is infrequently used. - Prevailing wind conditions are such that a large percentage (that is, over 80%) of the operations are in one direction. - Local accident history indicates consideration of different areas. - Most aircraft do not overfly an APZ area as defined here during normal flight operations (modifications may be made to alter these zones and adjust them to conform to the line of flight). - Other unusual conditions exist.
2	APZ I width	152.4m [500']	36.58m [120']	152.4m [500']	
3	APZ II length	304.8m [1000']			APZ II starts at the end of the APZ I and is centered and measured on the extended runway centerline. Modifications will be considered if: - The runway is infrequently used. - Prevailing wind conditions are such that a large percentage (that is, over 80 percent) of the operations are in one direction. - Local accident history indicates consideration of different areas. - Most aircraft do not overfly an APZ area as defined here during normal flight operations (modifications may be made to alter these zones and adjust them to conform to the line of flight). - Other unusual conditions exist.
4	APZ II width	152.4m [500']	36.58m [120']	152.4m [500']

Table 9-6. Airspace Imaginary Surfaces (See Figures 9-1 thru 9-6)						
Item		Legend	UAS Runway			Remarks
No.	Description		MQ-1	RQ-7Bv2	MQ-9	
1	Primary surface width	A	152.4m [500’]	36.58m [120’]	152.4m [500’]	Centered on the runway centerline.
2	Primary surface length	A	60.96m [200’]	36.58m [100’]	60.96m [200’]	Runway length plus value indicated on each end of the runway (extends beyond each end of the runway).
3	Primary surface elevation	A	The elevation of any point on the primary surface is the same as the elevation of the nearest point on the runway centerline.			
4	Clear zone surface (graded area)	B	152.4m [500’]	30.48m [100’]	152.4m [500’]	For land use outside the graded area of the clear zone, apply AICUZ standards.
5	Start of approach-departure surface	C	60.96m [200’]	30.48m [100’]	60.96m [200’]	Measured from the end of the runway.
6	Length of sloped portion of approach-departure surface	C	3048m [10,000’]	1524m [5,000’]	3048m [10,000’]	Measured horizontally. For MQ-1C the length can be reduced to 1851.96m [6,076’].
7	Slope of approach-departure surface	C	40:1	20:1	40:1	Slope ratio is horizontal: vertical. Example: 40:1 is 12.19m [40’] horizontal to 0.30m [1’] vertical. For clearances over highway and railroads, see Table 3-8.
8	Width of approach-departure surface at start of sloped portion	C	152.4m [500’]	36.58m [120’]	152.4m [500’]	Centered on the extended runway centerline, and is the same width as the Primary Surface.
9	Width of approach-departure surface at end of sloped portion	C	1066.8m [3500’]	493.78m [1620’]	1066.8m [3500’]	Centered on the extended runway centerline. For MQ-1C the width can be reduced to 354m [1,161.4’]
10	Elevation of approach-departure	C	Same as the runway centerline elevation at the threshold.			

Table 9-6. Airspace Imaginary Surfaces (See Figures 9-1 thru 9-6)						
Item		Legend	UAS Runway			Remarks
No.	Description		MQ-1	RQ-7Bv2	MQ-9	
	surface at start of sloped portion					
11	Elevation of approach-departure surface at end of sloped portion	C	76.2m [250’]			Above the established airfield elevation.
12	Start of transitional surface	H	76.2m [250’]	18.29m [60’]	76.2m [250’]	Measured from runway centerline.
13	End of transitional surface	H	See Remarks			The transitional surface ends at the inner horizontal surface, conical surface, outer horizontal surface, or at an elevation of 45.72m [150’].
14	Slope of transitional surfaces	H	4:1			Slope ratio is horizontal:vertical. 4:1 is 1.22m [4’] horizontal to 0.30m [1’] vertical. Vertical height of vegetation and other fixed or mobile obstacles and/or structures will not penetrate the transitional surface. Taxiing aircraft are exempt from this requirement.

NOTE: See Figures 9-1 & 9-6

9-7 TAXIWAYS.

Taxiways provide for ground movement of aircraft. Taxiways connect the runway(s) of the airfield with the parking and maintenance areas and provide access to hangars, docks, and various parking aprons and pads. Taxiways are designated alphabetically, avoiding the use of I, O, (could be mistaken for runway numbers) and X (closure marking). Alphanumeric designations may be used when necessary, for example, A1, B3. RQ-7A/B do not require taxiways, however do require paved towways for wing walkers.

9-7.1 Basic.

The basic airfield layout consists of a taxiway connecting the center of the runway with the hangar access apron. This system limits the number of aircraft operations at an airfield. Departing aircraft must taxi on the runway to reach the runway threshold. When aircraft are taxiing on the runway, no other aircraft is allowed to use the runway. If runway operations are minimal or capacity is low, the basic airfield layout with one taxiway may be an acceptable layout.

9-7.2 Parallel Taxiway.

A taxiway parallel for the length of the runway, with connectors to the end of the runway and hangar access apron, is the most efficient taxiway system. Aircraft movement is not hindered by taxiing operations on the runway, and the connectors permit rapid entrance and exit of traffic.

9-7.3 Taxiway Intersection Criteria.

To prevent the main gear of an aircraft from coming dangerously close to the outside edge of the taxiway during a turn, fillets are provided at taxiway intersections. When an aircraft turns at an intersection, the nose gear of the aircraft usually follows the painted centerline marking. The main gears, located to the rear of the nose gear, do not remain a constant distance from the centerline stripe during the turn due to the physical design of the aircraft. The main gears pivot on a shorter radius than does the nose gear during a turn. Intersections should be designed to ensure that the main gear wheels stay a minimum of 5 feet from the pavement edge.

9-7.4 Hangar Access Taxiways.

Hangar access taxiways are provided for aircraft access onto a hangar access apron. The apron access taxiways should be located to enhance the aircraft's departing sequence and route.

9-7.5 Shoulders.

Shoulders are provided along a taxiway to allow aircraft to recover if they leave the paved taxiway. Paved shoulders prevent erosion caused by prop wash, support an occasional aircraft that wanders off the taxiway, support vehicular traffic, and reduce maintenance of unpaved shoulder areas. Criteria for UAS taxiway shoulders, including widths and grading requirements to prevent the ponding of storm water, are presented in Table 9-7. Manholes, hand holes, and drainage structures constructed within these areas should, at a minimum, be designed as provided in this section. Beyond the paved or unpaved shoulders, sub-grade structures are not designed to support aircraft wheel loads. The top surface of foundations, manhole covers, hand hole covers, and frames should be flush with the grade. Maintenance action is required if the drop-off at the edge of the structure or foundation exceeds three inches.

Table 9-7. UAS Taxiways

Table 9-7. UAS Taxiways				
Item		MQ-1/9	RQ-7Bv2	Remarks
No.	Description	Requirement		
1	Width (ft)	15.24m [50']	4.57m [15']	9.14m [30'] for MQ-1C
2	Total width of shoulders (paved and unpaved) (ft)	3.05m [10']	NA	Any or all of the shoulders may be paved or unpaved. For unpaved shoulders turfed/grassed shoulders are recommended except in desert locations where gravel surfacing is also acceptable.
3	Longitudinal grade of taxiway and shoulders	Max 3.0%		Grades may be positive or negative but must not exceed the limits specified.
4	Rate of longitudinal taxiway grade change	Max 2.0% per 30.48m [100']	NA	The minimum distance between two successive points of intersection (PI) is 152.4m [500']. Changes are to be accomplished by means of vertical curves. Up to a 0.4% change in grade is allowed without a vertical curve. A vertical curve is not necessary where a taxiway crosses a runway or taxiway crown..
5	Transverse grade of taxiway	Min 1.0% Max 1.5%	NA	Taxiway pavements will be centerline crowned. Slope pavement downward from the centerline of the taxiway. When existing taxiway pavements have insufficient transverse gradients for rapid drainage, provide for increased gradients when the pavements are overlaid or reconstructed. The transverse gradients requirements are not applicable at or adjacent to intersections where pavements must be warped to match abutting pavements.
6	Transverse grade of optional paved shoulders	Min 2.0% Max 4.0%	NA	
7	Transverse grade of unpaved shoulders	40mm [1.5"] drop-off at edge of pavement +/- 13mm [0.5"] 2.0% min, 4.0% max	NA	Unpaved shoulders shall be graded to provide positive surface drainage away from paved surfaces.

Table 9-7. UAS Taxiways				
Item		MQ-1/9	RQ-7Bv2	Remarks
No.	Description	Requirement		
8	Taxiway turning radius (ft)	19.81m [65']	NA	
9	Fillet radius at intersections (ft)	15.24m [50']	NA	
10	Clearance from edge of access apron to other taxiways and aprons (ft)	30.48m [100']	NA	Where hover taxi is involved the minimum distance is 60.96m [200']
11	Clearance from taxiway centerline to fixed or mobile obstacles (taxiway clearance line) (ft)	30.48m [100']	NA	
12	Distance between taxiway centerline and parallel taxiway/taxilane centerline (ft)	38.1m [125']	NA	
13	Grade of area between taxiway shoulder and taxiway clearance line	Min of 2.0% prior to channelization Max 10.0%		Unpaved areas shall be graded to provide positive surface drainage away from paved surfaces. 40mm [1.5"] drop-off at pavement edge, +/- 13mm [0.5"]

9-7.6 Towways.

A towway is used to tow aircraft from one location to another or from the runway/taxiway to a hangar/storage facility.

9-7.6.1 Dimensions.

Table 9-8 presents the criteria for towway layout and design, including clearances, slopes, and grading dimensions. When designing for access to a hangar, flare the pavement to the width of the hangar door from a distance beyond the hangar sufficient to allow maintenance personnel to turn the aircraft around.

Table 9-8. UAS Towways

Table 9-8. UAS Towways				
Item		MQ-1/9	RQ-7A/B	Remarks
No.	Description	Requirement		
1	Width (ft)	9.14m [30']	4.57m [15']	RQ-7 requires a paved towway.
2	Total width of shoulders (ft)	3.05m [10']	3.05m [10']	Any or all of the shoulders may be paved or unpaved. For unpaved shoulders turfed/grassed shoulders are recommended except in dessert locations where gravel surfacing is also acceptable.
3	Longitudinal grade of towway	Max 3.0%		Grades may be both positive and negative but must not exceed the limit specified.
4	Rate of longitudinal grade change per 30 m (100 ft)	Max 2.0%		The minimum distance between two successive PI is 150 m (500 ft). Changes are to be accomplished by means of vertical curves. For the Air Force and Army, up to a 0.4% change in grade is allowed without a vertical curve. A vertical curve is not necessary where a taxiway crosses a runway or taxiway crown.
5	Longitudinal sight distance	N/A (See note 1.)		
6	Transverse grade	Min 1.0% Max 3.0%		Pavement crowned at towway centerline. Slope pavement downward from centerline of towway.
7	Towway turning radius (ft)	27.43m [90']	15.24m [50']	Criteria presented here are for straight sections of towway. Pavement width and horizontal clearance lines may need to be increased at horizontal curve locations, based on aircraft alignment on the horizontal curve.
8	Fillet radius at intersections (ft)	15.24m [50']	9.14m [30']	
9	Transverse grade of shoulder	(a) 40 mm (1.5 in) drop-off at edge of pavement, +/- 13 mm (0.5 in). (b) 2.0% min, 4.0% max.		
10	Horizontal clearance from towway centerline to fixed or mobile obstacles	The greater of: ½ the wing width of the towed +25 ft.; or the minimum of 18.29m [60'].		
11	Vertical clearance from towway pavement surface to fixed or mobile obstacles	(Height of towed mission aircraft) + 3 m (10 ft)		

12	Grade (area between towway shoulder and towway clearance line)	Min of 2.0% prior to channelization Max 10%. (See note 2.)	

NOTES:
1. N/A = not applicable
2. Bed of channel may be flat.

9-8 APRONS AND OTHER PAVEMENTS.

9-8.1 Apron Requirements.

Aprons should be sized to allow safe movement of towed aircraft or aircraft operating under their own power.

9-8.1.1 Location.

Aprons should be located contiguous to maintenance and hangar facilities. Do not locate them within runway and taxiway lateral clearance distances. A typical access apron is illustrated in Figure 9-9. (For Army, based on Vice Chief of Staff of the Army (VCSA) approval of concept, there is no aircraft parking apron authorized for Army UAS.)

9-8.1.2 Size.

As a general rule, there are no standard sizes for aircraft aprons. Aprons are individually designed to support aircraft and missions at specific facilities. The actual dimensions of an apron are based on the number of authorized aircraft, the maneuvering space, and the type of activity that the apron serves. The ideal apron size affords the maximum parking capacity with a minimum amount of paving.

9-8.2 Types of Aprons and Other Pavements.

Listed here are types of aprons and other aviation facilities:

- Parking Apron (RQ-1/4)
- Hangar access apron/Warm up pad (MQ-1/9, RQ-7Bv2)
- Arm/Dearm pad

9-8.3 RQ-4A/B Global Hawk Parking Apron.

Parking areas for the RQ-4A Global Hawk and the RQ-4B Global Hawk should be designed with dimensions shown in Figure 9-8. Locations for tie-downs on the RQ-4A are shown in Figure 9-7. Tie-downs should be designed to resist an uplift force equal to the rated capacity of the tie down chain (i.e., typically 44,482N [10,000 pounds]). Special apron areas for hot refueling or arming/dearming are not required for the Global Hawk.

9-8.3.1 Location.

Aprons should be located contiguous to maintenance and hangar facilities. Do not locate them within runway and taxiway lateral clearance distances. A typical access apron is illustrated in Figure 9-9 (For US Army based on Vice Chief of Staff of the Army (VCSA) approval of concept, there is no aircraft parking apron authorized for UAS.)

9-8.3.2 Size.

As a general rule, there are no standard sizes for aircraft aprons. Aprons are individually designed to support aircraft and missions at specific facilities. The actual dimensions of an apron are based on the number of authorized aircraft, the maneuvering space, and the type of activity that the apron serves. The ideal apron size affords the maximum parking capacity with a minimum amount of paving.

9-8.4 Hangar Access Apron.

The pavement that allows access from the taxiway/towway to the hangar is referred to as a “hangar access apron” and is discussed in more detail below based on Army usage.

9-8.4.1 MQ-1C.

For USA the MQ-1C parking space width is 19.81m [65’], and the parking space length is 12.19m [40’].

9-8.4.2 Specific Aircraft.

If the assigned aircraft are predominantly one type, the access apron will be based on the specific dimensions of that aircraft, i.e. an RQ-7Bv2 parking space is 9.45m [31’] in width and 6.71m [22’] in length.

9-8.4.3 Layout.

The hangar access/ parking apron will be sized to accommodate a minimum of two UAS’s with an area for one UAS to be towed by.

<tr><td>8</td><td>Grade
(area between access apron shoulder and wingtip clearance line)</td><td colspan="2">Max 10.0%</td><td>If the wingtip clearance line falls within the access apron shoulder, no grading is required beyond the access apron shoulder.</td></tr>
</table>

9-9 MOORING AND GROUNDING POINTS.

9-9.1 Layout.

The mooring points are located five feet fore and aft or left and right of the grounding point.

- Mooring point Layout for RQ-1/4 USAF/USN. See Figure 9-7.
- Mooring point Layout for UAS hangar access apron. See Figure 9-9.
- See Appendix B, Section 11 for typical mooring point details and testing procedures.

Figure 9-7. Mooring Layout for the RQ-4A Global Hawk

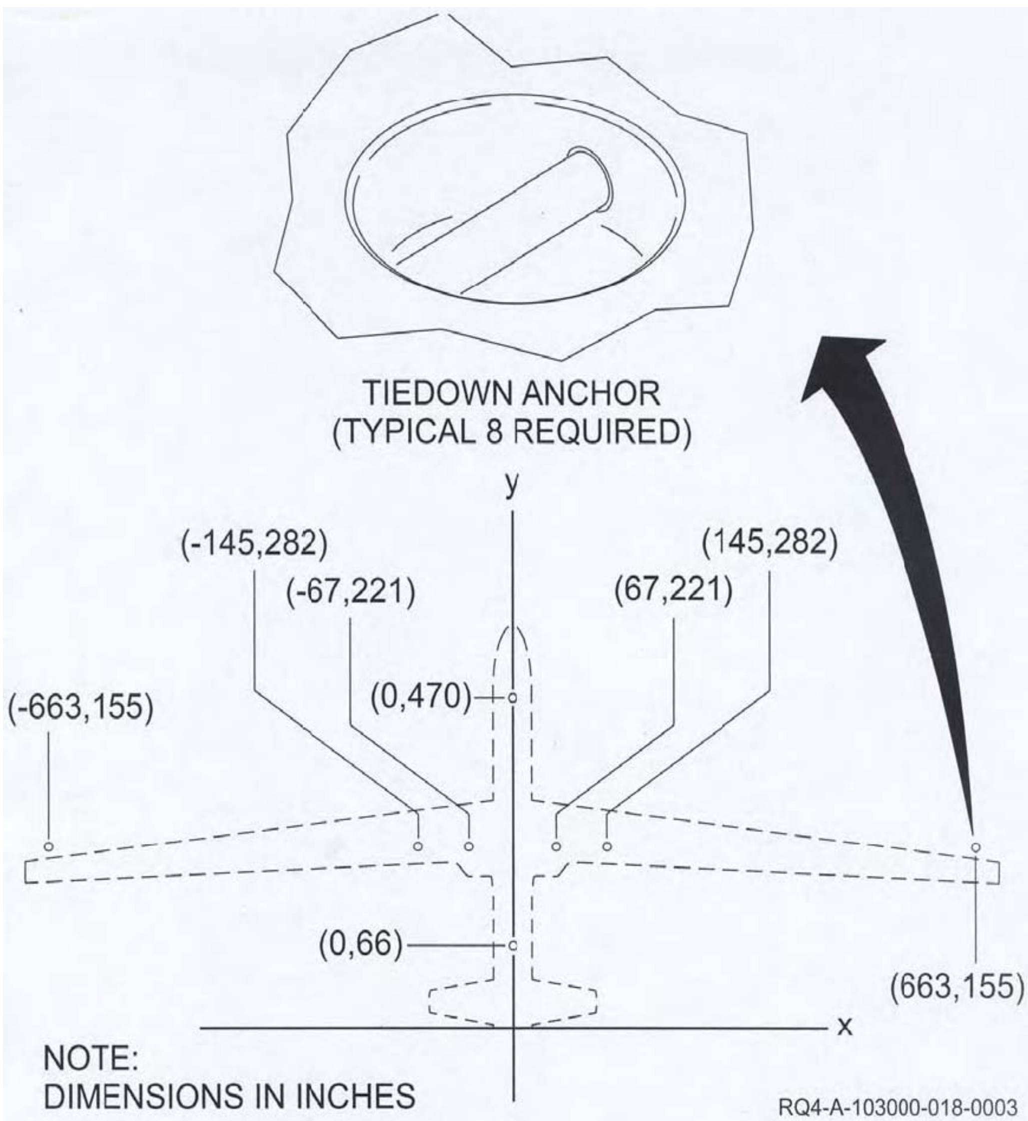

Figure 9-8. Parking Area Dimensions for RQ-4A and RQ-4B Global Hawk

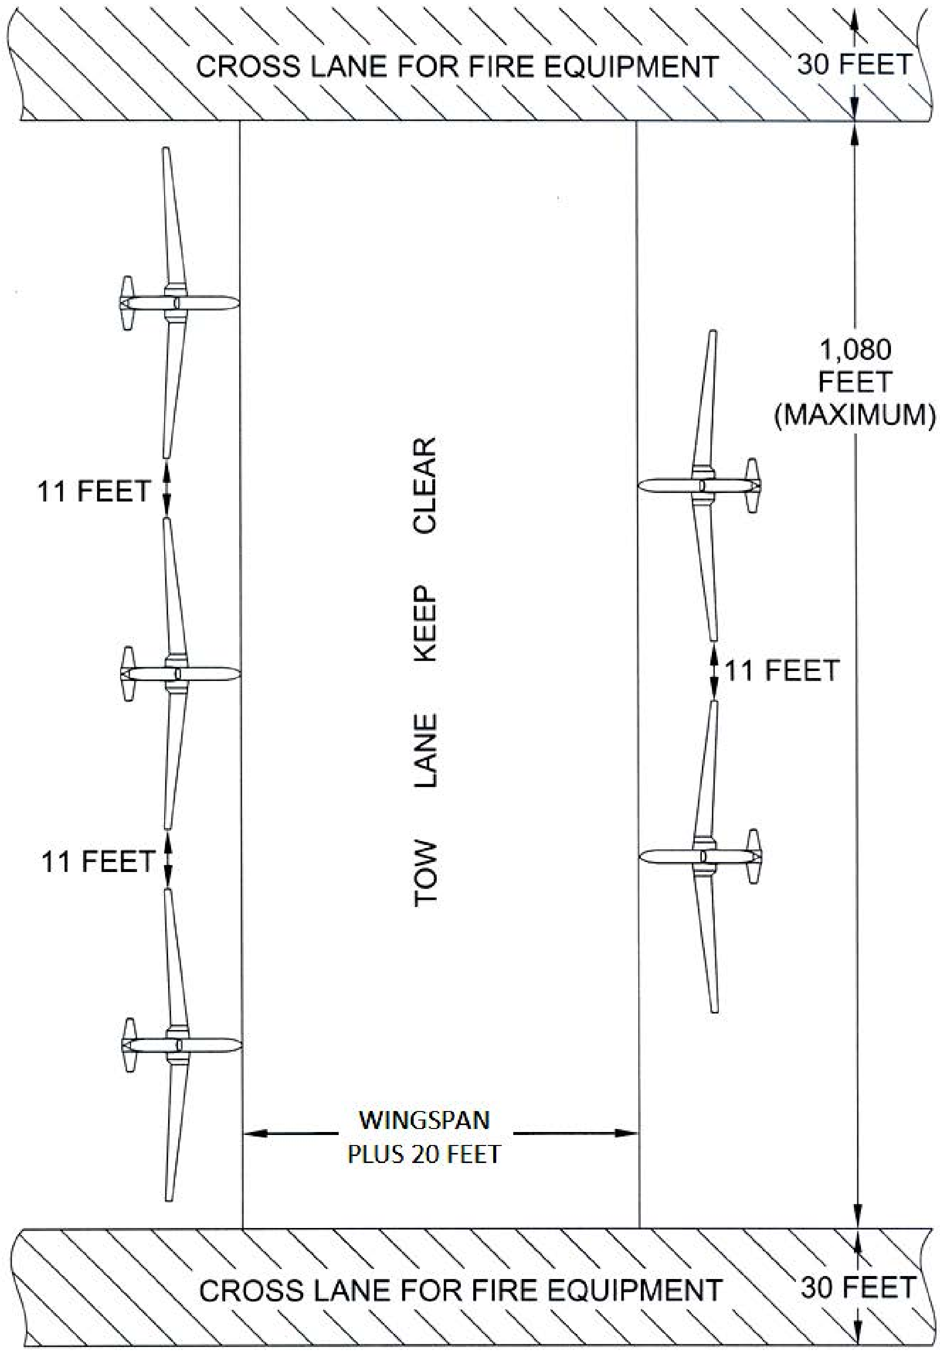

Figure 9-9. Standard Army MQ-1C Hangar Access Apron

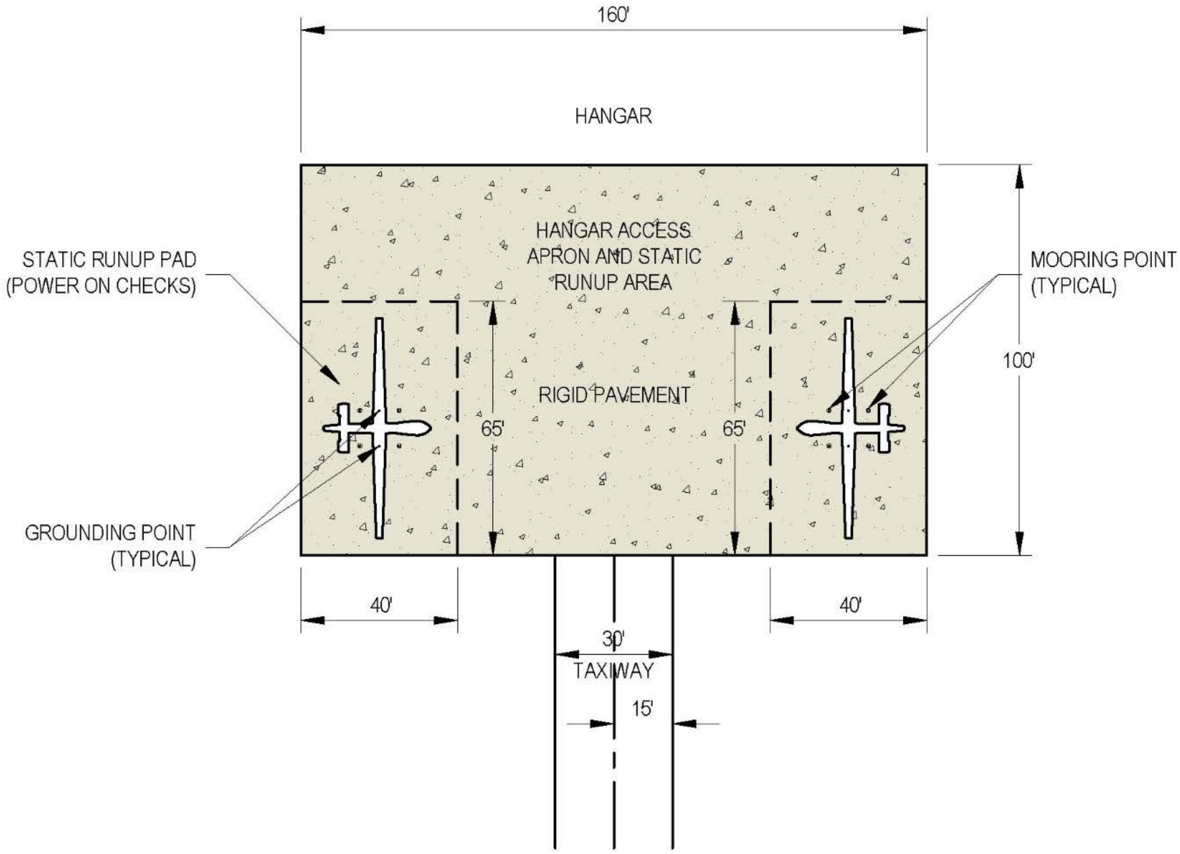

Figure 9-10. Navy MQ-4C Triton Hangar Access Apron

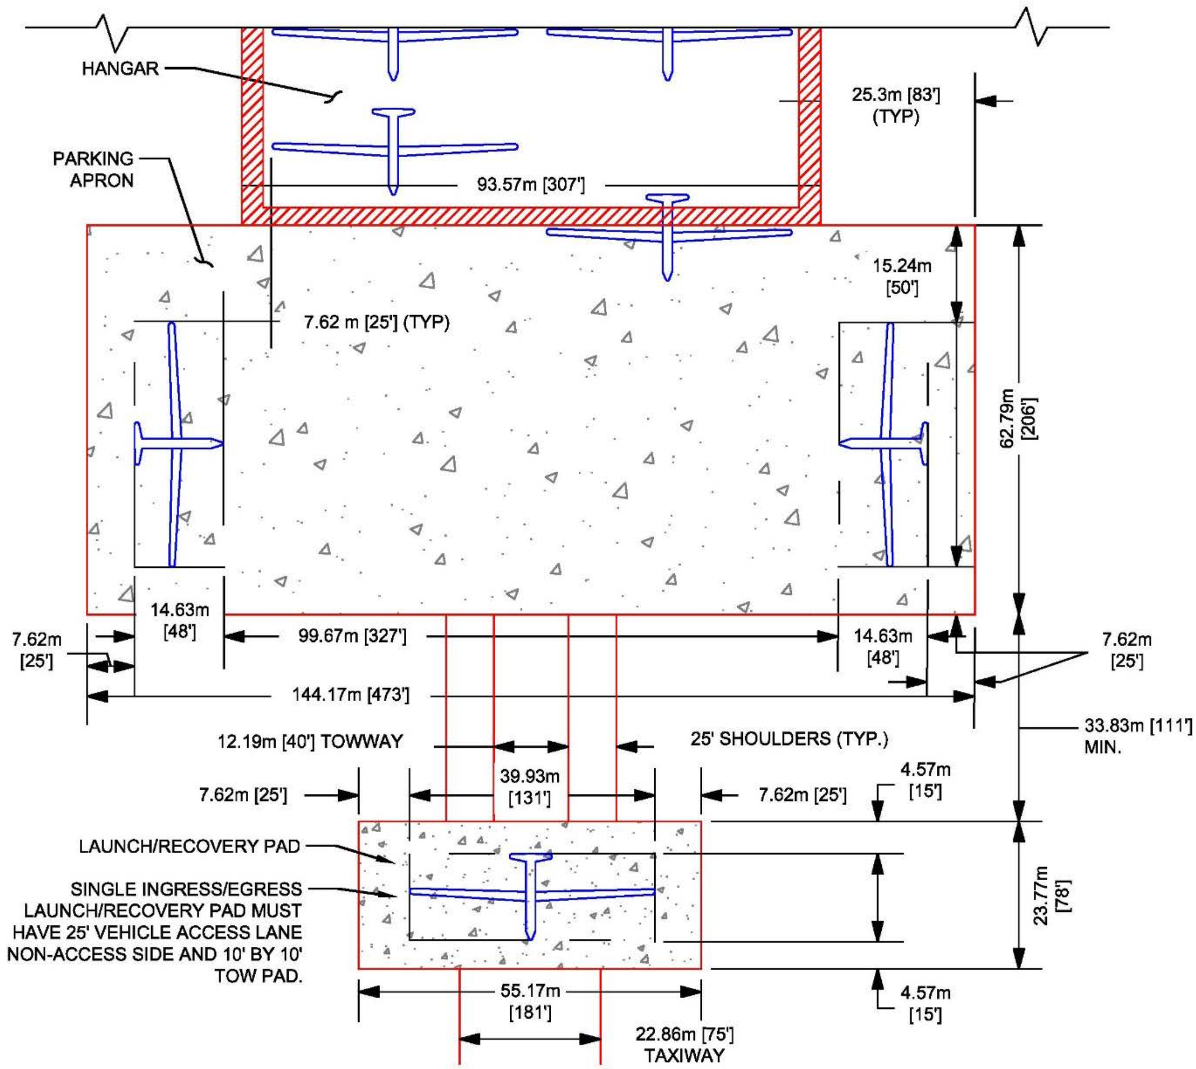
Note: The Triton unmanned aircraft system (UAS) requires a dedicated launch location to allow the Global Positioning System codes to be incorporated into the aircraft's mission plan for airfield ground taxi operations. The aircraft will utilize the UAS launch point for all programmed start and stop airfield operations. UAS dedicated aprons do not require peripheral taxiways.



NOTES:

1. THIS IS A BASIC APRON LAYOUT AND MAY BE SITE ADAPTED TO MEET ADDITIONAL CUSTOMER REQUIREMENTS.
2. LAYOUT OF PARKING APRON AND LAUNCH/RECOVERY PAD ALLOWS FOR SIMULTANEOUS OPERATIONS. AN OFFSET OF 111' IS REQUIRED.
3. AN OFFSET OF 25' IS REQUIRED BETWEEN PAVEMENT EDGE AND WINGTIP CLEARANCES FOR MAINTENANCE AND SAFETY.
4. WINGTIP CLEARANCE RADII ARE BASED ON A 45 DEGREE TURN.

9-10 LIGHTING.

Lighting will be IAW UFC 3-535-01.

9-11 MARKING.

Markings will be IAW UFC 3-260-04.

APPENDIX B
SECTION 1
WAIVER PROCESSING PROCEDURES

B1-1 ARMY.

B1-1.1 Waivers to Criteria and Standards.

Waivers are processed when compliance with criteria cannot be achieved, the obstruction poses little or no risk to flying safety, and there are no other alternatives. When proposed objects or facilities will violate airfield imaginary surfaces, safe clearance, or other design criteria established in this manual, they must be analyzed to determine potential impact and risks to aircraft operations, personnel, and infrastructure.

B1-1.1.1 Permanent Waivers.

Established for violations that cannot be reasonably corrected and either pose little to no threat to flight operations and personnel or risks have been accepted at the appropriate level. Permanent waivers are issued where no further mitigative actions are intended or necessary.

B1-1.1.2 Temporary Waivers.

Established for a specified period during which additional actions to mitigate the situation must be initiated to fully comply with criteria or to obtain a permanent waiver. Routine follow-up inspections are required to evaluate the effectiveness of implemented risk mitigation actions, control measures, and identification of new risks for each temporary waiver granted.

B1-1.1.3 Operational Waivers.

Establish operational waivers when a particular aircraft operation is required to operate on existing facilities that do not meet current airfield design criteria listed in this manual. Ensure a risk assessment is performed on all proposed operational waiver requests prior to submitting to the approval authority. All operational waiver requests must have the aviation mission commander’s endorsement.

B1-1.1.4 Construction Waivers.

A construction waiver (sometimes referred to as temporary construction waivers) is obtained when one or more elements of a construction project (equipment, facilities, personnel, etc.) violate airfield and airspace criteria in this manual. Construction waivers should only be planned for the duration of the construction project unless circumstances dictate otherwise. An FAA Form 7460-1 Notice of Proposed Construction or Alteration, must be submitted to the DAR prior to sending the request to the Installation/Garrison commander for approval. Temporary waiver requests for construction projects must be prepared in accordance with paragraphs B1-1.1 and B1-1.2.

NOTE: Emergency maintenance and repair requirements and routine maintenance activities, such as mowing and maintenance of airfield systems, are exempt from this requirement; however, the DPW Airfield Manager will ensure implementation of appropriate safety measures, including Notices to Airmen (NOTAM) or Local NOTAMs.

B1-1.1.5 Permissible Deviations.

Permissible deviations to airfield and airspace criteria which do not require waivers if properly sited are listed in Section 13 of this appendix, beginning at paragraph B13-2.

B1-1.1.6 Exemptions.

Existing airfield facilities (See paragraph 1-3.1) built under previous design standards should be documented as exemptions and programmed for replacement away from the airfield environment at the end of their useful life or when mission needs dictate earlier replacement. If improvements are proposed that would extend the useful life of the airfield facilities, a temporary/permanent waiver must be requested. If the exempted facility is demolished, any use of that site should conform to the criteria in this UFC.

Airfield managers will identify and document all airfield facilities built under previous design standards and not requiring a waiver and submit the following information to the ACOM/ASCC/DRU or ARNG for validation:

- Description of exempt facility. (e.g. fixed-wing runway lacks overruns, taxiway lacks shoulders).
- Pictures, diagrams or charts that clearly illustrate the current exempt condition.
- Original mission supported (e.g. runway designed for Air Force B-52, taxiways designed for rotary-wing aircraft, etc.) and current mission supported.
- Year built. (Supporting documentation that confirms when the facility was built or a previous determination was made).
- Previous design criteria used (regulation number, criteria and date if known).
- Current criteria required and description of violation. (e.g., Table 3-2., runway lateral clearance zone, 500 ft. requirement, Taxiway B is 400 ft. from centerline/100 ft. violation).
- Safety of operations (risk management). Use DD Form 2977 Deliberate Risk Assessment Worksheet. Include risk description of each risk level associated with the non-compliant condition and what mitigation actions will be taken. See DA PAM 385-30 and ATP 5-19 for guidance.
- Estimated cost to remove/relocate or correct condition.

The ACOM/ASCC/DRU or ARNG will determine whether documented facilities should be classified as an exemption, or should have a temporary or permanent waiver.

B1-1.2 Responsibilities.

B1-1.2.1 Installation.

The installation's design agent, aviation representative (safety officer, Airfield Manager, operations officer, and/or air traffic and airspace [AT&A] officer), Department of Public Works (DPW) and/or Construction Facilities Management Office (CFMO) master planner will:

- Jointly with DPW prepare/initiate all waiver requests. Project Designers must immediately notify the Airfield Manager when project designs will not meet design criteria listed in this manual.
- Submit requests through the installation to the ACOM/ASCC/DRU/or ARNG.
- Maintain a complete record of all waivers requested and their disposition (approved or disapproved). A list of waivers to be requested and those approved for a project should also be included in the project design analysis prepared by the design agent, aviation/airfield representative, or DPW/CFMO master planner.
- Annual review. All airfield waivers will be annually reviewed to validate if a requirement for the waiver still exists, and all appropriate safety precautions, mitigative measures, and conditions of approval are being effectively implemented. Waivers no longer required will be cancelled through the ACOM/ASCC/DRU/ or ARNG.

B1-1.2.2 The ACOM/ASCC/DRU or ARNG will:

- Ensure all required coordination has been accomplished.
- Ensure the type of waiver requested is clearly identified as either temporary or permanent.
- Review all command supported waiver requests and forward to USAASA for action.
- Provide a command level endorsement of the waiver request.

B1-1.2.3 USAASA.

USAASA is responsible for coordinating reviews for the waiver request with the following agencies:

- Air traffic control assessment by Air Traffic Services Command (ATSCOM).

- Safety and risk assessment by the U.S. Army Combat Readiness/Safety Center (USACRC).
- Technical engineering review by the Transportation Systems Center (TSC).
- Waivers that affect instrument flight procedures by the USAASA Instrument Procedures Branch.
- From these reviews, USAASA formulates a consolidated position and makes the final determination on all waiver requests.

B1-1.3 Waiver Process Procedures.

B1-1.3.1 Contents of Waiver Requests.

Each request must contain the following information:

- Reference by publication, paragraph, and page to the specific standard(s) and/or criterion to be waived. Include all applicable design criteria that is non-compliant.
- Complete justification for noncompliance with the airfield/airspace criteria and/or design standards. Demonstrate that noncompliance will provide an acceptable level of safety, economics, durability and quality for meeting the Army mission. This would include reference to special studies made to support the decision. For manmade obstacles, the date of construction needs to be stated/indicated. Specific justification for waivers to criteria and allowances must be included as follows:

a. When specific site conditions (physical and functional constraints) make compliance with existing criteria impractical and/or unsafe. For example, the need to provide hangar space for all aircraft because of recurring adverse weather conditions; the need to expand hangar space closer to and within the runway clearances due to lack of land; maintaining fixed-wing Class A clearances when support of Class B fixed-wing aircraft operations are over 10 percent of the airfield operations.

b. When deviation(s) from criteria fall within a reasonable margin of safety as determined by a documented risk assessment based on assigned and known future missions of airfield/heliport that are determined will not impair construction of long-range facility requirements. For example, locating security fencing around and within established clearance areas.

c. When construction that does not conform to criteria is the only alternative to meet mission requirements. Evidence of analysis and efforts taken to follow criteria and standards must be documented and referenced. Copies of this analysis will be included in the final designs and maintained by DPW real estate offices.

- The rationale for the waiver request, including specific impacts upon assigned mission, safety, and/or environment.
- Temporary waiver requests shall include the action planned to correct the violation, risk assessment, project/work order number, and estimated completion date.
- Safety of operations (risk management). Use DD Form 2977 Deliberate Risk Assessment Worksheet. Include risk description of each risk level associated with the non-compliant condition and what mitigation actions will be taken. See DA PAM 385-30 and ATP 5-19 for guidance.
- Pictures, diagrams, and charts that clearly illustrate condition, distances, etc.

B1-1.3.2 Additional Requirements.

B1-1.3.2.1 Operational Factors.

Include information on the following existing and/or proposed operational factors used in the assessment:

- Mission urgency.
- All aircraft by type and operational characteristics.
- Density of aircraft operations at each air operational facility.
- Facility capability (visual flight rules [VFR] or instrument flight rules [IFR]).
- Use of self-powered parking versus manual parking.
- Existing navigational aids (NAVAID).

B1-1.3.2.2 Documentation.

Record all alternatives considered, their consequences, necessary mitigative efforts, and evidence of coordination. The Garrison/Installation Commander will sign all requests for waivers regardless of level of residual risk determined.

B1-2 AIR FORCE.

B1-2.1 Waivers to Criteria.

B1-2.1.1 Waivers, Permissible Deviations, Exemptions and Non-Conforming Facilities/Structures/Objects.

Waivers are required when compliance with criteria cannot be achieved. The waiver process is designed to ensure leadership is aware of potential risk and to ensure that all alternatives have been considered. Approval of a waiver is an acknowledgment of the associated risk (it is not project approval). A thorough examination of potential alternatives must be completed and documented prior to installation site approval, and before a waiver is requested from the MAJCOM/CD. When requesting a waiver, consider grouping adjacent supporting items with a controlling obstruction or grouping related items, such as a series of drainage structures, as one waiver. UFC 3-260-01 waivers do not apply to off installation development or obstructions to airspace off-installation (TERPS are the data steward for obstructions to air space criteria for off installation as outlined in AFI 32-7062). The only exception would be building a new airfield in an area with existing development (e.g. AFCENT, AFRICOM, EUCOM, PACOM). Under most circumstances, funding or budgetary constraints are not adequate justification for granting a waiver. Criteria violations caused by terrain located on Air Force controlled property will be classified as a non-conforming object, exemption or temporary waiver, not a permanent waiver. Criteria violations located on property not controlled by the Air Force will be classified as non-conforming facilities/structures or objects (see B1-2.1.8). There are four types of waivers (permanent, temporary, construction, and airshow) that are described below.

NOTE: Projects may be part of a larger NEPA action (in compliance with 32 CFR 989) which requires consideration of alternatives. The waiver request package should be provided in the environmental analysis.

NOTE: Clear Zones. Additionally, waivers to criteria in this UFC should be pursued for violations located within the graded area of the clear zone. A land use variance should be pursued if the proposal creates an incompatible land use violation in the remaining area of Air Force controlled clear zones, (See AFI 32-7063, Air Installations Compatibility Use Zone Program, AICUZ). In some circumstances, a proposal may require a waiver from this UFC and an AICUZ clear zone variance, if the proposal creates an incompatible land use, and violates criteria in this UFC (i.e. penetration into an imaginary surface).

NOTE: Operational Waivers. Certain existing facilities may require the supported aircraft activity to have an operational waiver in order to operate, such as taking off and landing on a shorter runway or inadequate wingtip clearance inside existing hangars and sunshades. These are operational waivers and not UFC 3-260-01 waivers. See AFI 11-218, Flying Operations, for additional information (This note applies to wing tip clearance in sunshades).

B1-2.1.2 Permanent Waivers.

Permanent waivers are established for criteria violations that cannot be reasonably met. If the criteria to be waived under this UFC would also result in a violation of UFC 3-535-01 Visual Air Navigation Facilities then consult with the Air Force Flight Standards Agency (AFFSA) and/or the Air Force Safety Center. The waiver request should be initiated by the Base Civil Engineer's (BCE) designated representative as soon as it is determined criteria can't be met, and be approved before siting, programming, and/or design is finalized. Permanent waivers are appropriate for violations associated with development of facilities on overseas installations where the U.S. has no authority to implement Air Force standards. See Section B1-2.2 for waiver package content. These waivers are approved/disapproved by the owning MAJCOM Deputy Commander.

Approval of a waiver constitutes acceptance of the risk associated with criteria violations. The MAJCOM/CD may delegate approval/disapproval authority to another organization within the MAJCOM Headquarters.

B1-2.1.3 Temporary Waivers.

Temporary waivers are established for criteria violations that can be corrected within eight years. During the two years following waiver approval, CE will develop/program an action to correct the violation, including a description of the proposed action, project number, and cost estimate. The remaining six years will be used to implement the corrective action. If the violation cannot be brought into compliance within eight years, the violation should be reclassified as a permanent waiver (Reclassification requests to permanent status will require MAJCOM/CD approval). See Section B1-2.2 for waiver package content. These waivers are approved/disapproved by the owning MAJCOM Deputy Commander. Approval of a waiver constitutes acceptance of the risk associated with criteria violations. The MAJCOM/CD may delegate approval/disapproval authority to another organization within the MAJCOM Headquarters.

B1-2.1.4 Construction Waivers.

A construction waiver (sometimes referred to as temporary construction waiver) is obtained when one or more elements of a construction project (equipment, facilities, personnel, etc.) violates criteria in this UFC. Construction waivers should only be planned for the duration of the construction project unless circumstances dictate otherwise. An FAA Form 7460-1 Notice of Proposed Construction or Alteration, must be included in request package to Installation Commander for approval. See Section 14 of this appendix, “Construction Phasing Plan and Operational Safety on Airfields during Construction” for additional guidance. Construction waivers **\1** must **/1/** be approved before construction activities begin. The Installation Commander is the approval authority for construction waivers. See Section B1-2.2 for waiver package.

NOTE: Emergency maintenance and repair requirements, as well as routine maintenance activities (mowing, snow removal, rubber removal and maintenance of airfield systems), are exempt from this requirement; however, the BCE will coordinate with the airfield management, flight safety, and flight operations offices to ensure implementation of appropriate safety measures, including Notices to Airmen (NOTAM).

B1-2.1.5 Air Show Waivers.

Air Show waivers are processed for events that will temporarily create criteria violations. The Installation Commander is the approval authority for Air Show Waivers. See Section B1-2.2 for waiver package content. Event waivers other than airshows require MAJCOM/CD approval.

B1-2.1.6 Permissible Deviations.

Permissible deviations are for airfield support facilities or equipment that are not required to meet airfield criteria, however, they must meet siting criteria specified in Appendix B, Section 13, of this UFC. The MAJCOM Deputy Commander (MAJCOM/CD) may grant permissible deviation status for other airfield-related facilities or systems that are unique to the MAJCOM, but must provide acceptable construction standards, siting criteria, and aircraft clearance requirements for such items.

B1-2.1.7 Exemptions.

Facilities constructed under previous standards should be documented as exemptions and programmed for replacement away from the airfield environment at the end of their useful life or when mission needs dictate earlier replacement. If improvements are proposed that would extend the useful life of the facility, a waiver must be requested. If the exempted facility is demolished any use of that site should conform to the criteria in this UFC. Exception is allowed for facilities located beyond and beneath the Building Restriction Lines (BRL). These exempted facilities may remain without waiver for an indefinite period, and may be renovated to extend their life-cycle if the intended use of the facility fits within the approved category groups listed as appropriate for siting within the boundaries of the BRL. See Appendix B, Section 17 for guidelines provided to establish these areas and facilities approved for construction or renovation within this area.

B1-2.1.8 Non-Conforming Facilities/Structures/Objects.

Existing facilities, structures, or objects (which could include equipment or terrain features) identified as not meeting criteria in this UFC, and are not exempted or have an existing waiver, will be classified as Non-Conforming until they are evaluated to determine whether they should be classified as an exemption, or should have a permanent or temporary waiver. These may be identified during annual airfield inspections, special inspections, survey efforts, or while conducting day to day observations. The BCE will coordinate with airfield management, flight safety, and flight operations offices (and others as appropriate) to ensure implementation of appropriate safety measures.

B1-2.1.9 Amendment of Waivers.

Amendments to existing waivers (temporary and permanent) will be developed when there are proposed changes to the scope of the original violation. This may include increasing/decreasing criteria violations included in the original waiver request (e.g. lights, sunshades, improving grade, etc.). When the number/extent of criteria violations is reduced, note the improvement on the annual review. If the number/extent of criteria violations is increased, MAJCOM/CD approval is required.

B1-2.2 Contents of Waiver Request Package.

Each request must contain the following information unless otherwise noted:

- Criteria to be waived. Reference publication, paragraph, and page number of the specific criteria to be waived.
- Alternatives Courses of Action (COA) Considered. Describe any alternative courses of actions that were considered when developing the solution proposal and why they were not acceptable for meeting the purpose and need of the proposal/action.
- Rationale/Justification of Selected COA. Explain the rationale for the selected COA and why the approving official should accept the risks associated with the proposal.
- Risk Assessment. Complete the AF Form 4437 Deliberate Risk Assessment Worksheet. Utilize a cross functional team to complete the risk assessment. Contributing organizations may include civil engineering, safety, airfield operations and others as appropriate. See AFI 90-802 for additional information. The risk analysis should include a detailed explanation of the methodology used, data considered, and rationale for determining the risk (see Attachment 8 of AFPAM 90-803).
- Graphics. Pictures, diagrams, and charts must clearly illustrate condition, distances, imaginary surfaces, clear zones, etc.
- Federal Aviation Administration (FAA) Notification. Include if required per Title 14, Code of Federal Regulations (CFR), Part 77.
- Proof of Coordination. The waiver preparer documents installation coordination from the appropriate stakeholders, for example: Safety, Operations Support, Maintenance, terminal instrument procedures (TERPS), Security Forces, Communications, Civil Engineering (and any other organizations that the installation feels should coordinate on the waiver request) before requesting approval from the installation commander. At the MAJCOM level, Temporary and Permanent waiver requests should be coordinated with the same functional offices as at installation level in addition to any additional offices deemed necessary.

NOTE: Ensure any packages to support reclassification of waivers will include all the information above.

B1-2.3 Processing Waiver Requests.

Obtain current waiver processing procedures from AFCEC/CP. Waivers being reclassified will be accomplished through the standard waiver request process.

B1-2.4 Review of Waivers.

Installation review of all approved Permanent and Temporary airfield waivers will be conducted by a cross functional team to include Operations, Safety, and other appropriate stakeholders. The results are to be briefed to the Facilities Board with a copy sent to AFCEC/CP. Include the following in the review:

- A list of all waivers by waiver number.
- Waiver currency, accuracy and classification evaluation (any proposed reclassification of a waiver identified in the review will be accomplished through the waiver approval process). Note the rationale for any proposed reclassification in the summary presentation to the Facilities Board.
- Evaluate the effectiveness of implemented risk mitigation actions, control measures, and identification of any new risks for each temporary waiver.
- A summary of the number of waivers approved and/or cancelled within the last year.
- An update of the status of action/projects associated with each temporary waiver.

B1-2.5 Responsibilities.

B1-2.5.1 AFCEC/CO.

Develops and maintains United Facilities Criteria for Airfield and Heliport Planning and design and provides secondary technical support on the airfield waiver program.

B1-2.5.2 AFCEC/CP.

Provides policy direction on the airfield waiver and waiver review programs. Determines technical sufficiency of permanent and temporary airfield waiver requests. Maintains completed airfield waivers and waiver reviews on its website. Forwards a record copy of installation waiver review summary to the MAJCOM for information.

B1-2.5.3 HQ AFFSA.

- Reviews all policy changes to airfield planning and design criteria before implementation to determine operational impact on airfield and aircraft operations.
- Reviews all requests for waivers to instrument procedure criteria.
- Processes requests for waivers to instrument procedure design criteria in accordance with guidance outlined in AFI 11-230.
- Provides documentation to AFCEC/CO to justify adding any new permissible deviations (such as newer navigational aids or weather equipment) in B13-2 Permissible Deviations. Documentation would

include siting diagrams and signed Risk Assessment by AFFSA/CC or AFFSA/CD recommending the item and associated siting requirements be added to UFC 3-260-01 for the new permissible deviation.

B1-2.5.4 Base Civil Engineer (BCE).

- Coordinates with airfield management, flying and ground safety, flight operations, logistics, TERPS (typically at MAJCOM), security forces, and communications during waiver package preparation.
- **Establishes and updates (at least annually) geospatial data sets of approved waivered items in accordance with AFI 32-7062, Comprehensive Planning, in conjunction with the latest published Installation Development Plan (IDP) GIS guidance. Also see AFI 11-230, *Instrument Procedures*.**
- Develops a military construction (MILCON) program or other project to systematically correct violations noted in temporary waivers. Project listing should include (by waiver) facilities board priority, facility investment metric (FIM) rating, integrated priority list (IPL) rating (or other installation or AFIMSC prioritization rating system), risk assessment rating, funds type required (e.g., O&M, MILCON, 3080), and projected fiscal year.
- Record, review, and process waiver requests (see paragraph B1-2.3 and B1-2.4) and maintain (for record) one copy of all pertinent documents relative to each waiver, including a record of staff coordination on actions at base, AFCEC/CP and MAJCOM levels.
- Lead the annual review of Permanent and Temporary waivers and brief the Facilities Board per paragraph B 1-2.4 above.
- Participates in an annual assessment of the airfield/airspace criteria using the Air Force Airfield Certification/Safety Inspection Checklist (see AFI 13-213).

B1-2.5.5 NGB/A7CP (for ANG facilities).

- Develops policy on waivers and manages the ANG waiver program.
- Processes and coordinates inquiries and actions for deviations to criteria and standards.
- ANG tenant units on active duty installations must use AFCEC/CP waiver processing guidelines.

B1-2.5.6 HQ AFRC/A4C (for AFRC facilities).

- Develops policy on waivers and manages the AFRC waiver program.
- Processes and coordinates inquiries and actions for deviations to criteria and standards.

- AFRC tenant units on active duty installations must use AFCEC/CP waiver processing guidelines.

B1-3 NAVY AND MARINE CORPS.

B1-3.1 Applicability.

See Chapter 1 for Scope and Applicability of criteria.

B1-3.1.1 Use of Criteria.

The criteria in this UFC apply to Navy and Marine Corps aviation facilities located in the United States, its territories, trusts, and possessions. Where a Navy or Marine Corps aviation facility is a tenant on a civil airport, use these criteria to the extent practicable; otherwise, FAA criteria apply. Where a Navy or Marine Corps aviation facility is host to a civilian airport, these criteria will apply. Apply these standards to the extent practical at overseas locations where the Navy and Marine Corps have vested base rights. While the criteria in this UFC are not intended for use in a theater-of-operations situation, they may be used as a guideline where prolonged use is anticipated and no other standard has been designated.

B1-3.1.2 Criteria at Existing Facilities.

See Chapter 1, Paragraph 1-3 for additional guidance and requirements for existing facilities where mission has changed. The criteria will be used for planning new aviation facilities and new airfield pavements at existing aviation facilities (exception: primary surface width for Class B runway). Existing aviation facilities have been developed using previous standards which may not conform to the criteria herein. Safety clearances at existing aviation facilities need not be upgraded solely for the purpose of conforming to these criteria. However, at existing aviation facilities where few structures have been constructed in accordance with previous safety clearances, it may be feasible to apply the revised standards herein.

B1-3.2 Navy/Marine Corps Design and Airfield Safety Waiver Processes.

Waivers can be temporary or permanent in nature and various NAVY, NAVFAC, NAVAIR and USMC documents may use different terminology for their respective purposes. The primary purpose of this UFC is to offer criteria for new facilities. Mil-STD 3007 contains NAVFAC waiver and exemption requirements. However, waivers may be required from multiple authorities.

B1-3.2.1 NAVFAC UFC Waivers.

NAVFAC UFC Waivers are waivers or exemptions to criteria (per Mil-STD 3007) addressing design considerations of new facilities. The need for such waiver may arise during the planning site approval process or during project design. The site approval process and resources are documented in NAVFACINST 11010.45A, Site Approval Request (SAR) Process. Generally, if criteria is not being met during the planning or design phase, both NAVFAC UFC and NAVAIR Airfield Safety Waivers are required if another site avoiding violations cannot be selected. All waivers to the NAVFAC UFC program are contained in MIL-STD 3007. However, a joint process using the NAVAIR IBONS system has been developed to satisfy the NAVFAC Mil-STD process and the NAVAIR process since it will also be necessary to seek a NAVAIR Airfield Safety Waiver to support the NAVFAC UFC Waiver (see Paragraph B1-3.2.2).

For additional information about the NAVFAC Site Approval Request (SAR) process, copies of policies, Asset Management Bulletins, and latest Installation Site Approval Request Team (ISART) Resource, in addition to links to relevant NAVFAC Business Management Systems (e.g. Standard BMS, Airfield Safety BMS), and Points of Contact (POCs), etc., visit the SAR process website on the NAVFAC portal, at:

https://hub.navfac.navy.mil/webcenter/portal/am/page1848/

NOTE: Authorized DOD personnel must have a CAC card. When prompted, you may utilize the name and email address of the NAVFAC SAR Process program manager to obtain access to the HQ NAVFAC website.

B1-3.2.2 NAVAIR Airfield Safety Waivers.

NAVAIR Airfield Safety Waivers are temporary or permanent waivers to criteria which incorporate air operations safety and risk considerations and operational mitigations. It is acknowledged that NAVAIR is the authority for Airfield Safety and shares this UFC for the purposes of managing the NAVAIR Airfield Safety Waiver Program. Generally, it is necessary to seek NAVAIR waivers during the site planning/approval, design, and construction phases or for existing facilities and other situations as defined by CNIC (per NAVAIR 00-80T-124 NATOPS Air Operations Manual) and other NAVAIR policies. The NAVAIR IBONS system can be used to request both a NAVFAC and NAVAIR waiver or just a NAVAIR waiver depending on the situation.

The joint NAVFAC/NAVAIR process is under development and if not available, separate waivers using separate processes must be sought. For IBONS Access: Go to the following link : https://ibons.navair.navy.mil/ibons

Must have CAC and utilize your CAC for log in.

Go to "Get an entry URL"

Complete the information and submit.

Access will be granted within 24 hours.

B1-3.3 Exceptions from Waivers.

See Chapter 2 for Navy and Marine Corps facilities excepted from waivers.

APPENDIX B
SECTION 2
LAND USE AND FACILITY SPACE -- ALLOWANCES

B2-1 APPLICABILITY.

B2-1.1 Army.

For Army facility space allowances, see DAPAM 415-28, *Guide to Army Real Property Category Codes*.

B2-1.2 Air Force.

For Air Force facility space allowances, see AFI 32-1024, *Standard Facility Requirements* and AFH 32-1084, *Facility Requirements*.

B2-1.3 Navy and Marine Corps.

This section does not apply to the Navy and Marine Corps. For Navy and Marine Corps facility space allowances, see UFC 2-000-05N, *Facility Planning for Navy and Marine Corps Shore Installations*.

This Page Intentionally Blank

APPENDIX B
SECTION 3
DOD AIR INSTALLATIONS COMPATIBLE USE ZONES

B3-1 REFERENCES.

Refer to the following documents for the latest guidance on air installation land use compatibility guidelines. Also, refer to paragraph 3-12 and Table 3-5 for additional information on the graded area of clear zones.

B3-1.1 DoD.

DoDI 4165.57 provides the DoD policy for Service AICUZ program management.

B3-1.2 Air Force.

Air Force land use guidelines are provided in AFI 32-7063 and AFH 32-7084.

B3-1.3 Navy and Marine Corps.

For Navy and Marine Corps installations, see OPNAVINST 11010.36C/MCO 11010.16 (or latest version).

APPENDIX B
SECTION 4
WIND COVERAGE STUDIES

B4-1 APPLICABILITY.

B4-1.1 Army.

One factor in the determination of the runway and helipad orientation is wind coverage, as discussed in Chapter 3. Runway and helipad orientation based on wind coverage for Army airfields will be determined in accordance with the methodology presented in FAA AC 150/5300-13, Appendix 1, "Wind Analysis." The runway or helipad orientation should obtain 95 percent wind coverage with a 19.5 kilometer-per-hour (10.5 knot) crosswind. If this coverage cannot be attained, a crosswind runway would be desirable.

B4-1.2 Air Force.

One factor in the determination of the runway orientation is wind coverage, as discussed in Chapter 3. Runway orientation based on wind coverage for Air Force airfields will be determined in accordance with the methodology presented in FAA AC 150/5300-13, Appendix 1, "Wind Analysis." Criteria for crosswind runway authorization will be in accordance with criteria presented in AFH 32-1084. AF/A3O, Director of Operations, must approve authorization for crosswind runways.

B4-1.3 Navy and Marine Corps.

Runway orientation for Navy and Marine Corps airfields will be determined in accordance with this section. Criteria for the crosswind runways are found in paragraph B4-6.

B4-2 OBJECTIVE.

This section provides guidance on the assembly and analysis of wind data to prepare a wind coverage study to determine runway and helipad orientation. It also provides guidance on analyzing the operational impact of winds on existing runways and helipads.

B4-3 GENERAL.

A factor influencing runway and helipad orientation is wind. Ideally, a runway or helipad should be aligned with the prevailing wind. Wind conditions affect all airplanes in varying degrees. Generally, the smaller the airplane, the more it is affected by wind, particularly crosswind components.

B4-3.1 Basic Conditions.

The most desirable runway or helipad orientation based on wind is the one which has the largest wind coverage and minimum crosswind components. Wind coverage is that percent of time crosswind components are below an acceptable velocity. The desirable wind coverage for an airport is 95 percent, based on the total number of weather observations.

B4-3.2 Meteorological Conditions.

The latest and best wind information should be used to carry out a wind coverage study. A record which covers the last five consecutive years of wind observations is preferred. Ascertain frequency of occurrence, singly and in combination, for wind (direction and velocity), temperature, humidity, barometric pressure, clouds (type and amount), visibility (ceiling), precipitation (type and amount), thunderstorms, and any other unusual weather conditions peculiar to the area.

B4-3.2.1 Usable Data.

Use only data which give representative average values. For example, do not consider extremes of wind velocity during infrequent thunderstorms of short duration.

B4-3.2.2 Source of Data.

Obtain meteorological data from one or more of the following sources:

- National Oceanic and Atmospheric Administration, Environmental Data Service
- National Weather Service
- Bureau of Reclamation
- Forest Service
- Soil Conservation Service
- Federal Aviation Administration
- Army Corps of Engineers
- Navy Oceanographic Office
- Geological Survey
- US Air Force

B4-4 WIND VELOCITY AND DIRECTION.

The following are the most important meteorological factors determining runway and helipad orientation:

B4-4.1 Composite Windrose.

When weather recording stations are located near a proposed site and intervening terrain is level or slightly rolling, prepare a composite windrose from data of surrounding stations.

B4-4.2 Terrain.

If intervening terrain is mountainous or contains lakes or large rivers, allow for their effects on wind velocities and directions by judgment, after study of topographical information and available meteorological data.

B4-4.3 Additional Weather Data.

Consider wind directions and velocities in conjunction with visibility, precipitation, and other pertinent weather information.

B4-4.4 Wind Distribution.

Determine wind distribution to accompany instrument flight rule (IFR) conditions when considering orientation of an instrument runway.

B4-5 USE OF WINDROSE DIAGRAMS.

Prepare a windrose diagram for each new runway or helipad in the planning stage or to analyze the operational impact of wind on existing runways or helipads.

B4-5.1 Drawing the Windrose.

The standard windrose (Figures B4-1 and B4-2) consists of a series of concentric circles cut by radial lines. The perimeter of each concentric circle represents the division between successive wind speed groupings. Radial lines are drawn so that the area between each successive pair is centered on the direction of the reported wind.

B4-5.2 Special Conditions.

Windrose diagrams for special meteorological conditions, such as wind velocities and directions during IFR conditions, should be prepared when necessary for local airfield needs.

B4-5.2.1 Wind Direction.

Use radial lines to represent compass directions based on true north, and concentric circles, drawn to scale, to represent wind velocities measured from the center of the circle.

B4-5.2.2 Calm Wind.

Use the innermost circle to encompass calm periods and wind velocities up to the allowable crosswind component for the airfield under consideration.

B4-5.2.3 Computations.

Compute percentages of time that winds of indicated velocities and directions occur, and insert them in the segments bounded by the appropriate radial direction lines and concentric wind velocity circles. Express percentages to the nearest tenth, which is adequate and consistent with wind data accuracy. Figure B4-3 displays a completed windrose.

Figure B4-1. Windrose Blank Showing Direction and Divisions (16-Sector [22.5°] Windrose)

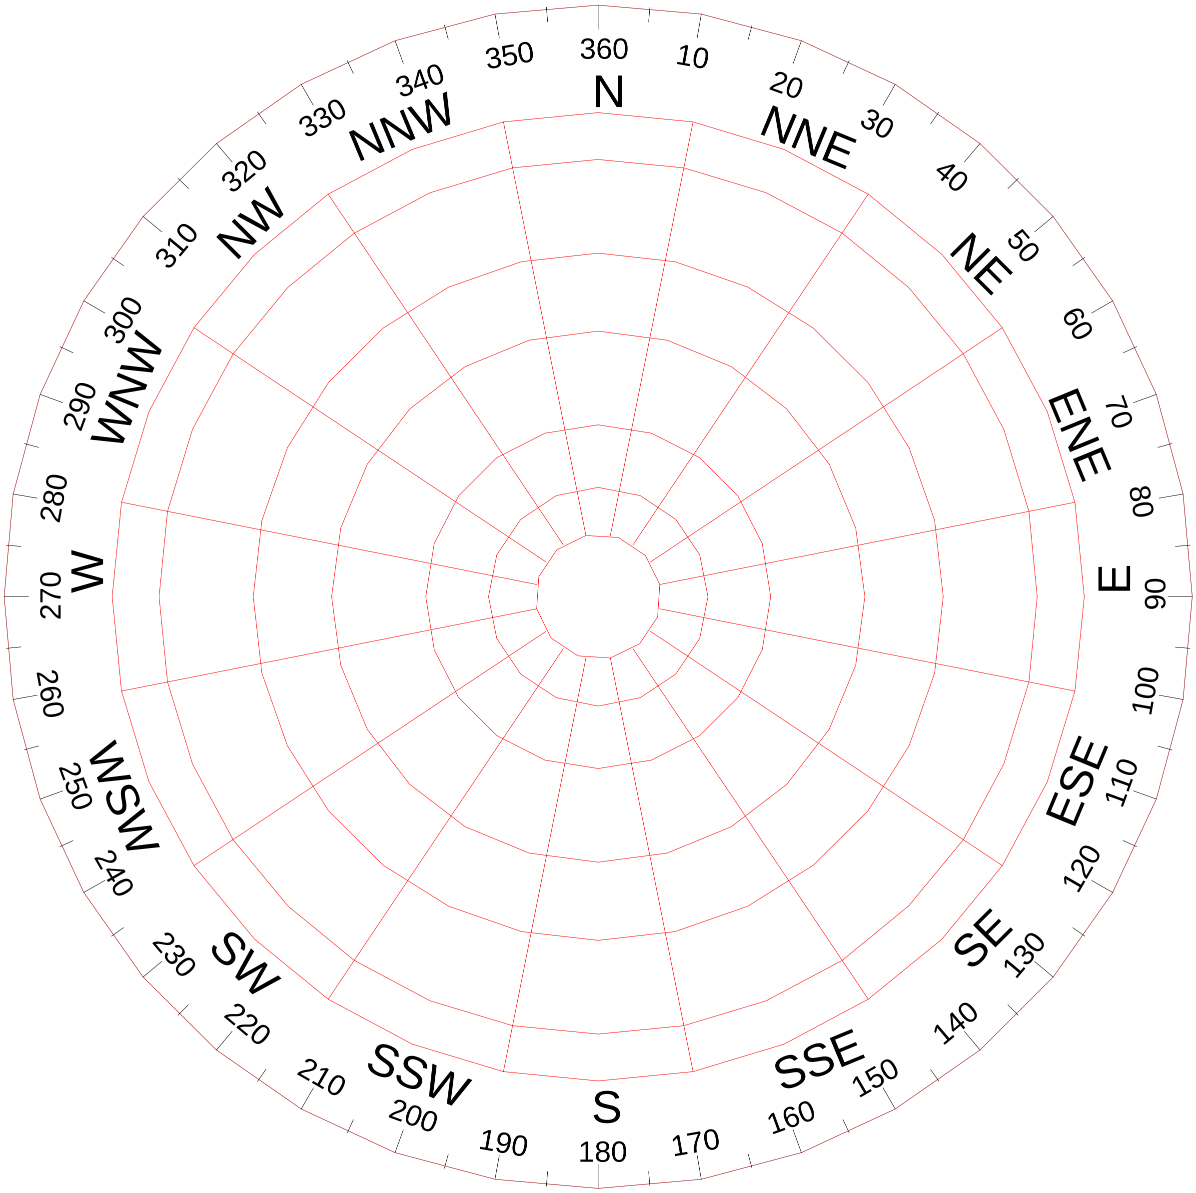

Figure B4-2. Windrose Blank Showing Direction and Divisions (36-Sector [10°] Windrose)

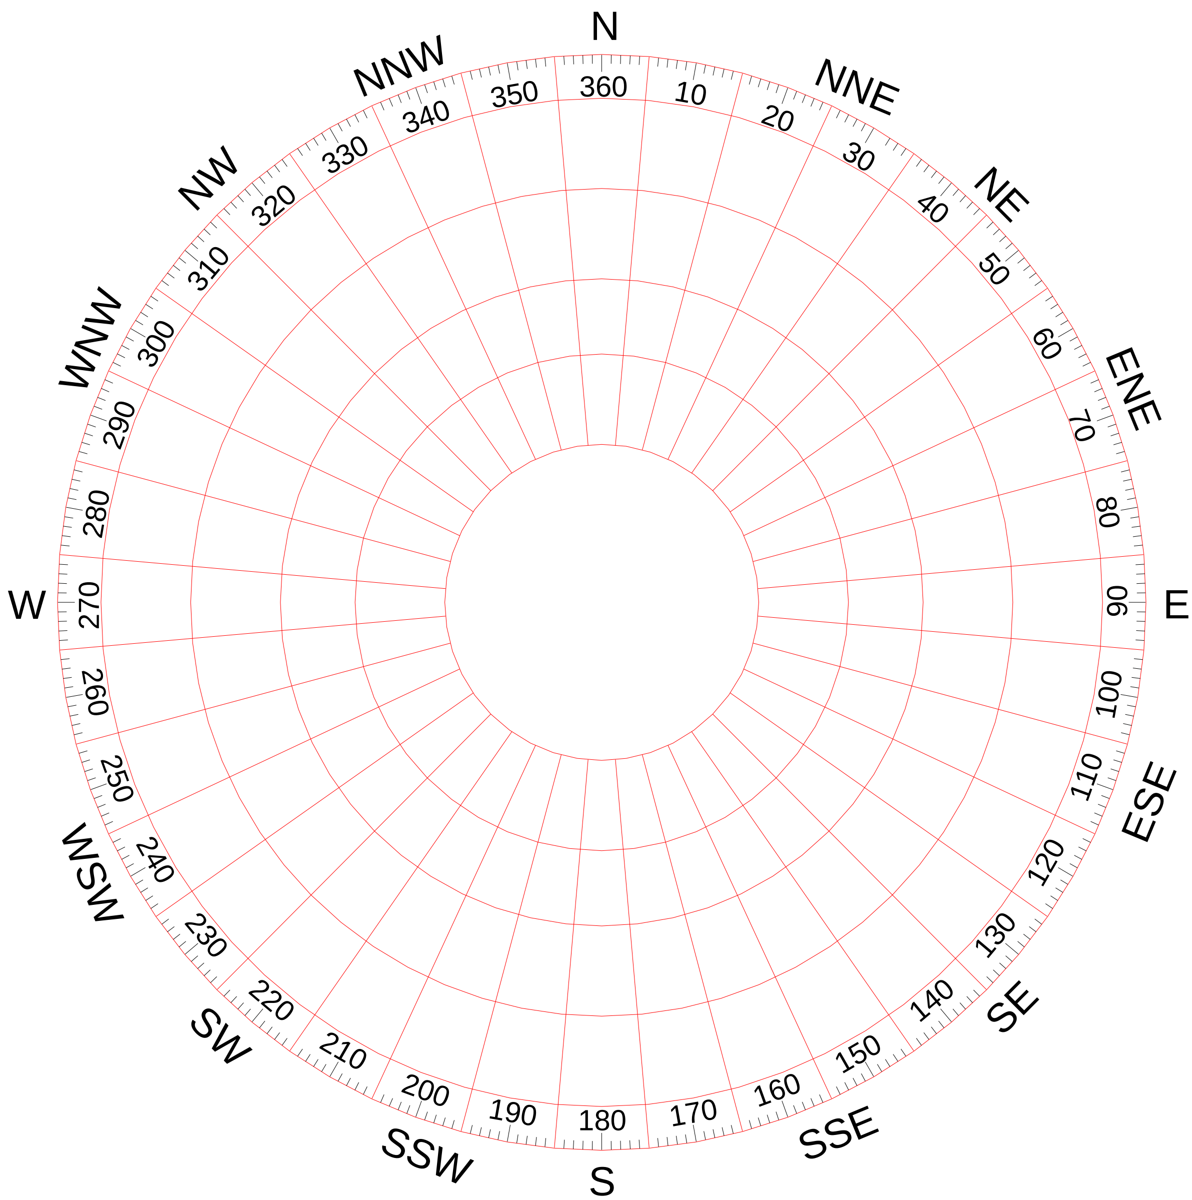

Figure B4-3. Completed Windrose and Wind Velocity Equivalents (16-Sector [22.5°] Windrose)

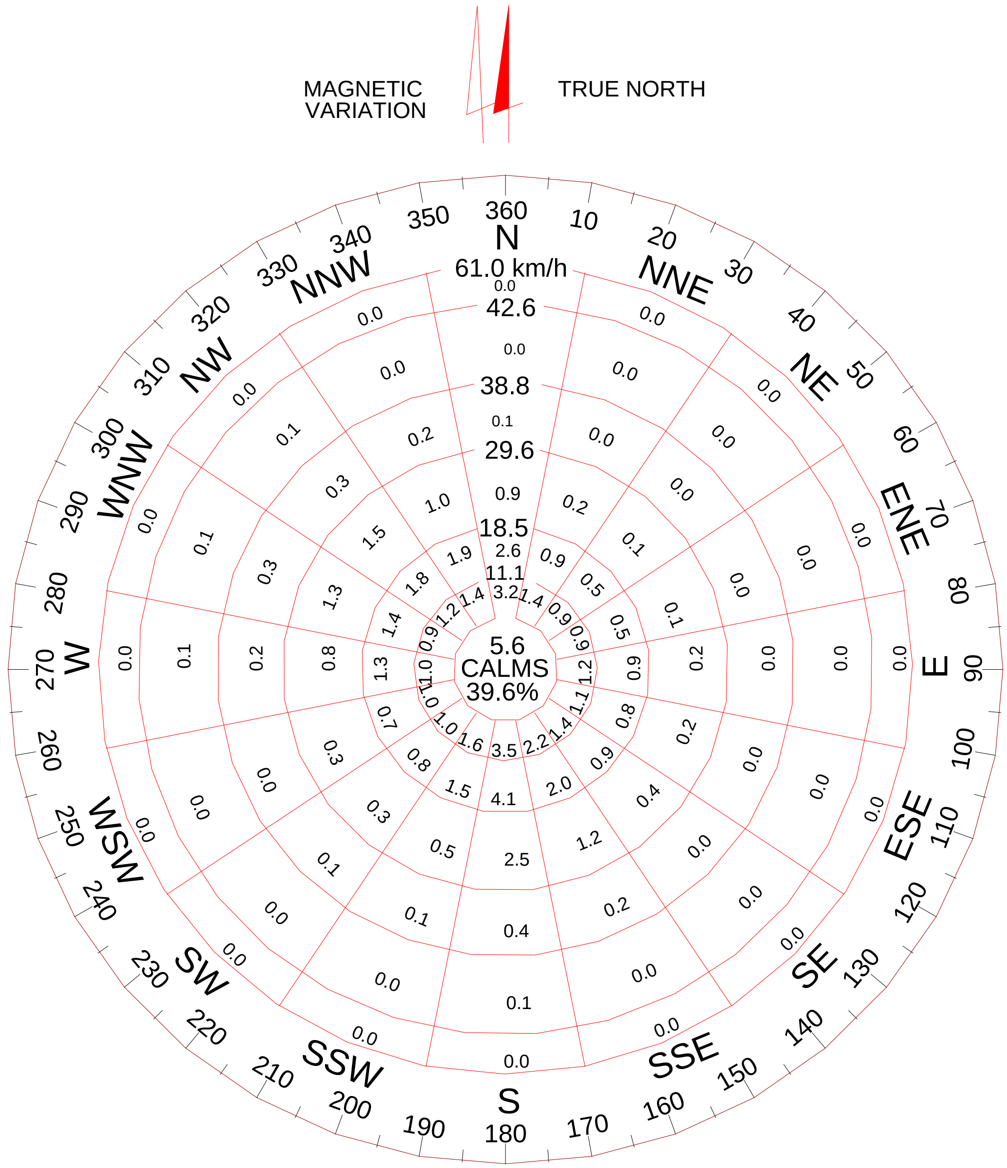


WIND VELOCITY EQUIVALENTS		
KNOTS	KM/H	MPH
3	5.6	3.5
6	11.1	6.9
10	18.5	11.5
16	29.6	18.4
21	38.8	24.2
23	42.6	26.5
33	61.0	37.9

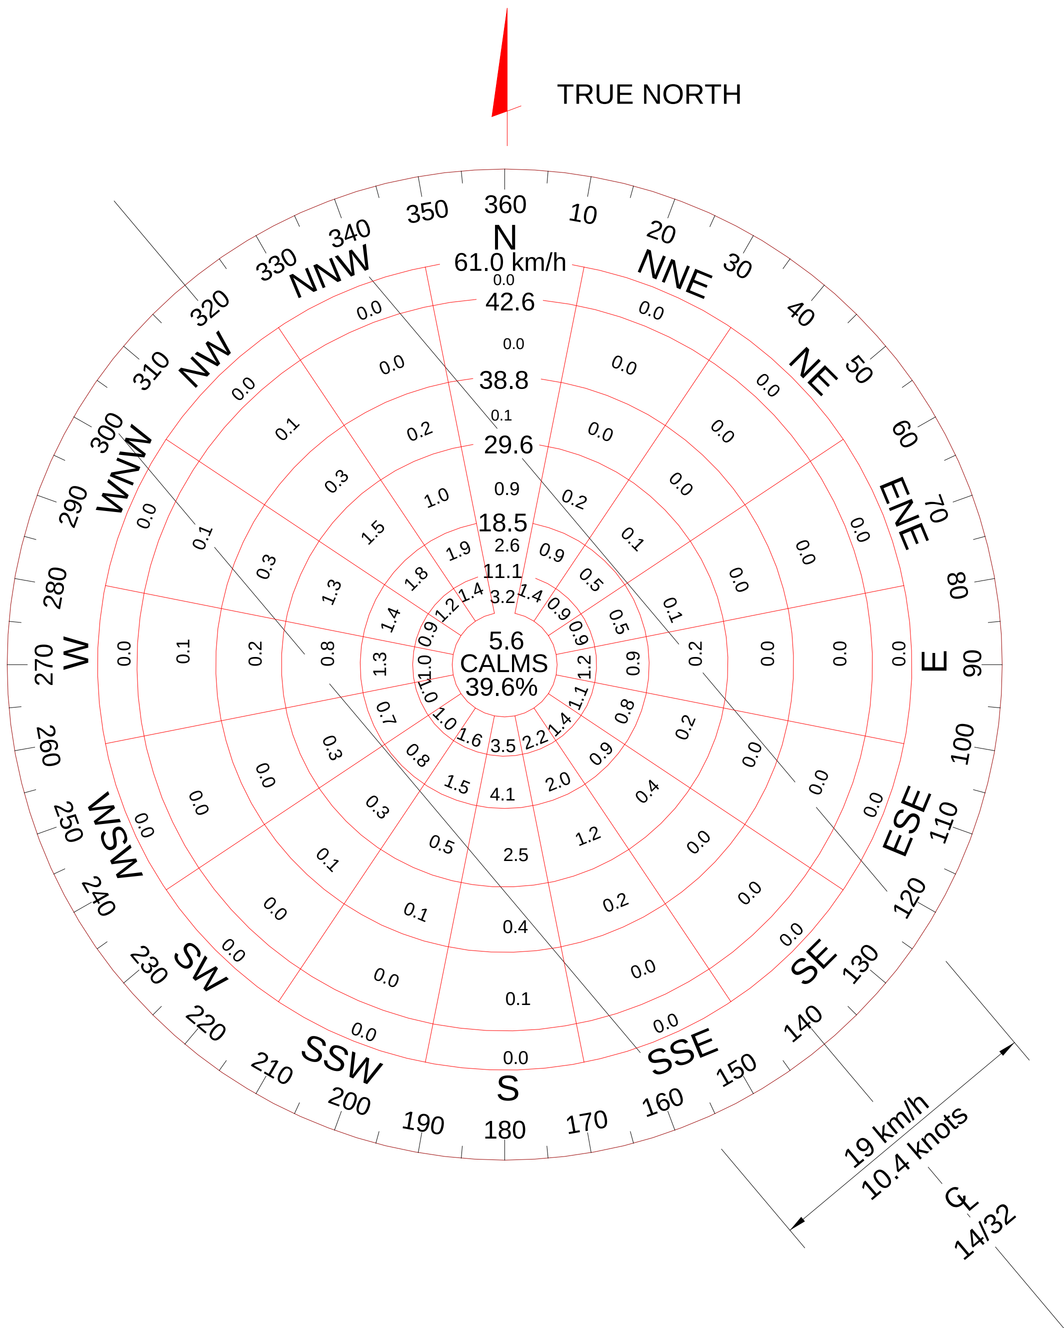
B4-5.2.4 Crosswind Template.

A transparent crosswind template is a useful aid in carrying out the windrose analysis. The template is essentially a series of three parallel lines drawn to the same scale as the windrose circles. The allowable crosswind for the runway width establishes the physical distance between the outer parallel lines and the centerline.

B4-5.3 Desired Runway or Helipad Orientation.

For the use of windrose diagrams and crosswind templates in determining desirable runway or helipad orientations with respect to wind coverage, see Figure B4-4.

Figure B4-4. Windrose Analysis



NOTE: A runway oriented 140° to 320° (true) would have 3.1 percent of winds exceeding the design crosswind component of 19 km/h.

B4-6 WIND COVERAGE REQUIREMENTS FOR RUNWAYS.

Determine the runway orientation which provides the greatest wind coverage within the allowable crosswind limits. Place runways to obtain at least 95 percent wind coverage of the maximum allowable crosswind components, as discussed in paragraph B4-6.3. It is accepted practice to total the percentages of the segments appearing outside the limit lines and to subtract this number from 100. For analysis purposes, winds are assumed to be uniformly distributed throughout each of the individual segments. The larger the area or segment, the less accurate this presumption.

B4-6.1 Primary Runways or Helipads.

Orient a primary runway or helipad for the maximum possible wind coverage. See Figure B4-4 for the method of determining wind coverage.

B4-6.2 Secondary Runways.

Where wind coverage of the primary runway is less than 95 percent, or in the case of some localities where during periods of restricted visibility the wind is from a direction other than the direction of the primary runway, a secondary (crosswind) runway is required. Normally, secondary runways will not be planned without prior authorization from Naval Air Systems Command. The secondary runway will be oriented so that the angle between the primary and secondary runway centerline is as near 90 degrees as is feasible, considering local site conditions and the need to provide maximum crosswind coverage.

B4-6.3 Maximum Allowable Crosswind Components (Navy Only).

Select these components according to type of aircraft, as follows: (1) tricycle gear aircraft, 28.0 kilometers per hour (15.0 knots); and (2) conventional gear aircraft, 19.5 kilometers per hour (10.5 knots).

B4-6.4 Allowable Variations of Wind Direction.

See Figure B4-5 for allowable wind directions.

Figure B4-5. Allowable Wind Variation for 19 Kilometer-per-Hour (10.4 Knot) and 28 Kilometer-per-Hour (15 Knot) Beam Wind Components

APPENDIX B
SECTION 6
AIRCRAFT CHARACTERISTICS FOR AIRFIELD-HELIPORT DESIGN AND EVALUATION

B6-1 GENERAL.

Aircraft characteristics, including aircraft dimensions, weights, and other information for Military Aircraft are available in Technical Report TSC 13-2, and for Selective Commercial Aircraft are available in Technical Report TSC 13-3. Both documents are available at https://transportation.erdc.dren.mil/tsmcx/criteria.aspx. This ETL is not all-inclusive. Refer to the Mission Design Series (MDS) Facilities Requirements Document (FRD) for late model aircraft characteristics.

This Page Intentionally Blank

APPENDIX B
SECTION 7
JET BLAST EFFECTS

B7-1 CONTENTS.

Jet blast affects various operational areas at an airport. Personnel safety is a major concern in terminal, maintenance, and cargo areas.

B7-2 CONSIDERATIONS.

The effects of jet blast are far more serious than those of prop wash and must be considered when designing aircraft parking configurations for all military and civil aircraft. These high velocities are capable of causing bodily injury to personnel, damage to airport equipment, or damage to certain pavements and other erodible surfaces.

B7-2.1 Blast Temperatures.

High temperatures are also a by-product of jet exhaust. The area exposed to hazardous high temperatures is typically smaller than the area subjected to hazardous blast velocities.

B7-2.2 Blast Velocities.

Blast velocities greater than 48 kilometers per hour (30 miles per hour) can cause loose objects on the pavement to become airborne and injure personnel who may be a considerable distance behind the aircraft. The layout of aviation facilities must protect personnel from projectiles.

B7-2.3 Minimum Clearances.

The minimum clearance from the rear of a jet operating at military power to dissipate the temperature and velocity to levels that will not endanger aircraft personnel and damage other aircraft is referred to as the safe distance. Safe distances are discussed in paragraph B7-5.

B7-2.4 Engine Blast Relationship.

Each jet engine has its own footprint of temperature and velocity versus distance. Jet blast relationships for Army, Air Force, and selected civil aircraft may be obtained from the source listed in Appendix B, Section 6, or from the Facilities Requirements Document (FRD) for the specific Mission Design Series (MDS). The relationships are in graphical format showing velocity versus distance and temperature versus distance at various power settings. The planner/designer should obtain the jet blast relationship when the effects of jet blast could create a hazardous condition for personnel and equipment.

B7-3 PROTECTION FROM JET BLAST EFFECTS.

B7-3.1 Blast Deflectors.

Equipment such as blast deflectors may be required at locations where continued jet engine run-up interferes with the parking or taxiing of aircraft, the movement of vehicles, and the activities of maintenance or aircraft personnel. Additional information on jet blast deflectors is presented in Appendix B, Section 8.

B7-3.2 Unprotected Areas.

Unprotected areas of the airfield which receive continued exposure to jet blast can erode and cause release of soil, stones, and other debris that can be ingested into jet engines and cause engine damage.

B7-3.3 Minimum Distances for Run-Up.

See Appendix B, Section 12 for minimum distances from the rear of jet aircraft to the edge of adjacent asphalt pavements. Run-up pads must be sized to provide a minimum of 7.62 meters (25 feet) of Portland cement concrete (PCC) aft of the aircraft fuselage to prevent damage to the aircraft in the event the pavement fails due to jet blast.

B7-4 NOISE CONSIDERATIONS.

Protection against noise exposure is required whenever the sound level exceeds 85 dB(A) continuous, or 140 dB(A) impulse, regardless of the duration of exposure.

B7-5 JET BLAST REQUIREMENTS.

B7-5.1 Parked Aircraft.

A minimum clearance (safe distance) is needed to the rear of an engine to dissipate jet blast to less than 56 kilometers per hour (35 miles per hour) and jet exhaust temperatures to 38 degrees Celsius (100 degrees Fahrenheit) or ambient, whichever is more—otherwise, a jet blast deflector is needed. Velocities of 48 kilometers per hour (30 miles per hour) to 56 kilometers per hour (35 miles per hour) can occur over 490 meters (1,600 feet) to the rear of certain aircraft with engines operating at takeoff thrust. However, these velocities decrease rapidly with distance behind the jet engine.

B7-5.2 Taxiing Aircraft.

The distance from the rear of the aircraft engine to the wingtip of other aircraft will be:

- A distance such that jet blast temperature will not exceed 38 degrees Celsius (100 degrees Fahrenheit);
- A distance such that jet blast velocity will not exceed 56 kilometers per hour (35 miles per hour).

APPENDIX B
SECTION 8
JET BLAST DEFLECTOR

B8-1 OVERVIEW.

Jet blast deflectors can substantially reduce the damaging effects of jet blast on structures, equipment, and personnel. Jet blast deflectors can also reduce the effects of noise and fumes associated with jet engine operation. Erosion of shoulders not protected by asphaltic concrete surfacing can be mitigated by blast deflectors. Blast deflectors consist of a concave corrugated sheet metal surface, with or without baffles, fastened and braced to a concrete base to withstand the force of the jet blast and deflect it upward.

B8-1.1 Location.

The deflector is usually located 21 meters (70 feet) to 37 meters (120 feet) aft of the jet engine nozzle, but not less than 15 meters (50 feet) from the tail of the aircraft.

B8-1.2 Size and Configuration.

Size and configuration of jet blast deflectors are based on jet blast velocity and location and elevation of nozzles. Commercially available jet blast deflectors should be considered when designing jet blast protection.

B8-1.3 Paved Shoulders.

For blast deflectors placed off the edge of a paved apron, a paved shoulder is required between the blast deflector and the edge of the paved apron.

This Page Intentionally Blank

APPENDIX B
SECTION 9
EXPLOSIVES ON OR NEAR AIRFIELDS

B9-1 CONTENTS.

All explosives locations, including locations where aircraft loaded with explosives are parked, must be sited in accordance with DoD Standard 6055.09-M and applicable Service explosives safety regulations. Explosives site plans, approved through command channels to DoD, ensure that minimal acceptable risk exists between explosives and other airfield resources. To prevent inadvertent ignition of Electrically Initiated Devises (EID), separation between sources of electromagnetic radiation is required. Separation distances must be according to safe separation distance criteria. Grounding requirements, lightning protection, and further considerations for explosives on aircraft are presented below.

B9-2 SEPARATION DISTANCE REQUIREMENTS.

See Chapter 1, Paragraph 1-4.1 for explosive safety criteria requirements and other facility design criteria.

B9-3 PROHIBITED ZONES.

Explosives, explosive facilities, and parked explosives-loaded aircraft (or those being loaded or unloaded) are prohibited from being located in Accident Potential Zones (APZ) I and II and clear zones as set forth in AR 385-10; DAPAM 385-64, Chapter 5; AFMAN 91-201; and AFI 32-7063.

B9-4 HAZARDS OF ELECTROMAGNETIC RADIATION TO EID.

EID on aircraft are initiated electrically. The accidental firing of EID carried on aircraft initiated by stray electromagnetic energy is a possible hazard on an airfield. A large number of these devices are initiated by low levels of electrical energy and are susceptible to unintentional ignition by many forms of direct or induced stray electrical energy, such as radio frequency (RF) energy from ground and airborne emitters (transmitters). Additional sources of stray electrical energy are lightning discharges, static electricity or triboelectric (friction-generated) effects, and the operation of electrical and electronic subsystem onboard weapon systems. AFMAN 91-201 should be used as a guide in setting up safe separation between aircraft loaded with EID.

B9-5 LIGHTNING PROTECTION.

Lightning protection must be installed on open pads used for manufacturing, processing, handling, or storing explosives and ammunition. Lightning protection systems must comply with DoD 6055.09-M; AFM 88-9CH3/TM 5-811-3; AFI 32-1065; and National Fire Protection Association (NFPA) 780.

B9-6 GROUNDING OF AIRCRAFT.

Aircraft that are being loaded with explosives must be grounded at all times. Air Force grounding of aircraft will be in accordance with AFMAN 91-201 and applicable weapons systems technical orders (T.O.).

B9-7 HOT REFUELING.

Hot refueling is the transfer of fuel into an aircraft with one or more engines running. The purpose of hot refueling is to reduce aircraft ground time, personnel and support equipment requirements, and increase system reliability and effectiveness by eliminating system shut-down and restart. All hot refueling locations must be sited in accordance with DoD 6055.09-M and applicable Service explosives safety criteria.

APPENDIX B
SECTION 10
COMPASS CALIBRATION PAD MAGNETIC SURVEY

B10-1 CONTENTS.

This section describes the procedures for performing a magnetic survey for new or existing compass calibration pad (CCP) by a state-registered land surveyor. These surveys will determine the following:

- Suitability of a particular site for use as a CCP.
- Variations of the magnetic field within the surveyed area.
- Magnetic declination of the area at the time of the survey.

B10-2 AIR FORCE REQUIREMENTS.

Air Force designers may use these criteria or the criteria given in Appendix 4 of FAA Advisory Circular (AC) 150/5300-13 (see paragraph 6-11.2).

B10-3 CCP SURVEY AUTHORITIES AND RESOURCES.

Many resources are available to perform CCP surveys including Registered Land Surveyors. However, additional government resources exist including:

U.S. Geological Survey

The U.S. Geological Survey (USGS) of the Department of Interior is available to provide information to airports and others on the necessary surveys and equipment to certify a compass rose. In addition, the USGS is available to calibrate magnetometers and other suitable instruments used to measure the magnetic field. The instruments are necessary to determine the difference between true and magnetic north and the uniformity of the magnetic field in the area of a compass calibration pad and must be regularly calibrated to make accurate measurements. The cost for calibration service is only that necessary to cover the cost. Requests for this service should be made to the following:

U.S. Geological Survey
Geomagnetism Group
Box 25046, MS 966
Denver, CO 80225
website: https://www.geomag.usgs.gov

National Geospatial-Intelligence Agency (NGA)

The NGA has capabilities to perform CCP surveys as well as other services. Each DoD branch of service must contact their respective representative to request compete their project need.

Navy Contact in NGA:
GI&S Officer
OPNAV N2N6E4 PNT
Pentagon, 1D479
571-256-8222

For the Navy, additional technical resources may be available from Naval Air Technical Data and Engineering Services Center (NATEC). See additional guidance in NAVAIR 05-15C-2 OPERATION, ORGANIZATIONAL AND INTERMEDIATE MAINTENANCE WITH ILLUSTRATED PARTS BREAKDOWN: A/E36T-2 MAGNETIC COMPASS CALIBRATOR SET or contact Naval Air Technical Data and Engineering Services Center (NATEC).

B10-4 CCP SURVEY ACCURACY REQUIREMENTS.

For the purpose of this survey, final calculations should be reported to the nearest one minute (1') of arc with an accuracy of ±10 minutes (10'). Typically, magnetic variations can be determined to the nearest 30 minutes (30') of arc by using a conventional transit with a compass. The finer precision needed for these surveys may be obtained by taking a minimum of three readings at each site and then reporting their average. All azimuths must be established by the Global Positioning System (GPS) or Second Order Class II conventional control survey referenced to known positions within the North American Datum of 1983 (NAD83) adjustment network, or convert host nation datum to World Geodetic System 1984 (WGS-84).

B10-5 PRELIMINARY SURVEY REQUIREMENTS.

Preliminary surveys are conducted for proposed sites to determine that the areas are magnetically quiet and thus suitable for a CCP. They are also used to determine if newly constructed items within the influence zone (see paragraph B10-10.1) of an existing CCP are causing magnetic interference. When siting a new CCP, the location should be chosen such that all separation distances, as defined in paragraph B10-10.1, are allowed for to the greatest extent practical. A preliminary magnetic survey will then be conducted to determine if the area is magnetically quiet with no natural or manmade magnetic disturbances. When conducting the preliminary survey, the surveyor must immediately notify the agency requesting the survey of any areas they find that are causing magnetic interferences so they can try to identify and remove the interference and also determine if the survey should continue any further. The location of the anomaly can be pinpointed by taking readings at additional points around the disturbed area and finding the location with the highest disturbance. If the magnetic anomaly cannot be removed and the site made magnetically quiet, then a new site will need to be chosen. One of the following methods is suggested for a preliminary survey.

B10-5.1 Proton Magnetometer Method.

A proton magnetometer can be used by walking over the area and making observations approximately every 6 meters (20 feet) in a grid pattern covering the site. If the values measured do not vary from any other reading by more than 25 gammas for the whole area, then the site can be considered magnetically quiet.

B10-5.2 Distant Object Method.

A distant landmark is selected for siting from the various points, 6-meter (20-foot) grid pattern, of the area being checked. A second distant object at approximately 90 degrees (90º) can also be chosen to increase accuracy. The further away the distant object is, the wider an area of points that can be compared to each other and still obtain the accuracy needed. An 8-kilometer (5-mile) -distant object will allow a comparison of magnetic declinations of points within a 24-meter (80-foot) -wide path in the direction of the distant object; while a 24-kilometer (15-mile) -distant object will allow a comparison of points within a 73-meter (240-foot) width, or effectively, the whole CCP site. If the magnetic declinations of the different points vary by more than 12 minutes (12') of arc then the site is not magnetically quiet.

B10-5.3 Reciprocal Observation Method.

Several scattered points are selected and marked in the area to be tested. The transit is set up over one central point and the magnetic azimuth to all of the other points is determined and recorded. Then the transit is set up over all the other points and a back azimuth to the central point is determined and recorded. If there are no magnetic disturbances then the original azimuth and the back azimuth should be the same for each of the points checked. If there is a difference between the azimuth and back azimuth of any of the points which is greater than 12 minutes (12') of arc, then the site is not magnetically quiet.

B10-6 MAGNETIC SURVEY REQUIREMENTS.

See paragraph 6-11 for CCP initial, re-surveying, and re-marking requirements.

B10-7 MAGNETIC SURVEY PROCEDURES.

These procedures consist of the magnetic field survey used to determine the magnetic declination of a site and the magnetic direction survey used to lay out the CCP markings. Both a magnetic field survey and a magnetic direction survey of the CCP will be performed at the frequency defined in Chapter 6 and when magnetic influences have occurred within or adjacent to the CCP. Magnetic influences are considered to be additions of power lines, installation of items containing ferrous metals, or similar activities within an influencing distance of the CCP as defined in paragraph B10-10.1.

B10-7.1 Magnetic Field Survey.

This survey is to measure the magnetic declination within the CCP area. The surveyor will be required to certify that the variations of the magnetic field are within the allowable range and to provide the average magnetic declination of the area. The direction of the horizontal component of the Earth's magnetic field (magnetic declination) measured at any point within a space between 0.6 meter (2 feet) and 1.8 meters (6 feet) above the surface of the CCP and extending over the entire area of the CCP must not differ by more than 12 minutes (12') of arc from the direction measured at any other point within this area. All raw data, intermediate computations, and final results shall be submitted in a clear, neat, and concise format. The surveyor shall accurately lay out a 6-meter by 6-meter (20-foot by 20-foot) grid with its center point coincident with the center point of the CCP. The grid will be laid out so the entire area of the CCP plus a minimum of 6 meters (20 feet) outside each edge of the CCP is covered. The grid may be laid out in any direction, but a true north or a magnetic north direction is preferred since it will simplify the azimuth calculations and allow immediate recognition of points outside the allowable declination limits. In any case, the surveyor shall determine the true azimuth of the grid layout by standard surveying procedures so the azimuth and declination of each point can be determined. After the grid is laid out, the surveyor shall check the declination of all the grid points by one of the following methods:

B10-7.1.1 Distant Object Method.

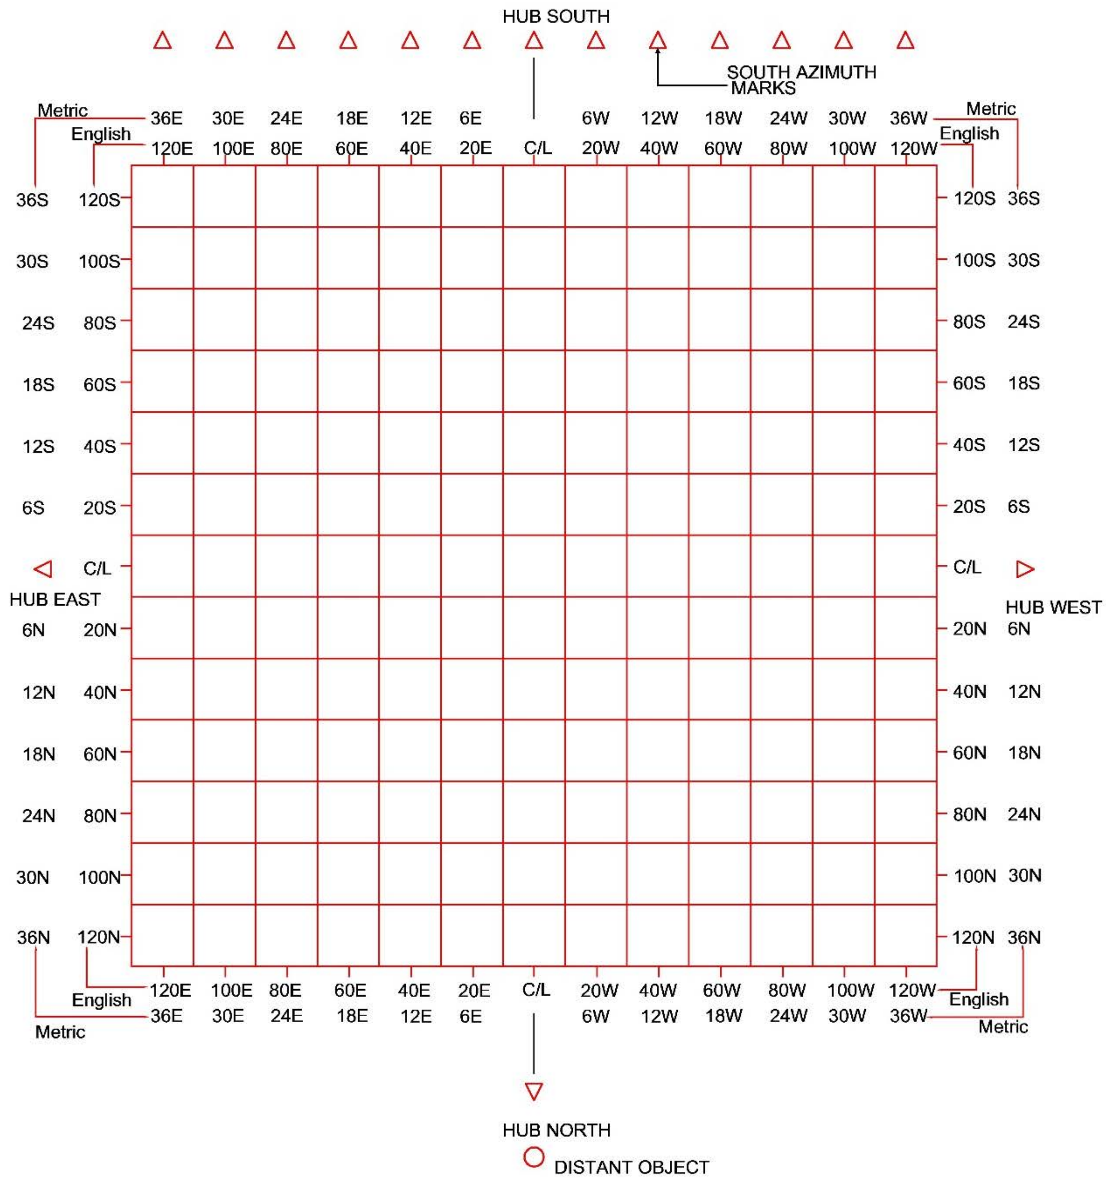
A distant landmark is selected for siting from the various points of the area being checked. A second distant object at approximately 90 degrees (90º) can also be chosen to increase accuracy. The further away the distant object is, the wider an area of points that can be compared to each other and still obtain the accuracy needed. An 8-kilometer (5-mile) -distant object will allow a comparison of magnetic declinations of points that are within a 24-meter (80-foot) -wide path in the direction of the distant object; while a 24-kilometer (15-mile) -distant object will allow a comparison of points within a 73-meter (240-foot) width, or effectively, the whole CCP site. If a distant object cannot be chosen far enough away to accurately compare the whole sight (at no time will a distant object be closer than 8 kilometers [5 miles]), then corrections for the eccentricity would have to be made. If the grid were laid out so its center was in line with the distant object and an equal number of points were laid out on either side of this centerline, then this eccentricity would automatically be corrected when the azimuths are averaged. But the points can only be compared to other points within the allowable path width when checking for disturbances in the declinations, unless corrections for the eccentricities are allowed for. The average value is then computed, adjusting for eccentricities if necessary, and reported as the site declination.

B10-7.1.2 Distant Hub Method.

After the grid is laid out, lay out additional hubs a minimum of 90 meters (300 feet) in all four directions from the center point of the grid and designated as "Hub N," "Hub S," "Hub E," and "Hub W." "South Azimuth Marks" are placed perpendicular to the "Hub S," 6 meters (20 feet) apart, and coincident to the grid layout, as shown in Figure B10-1.

Use these azimuth marks for sighting and taking declination readings. After the grid and azimuth marks are accurately set, the surveyor shall set up and level the transit over the center point and sight it on the "Hub S" mark and zero the vernier. The surveyor then must release the compass needle and turn the transit to center it on the compass needle while all the time tapping the compass to minimize friction effects. Take a reading here (to the nearest one minute [1']) then deflect the compass needle with a small magnet, realign the transit with the compass and take a third reading. Average these three readings to provide the declination for this spot. The surveyor shall accurately record the time to the nearest minute for the first and third reading. After the readings are completed for the center point (which will be used for reference), the surveyor shall then set up the transit over the other points of the grid and follow the same steps as above while sighting at the appropriate "Azimuth Mark" and determine the declination of each of these grid points. Approximately every 20 to 30 minutes, or any time a reading turns out to be outside the allowable 12 minutes (12') of arc, the surveyor must re-setup over the center point and take new readings to check for diurnal changes in the declination. If readings are found to be outside the allowable 12 minutes (12') of arc, after making corrections for diurnal changes, the surveyor shall set up at the bad point and re-check it to see if the results are repeatable. If all the readings are within the required 12 minutes (12') after the surveyor has made diurnal corrections, then average these readings and determine the site declination.

Figure B10-1. Magnetic Field Survey Sheet



B10-7.2 Magnetic Direction Survey.

A magnetic direction survey is an engineering survey used to establish and verify the location of control points and to layout and verify the markings for a CCP.

B10-8 CCP CONTROL POINTS.

CCP control points shall be located and verified using a magnetic direction survey.

B10-8.1 New CCP Control Points.

For new CCP, the surveyor shall determine the center of the pad and mark it with a bronze surveying marker accurately grouted in place. Stamp this point "Center of Calibration Pad." After the center point is located and set, the surveyor shall accurately locate and set the following control points and pavement markings in a similar manner. See Figures B10-2 and B10-3 for greater detail of the control point layout.

B10-8.1.1 True North and South Control Points.

Set a north and south control point on a "true north-south" line established through the center of the calibration pad marker. The north-south control points must be located radially from the center of the compass calibration pad at a distance of 9 meters (30 feet). Stamp these points "N_T" for the north point and "S_T" for the south point. Stamp the markers with "True North (South) - Established 'Day' 'Month' 'Year. ' "

B10-8.1.2 Magnetic North Control Point.

Set a magnetic north control point on the "magnetic north azimuth" as determined by the magnetic survey. The magnetic north control point must be located radially from the center of the compass calibration pad at a distance of 12 meters (40 feet). Mark this point on the pavement with a "Nm" above the point at 12.3 meters (41 feet) radially from the center point and " 'Month' 'Year' " below the point at 11.7 meters (39 feet) radially from the centerpoint. The date shall reflect when the magnetic north was established by a field magnetic survey. The markings shall consist of 300-millimeter (12-inch) -high block numerals with 75-millimeter (3-inch) -wide orange paint stripes. Stamp the bronze marker with "Magnetic North - Established 'Day' 'Month' 'Year'" and "Declination - 'Degrees' 'Minutes.' " True North-South.

B10-8.2 Type I CCP Control Points.

Type I CCPs require the Center, True North, True South, and Magnetic North Control Points described in paragraph B10-8.1. Figure B10-2 shows the control point layout for Type I CCPs.

B10-8.3 Type II CCP Control Points.

Type II CCPs require the Center, True North, True South, and Magnetic North Control Points described in paragraph B10-8.1. In addition, provide twenty-four (24) control points at 7.5 meters (25 feet) radially from the centerpoint beginning at true north and then every 15 degrees (15°). These points shall consist of bronze markers accurately grouted in place. Stamp each of these points with their true azimuth (for example, 15NT). Figure B10-3 shows the control point layout for Type II CCPs.

B10-8.4 Existing CCPs.

For existing CCP, the surveyor will be required to check the alignment of the magnetic north control point and adjust it if necessary. If the average magnetic declination, as determined by a magnetic field survey as described in paragraph B10-7.1, differs by more than 0.5 degree (30 arc-min) from what is marked on the CCP then the CCP must be re-calibrated (see Chapter 6, Paragraph 6-11). First, all magnetic markings must be removed from the pavement. Then the magnetic north control point marker must be removed and reset to the correct position as described above for a new CCP. The CCP markings are then laid out and marked as described in Paragraph B10-9.

Figure B10-2. Typical Type I Compass Rose Control Point and Marking Layout

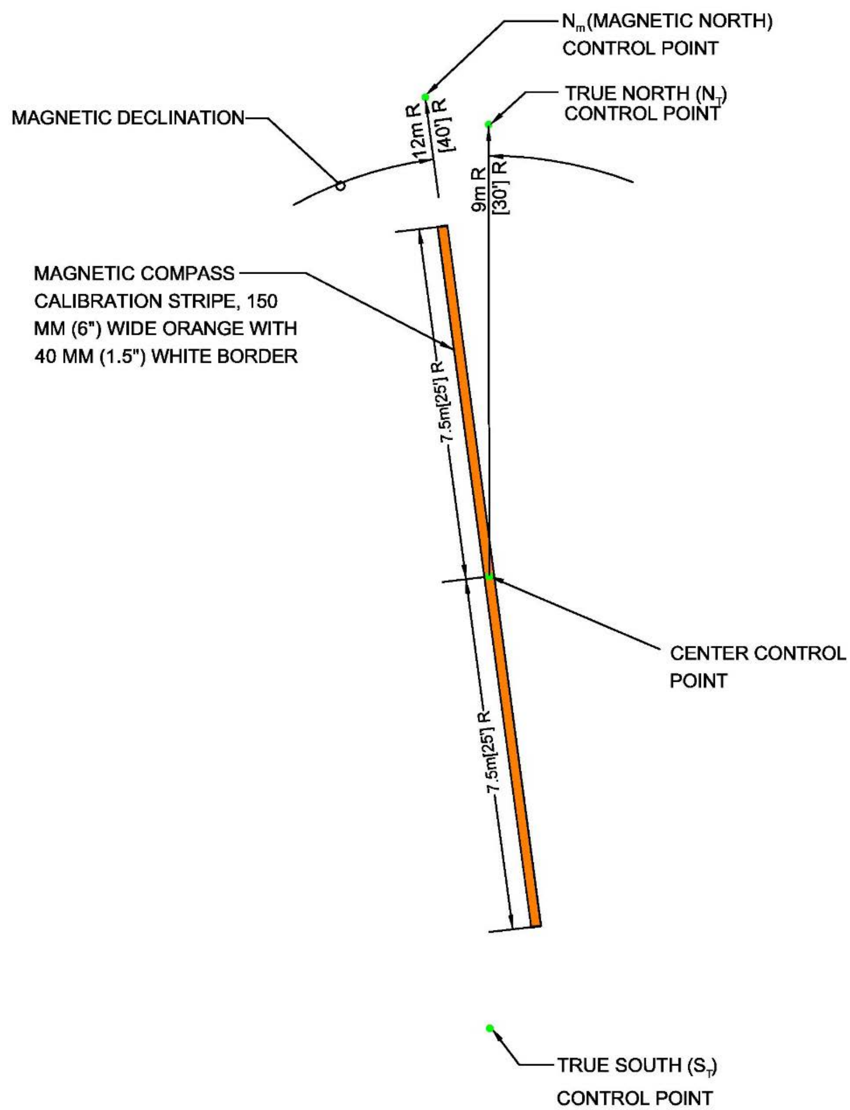


Figure B10-3. Type II Compass Rose Control Point and Marking Layout

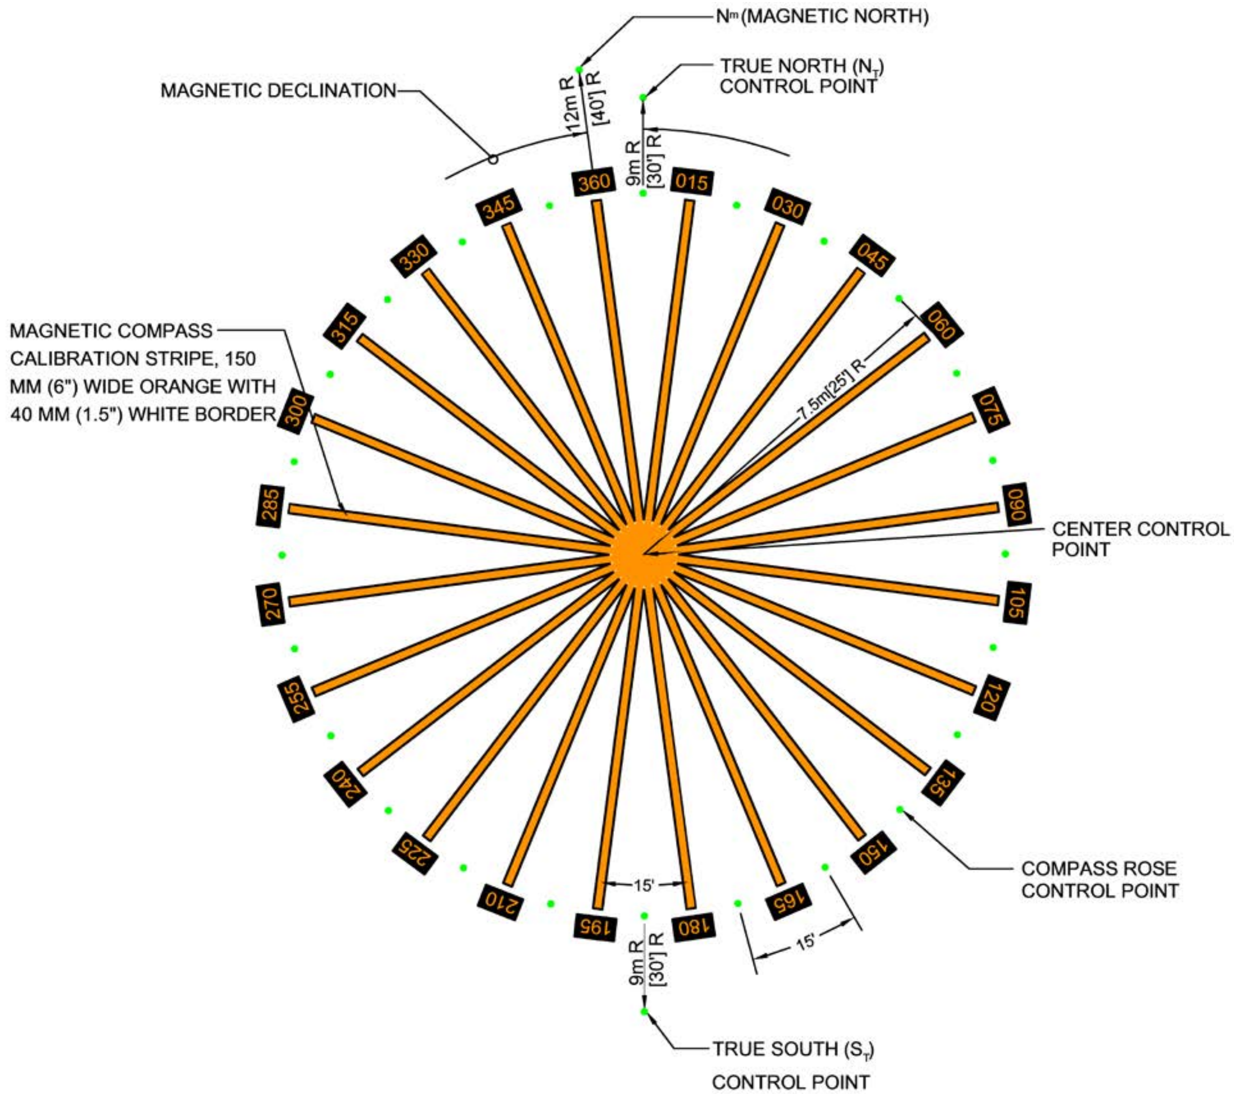

B10-9 CCP MARKINGS.

B10-9.1 Magnetic Compass Calibration Pad Type I Markings.

Type I marking should be determined by the controlling aircraft technical manual (coordinate with aircraft maintenance group to determine specific requirements). The number of lines and locations of the lines relative to each other is determined by the number of compass systems and their installation location relative to the aircraft centerline. Some aircraft types may need only 1 line, others may need 3 lines. Typical lines are 150-millimeter (6-inch) -wide orange stripes. These stripes begin at the center of the pad and extend outward for a minimum length of 7.5 meters (25 feet), aligned on the magnetic north and south control points. Border each stripe with a 40-millimeter

(1.5-inch) -wide white stripe. Where Type I and Type II pads overlap, select line colors and layout to deconflict the markings as much as possible.

B10-9.2 Magnetic Compass Calibration Pad Type II Markings.

Type II markings are set at magnetic directions from the corresponding true compass rose control point at every 15 degrees (15°). A 150-millimeter (6-inch) -wide orange stripe will be painted for each of the 24 compass rose control points. These stripes begin at the center of the pad and extend outward for a minimum length of 7.5 meters (25 feet). Border each stripe with a 40-millimeter (1.5-inch) -wide white stripe. At a distance of 8.2 meters (27 feet) from the center of the pad, identify the azimuth of each stripe as measured from magnetic north with 600-millimeter (24-inch) -high by 381-millimeter (15-inch) -wide orange block numerals. All azimuth numbers will contain 3 numerals (e.g., 045). The stroke of each numeral is a minimum of 90 millimeters (3.5 inches) wide. Each azimuth number will be painted on a solid white background formed from a rectangle 660 millimeters (26 inches) in height by 1,295 millimeters (51 inches) in width. The layout of the compass rose is detailed in Figure B10-3.

B10-9.3 Calibration Survey Data Markings.

Mark the latest survey information on the CCP pavement using black letters on a white background as shown in Figure B10-4. Update the survey data after every re-calibration.

B10-10 SITING CONSIDERATIONS.

B10-10.1 Separation Distances.

To meet the magnetically quiet zone requirements and prevent outside magnetic fields from influencing the aircraft compass calibration, all efforts possible will be taken to make sure the center of the pad meets the minimum separation distance guidelines.

The minimum recommended separation distances are as follows:

- 70 meters (230 feet) to underground metal conduits, metal piping (including reinforced concrete pipes), or similar items.
- 85 meters (280 feet) from the edge of any pavement that is not specifically designed and built for CCP operations.
- 150 meters (500 feet) to underground alternating current (AC) power lines (including runway/taxiway edge lighting).
- 185 meters (600 feet) to overhead steam lines; overhead conduits or metal piping; overhead AC power lines; any AC equipment; the nearest edge of any railroad track; the nearest fire hydrant; and the nearest portion of any building.
- 300 meters (1,000 feet) to any direct current (DC) power lines or equipment (including any underground or aboveground telephone lines).

B10-10.2 Checking Site.

Each proposed site for a CCP must be checked for magnetic influence to ensure the area is magnetically quiet, regardless of adherence to separation distances.

This Page Intentionally Blank

APPENDIX B
SECTION 11
TIEDOWNS, MOORING, AND GROUNDING POINTS

B11-1 TYPES OF EQUIPMENT.

B11-1.1 Mooring and Grounding Point.

A mooring and grounding point is a mooring casting with a grounding rod attached. Aircraft mooring and grounding points are used to secure parked aircraft and also serve as electrodes for grounding connectors for aircraft. Combined mooring and grounding points have previously been used by the Army but are not currently used as they do not meet mooring and grounding design loads required by TM 1-1500-250-23.

B11-1.2 Mooring Point.

A mooring point is a mooring casting without a grounding rod attached, used to secure parked aircraft. Mooring points are used by the Army.

B11-1.3 Static Grounding Point.

A static grounding point is a ground rod attached to a casting. The casting protects the ground rod but does not provide mooring capability. Static grounding points are used by the Army in aprons and hangars.

B11-1.4 Static Ground.

A static ground is a 3-meter (10-foot) rod with a closed-eye bend. The static ground is not intended to secure parked aircraft but may serve as an electrode connection for static grounding of aircraft. Static ground are installed at many Air Force installations.

B11-1.5 Tiedown Mooring Eye.

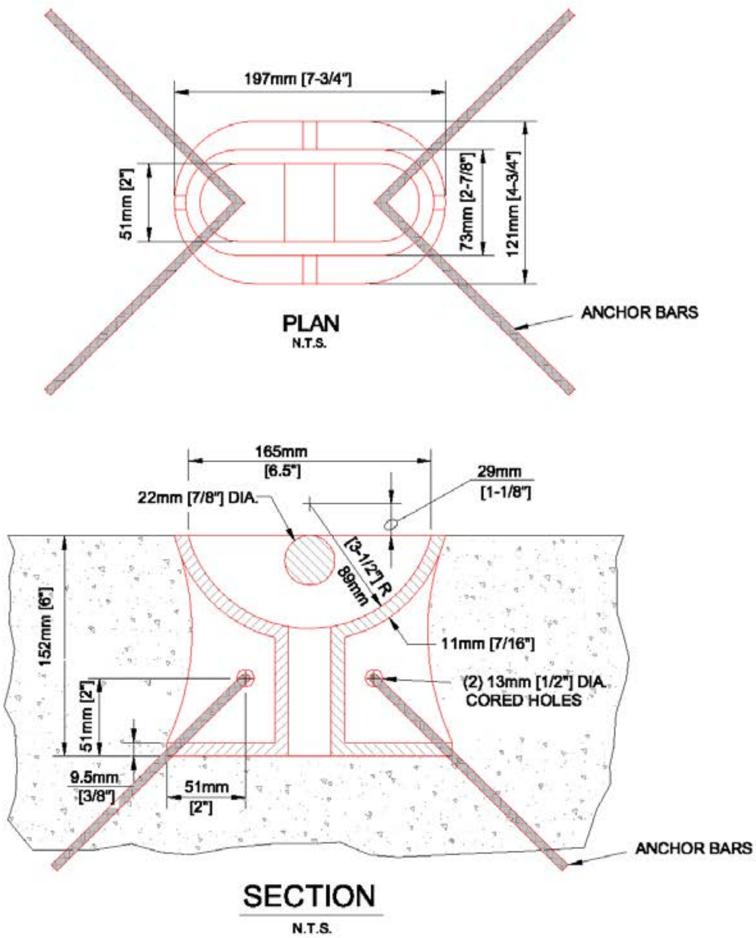
A tiedown mooring eye is a mooring casting with a grounding rod attached. They are similar to the mooring and grounding point discussed above. Tiedown mooring eyes are used by the Navy and Marine Corps.

B11-2 MOORING POINTS FOR ARMY FIXED- AND ROTARY-WING AIRCRAFT.

B11-2.1 Type.

A mooring point consists of a ductile iron casting, as shown in Figure B11-1. The mooring casting is an oval-shaped casting with a cross-rod to which mooring hooks are attached.

Figure B11-1. Army Mooring Point



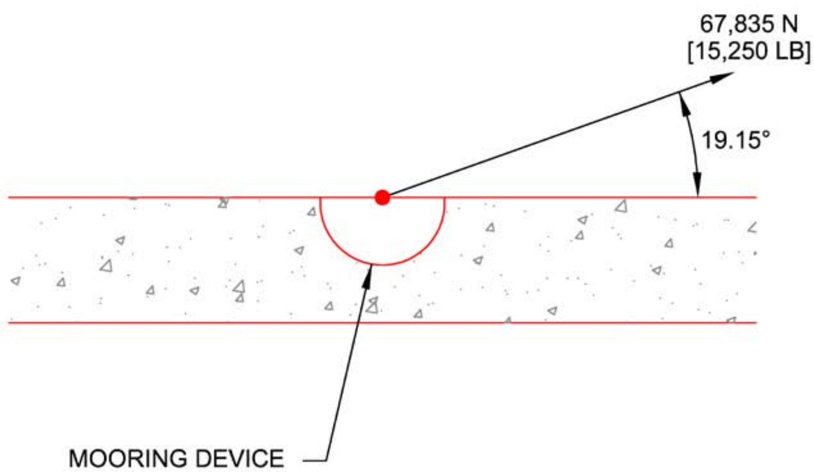
NOTES

1. MOORING DEVICE TO BE CAST IN DUCTILE IRON 80-55-06 OR EQUAL
2. ANCHOR RODS SHALL BE #3 DEFORMED REBAR, 380 mm (15") LONG AND BENT DOWNWARD AT 45 DEGREES. TWO ANCHOR BARS PER MOORING DEVICE.

B11-2.2 Design Load.

Unless specifically waived in writing by the facility commander, all new construction of Army aircraft parking aprons will include aircraft mooring points designed for a 67,800-Newton (15,250-pound) load, as specified in TM 1-1500-250-23 and applied at 19.15 degrees (19.15°) from the pavement surface, as illustrated in Figure B11-2. Testing of new mooring point installations is not required; however, follow Figure B11-2 if testing is performed.

Figure B11-2. Army Load Testing of Mooring Points



NOTES

1. MOORING TESTS SHALL BE ACCOMPLISHED USING A HYDRAULIC RAM OR SIMILAR DEVICE AND AN APPROPRIATE REACTION (HEAVY VEHICLE, ETC.) THAT IS CAPABLE OF APPLYING A TENSILE LOAD OF 71,172 N [16,000 LB]
2. THE LENGTH OF MOORING CHAIN AND CONNECTING SHACKLE SHALL BE SELECTED IN SUCH A WAY THAT AN ANGLE OF 19.15° FROM THE PAVEMENT SURFACE (SEE ABOVE FIGURE) CAN BE MAINTAINED DURING LOAD TESTING.
3. APPROPRIATE SAFETY PRECAUTIONS SHALL BE TAKEN AT ALL TIMES DURING LOAD TESTING OPERATIONS.
4. THE MOORING POINTS SHALL BE LOADED IN 1,130 kg [2,500 LB] INCREMENTS UP TO 44,482 N [10,000 LB] AND IN 4,448 N [1000 LB] INCREMENTS UP TO 71,172 N [16,000 LB] WITH EACH LOAD INCREMENT HELD FOR AT LEAST 60 SECONDS.
5. TO PASS TEST REQUIREMENTS, MOORING POINTS SHALL NOT DEFORM PERMANENTLY UNDER 71,172 N [16,000 LB] LOAD.

B11-2.3 Layout.

B11-2.3.1 Fixed-Wing Aprons.

Mooring points should be located as recommended by the aircraft manufacturer or as required by the base.

B11-2.3.2 Rotary-Wing Aprons.

B11-2.3.2.1 Number of Moored Parking Spaces.

All exterior aircraft parking spaces will be provided with mooring points.

B11-2.3.2.2 Number of Mooring Points at Each Parking Space.

Each rotary-wing aircraft parking space location will have six mooring points. Although some rotary-wing aircraft only require four mooring points, six will be installed to provide greater flexibility for the types of rotary-wing aircraft that can be moored at each parking space. The largest diameter rotor blade of the facilities' assigned aircraft will be used for locating the mooring points within the parking space. The allowable spacing and layout of the six mooring points is illustrated in Figure B11-3. Parking space width and length dimensions are presented in Table 6-2 of Chapter 6.

B11-2.3.2.3 Mooring Points on a Grid Pattern.

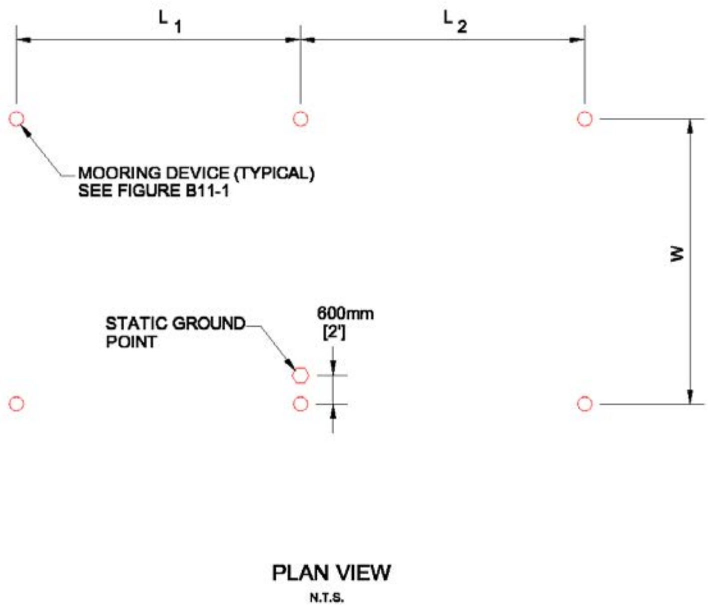
A 6-meter by 6-meter [20-foot by 20-foot] mooring point grid pattern throughout the apron for mass aircraft parking aprons will not be authorized unless economically and operationally justified in writing by the installation commander. Figure B11-4 provides the recommended pavement joint and mooring point spacing should grid pattern mooring be utilized.

B11-2.4 Installation.

B11-2.4.1 Mooring Points for New Rigid Pavement Equal to or Greater Than 150 Millimeters (6 Inches) Thick.

Mooring points for new rigid pavements will be provided by embedding the mooring devices in fresh Portland cement concrete (PCC). The layout of points is shown in Figure B11-3 with mooring points at least 600 millimeters (2 feet) from the new pavement joints. This spacing will require close coordination between the parking plan and the jointing plan. Mooring points should be located a minimum of 600 millimeters (2 feet) from any pavement edge or joint and should provide proper cover for the reinforcing steel. Reinforcing bars should be placed around the mooring points as illustrated in Figure B11-5.

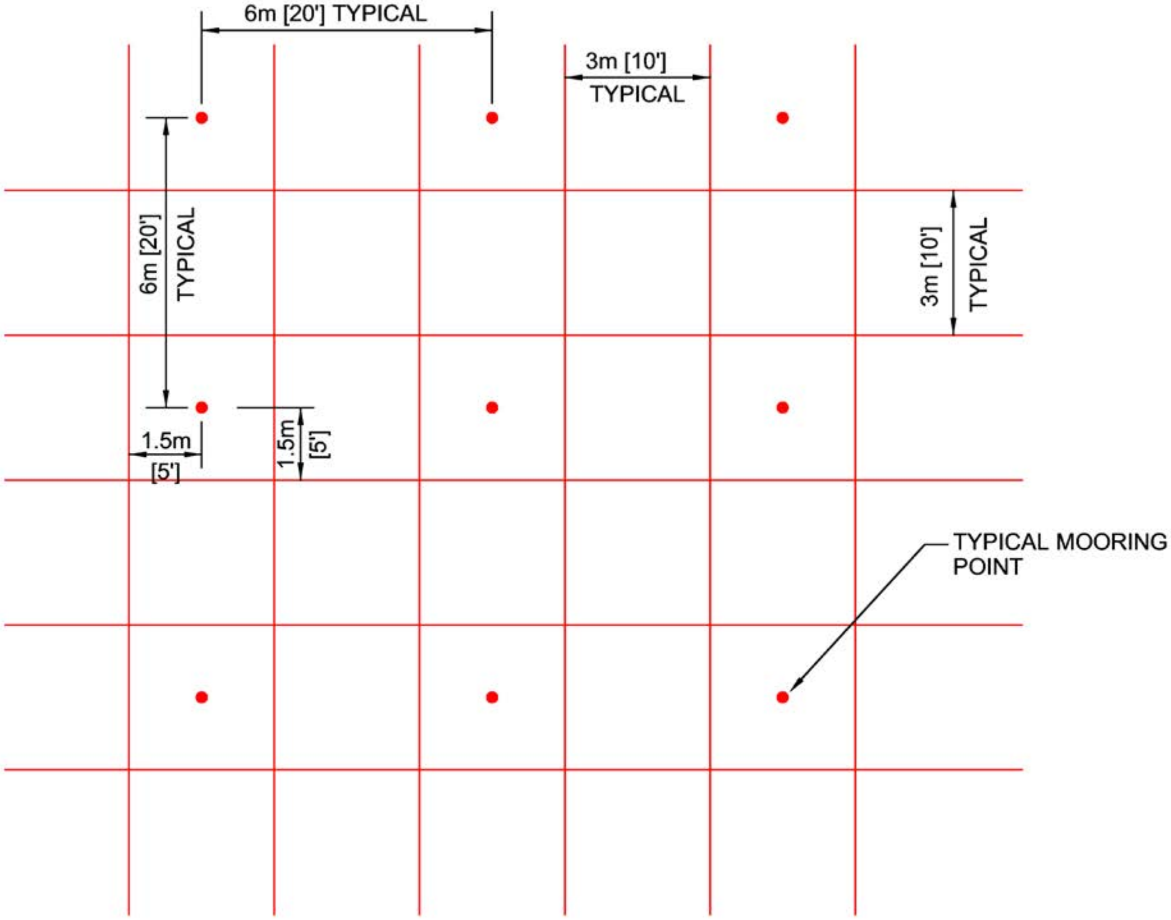
Figure B11-3. Army Rotary-Wing Allowable Mooring Point Spacing



NOTES

1. THE PREFERRED MOORING POINT SPACING FOR EACH AIRCRAFT PARKING POSITION IS L_1=L_2 = W = 6m [20.0']
2. IN NEW OR EXISTING RIGID PAVEMENT, THE MOORING POINTS SHALL BE AT LEAST 600mm [2'] AWAY FROM ANY PAVEMENT JOINT OR EDGE. TO MISS THE PAVING JOINTS, THE SPACING OF THE MOORING POINTS MAY BE VARIED AS FOLLOWS:
   A. W, L_1 AND L_2 MAY VARY FROM 5 TO 6m [17 TO 20'].
   B. W, L_1 AND l_2 NEED NOT BE EQUAL.
3. THE CONSTRUCTION TOLERANCE ON MOORING POINT LOCATION SHALL BE 50mm [±2"]

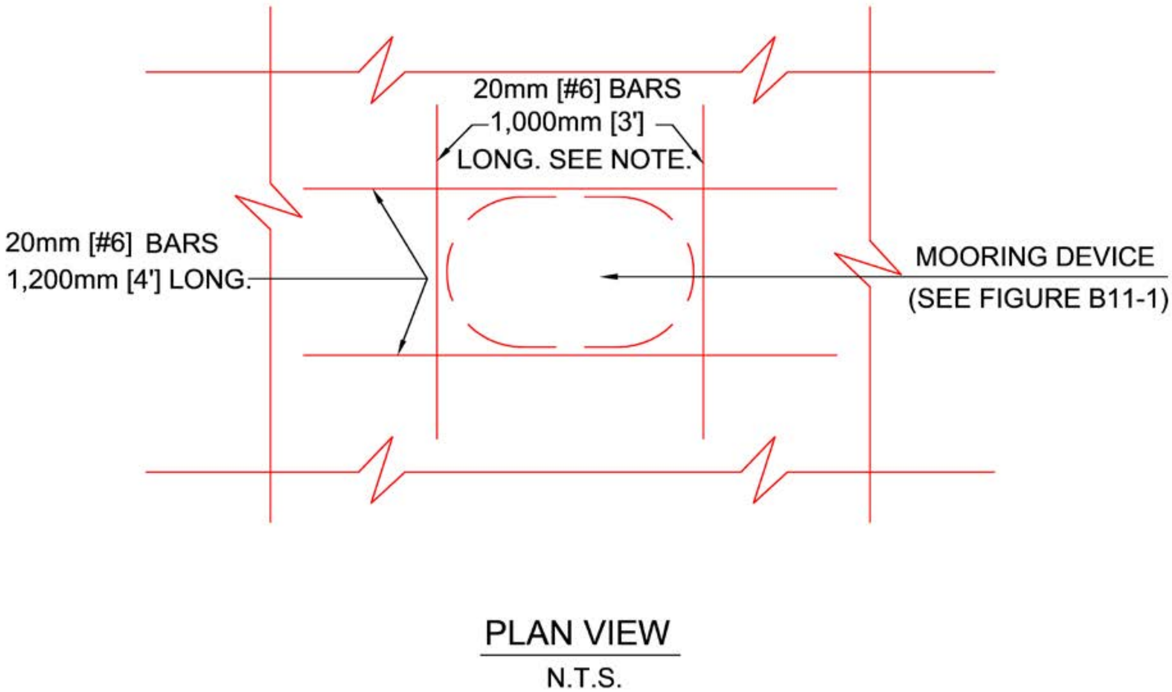
Figure B11-4. Army Rotary-Wing Mooring Points Layout



NOTE

THIS IS THE RECOMMENDED JOINT SPACING FOR NEW CONCRETE PAVEMENT WHERE MOORING DEVICES ARE JUSTIFIED AND AUTHORIZED THROUGHOUT THE APRON. OTHER JOINT SPACINGS MAY BE USED AS LONG AS MOORING DEVICES ARE SPACED AS SHOWN IN FIGURE B11-3.

Figure B11-5. Slab Reinforcement for Army Mooring Point



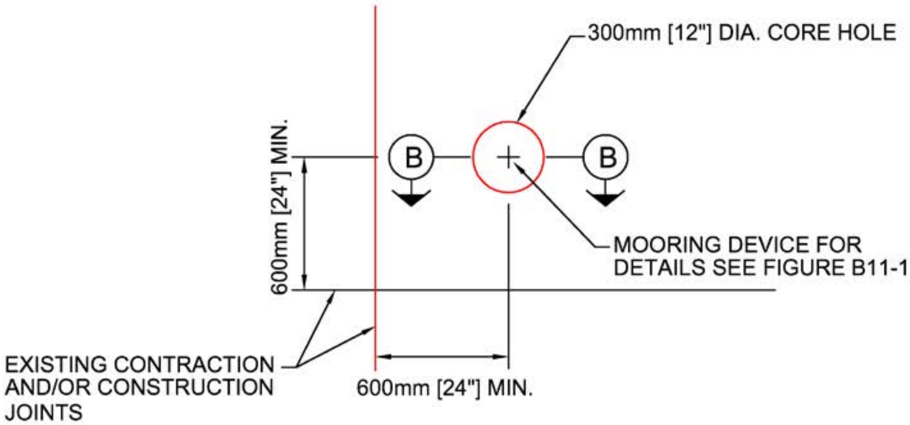
NOTES

1. #6 REINFORCING BARS SHALL BE PLACED 75mm [3"] FROM MOORING DEVICE AND 75mm [3"] BELOW PAVEMENT SURFACE.
2. ENDS OF REINFORCING BARS SHALL BE PLACED 75mm [3"] FROM PAVING JOINTS TO PROVIDE COVER.

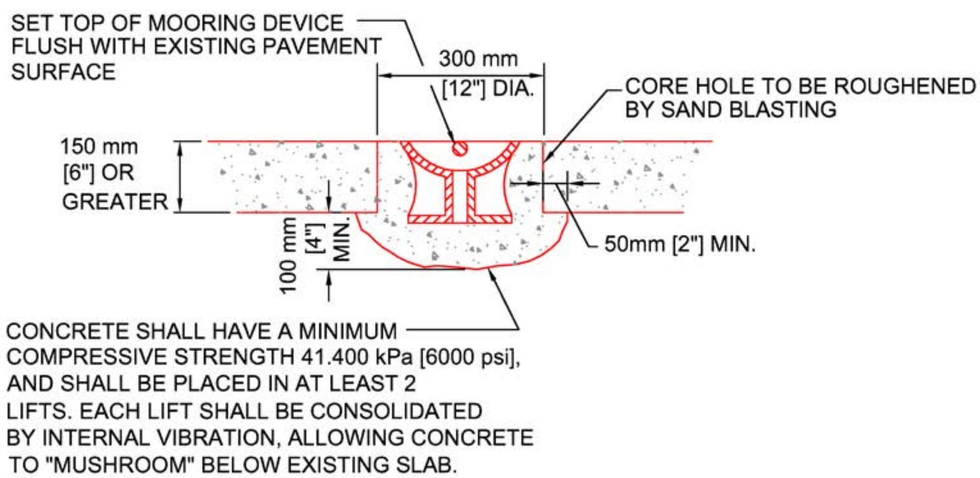
B11-2.4.2 Mooring Points for Existing Rigid Pavement Equal to or Greater Than 150 Millimeters (6 Inches) Thick and in Uncracked Condition.

The following method should be used to provide mooring points for existing rigid pavement in an uncracked condition. The pavement should have only a few slabs with random cracks and must not exhibit "D" cracking. Mooring points should be provided by core-drilling a 300-millimeter (12-inch) -diameter hole through the pavement and installing a mooring point as illustrated in Figure B11-6.

Figure B11-6. Mooring Point for Existing Rigid Pavement for Pavement Thickness Greater Than 150 Millimeters (6 Inches)



PLAN VIEW
N.T.S.



SECTION B
N.T.S.

NOTE

EXISTING CONCRETE SHOULD HAVE ONLY A FEW SLABS WITH CRACKS IF THIS OPTION IS TO BE USED.

B11-2.4.3 Mooring Points for Areas Not Covered Above.

The following installation options should be used to provide mooring points for rotary-wing aircraft parked on the following pavements: existing rigid pavement less than 150 millimeters (6 inches) thick; existing rigid pavement in a cracked or deteriorated condition; new or existing flexible pavement; turfed areas; and other areas where appropriate.

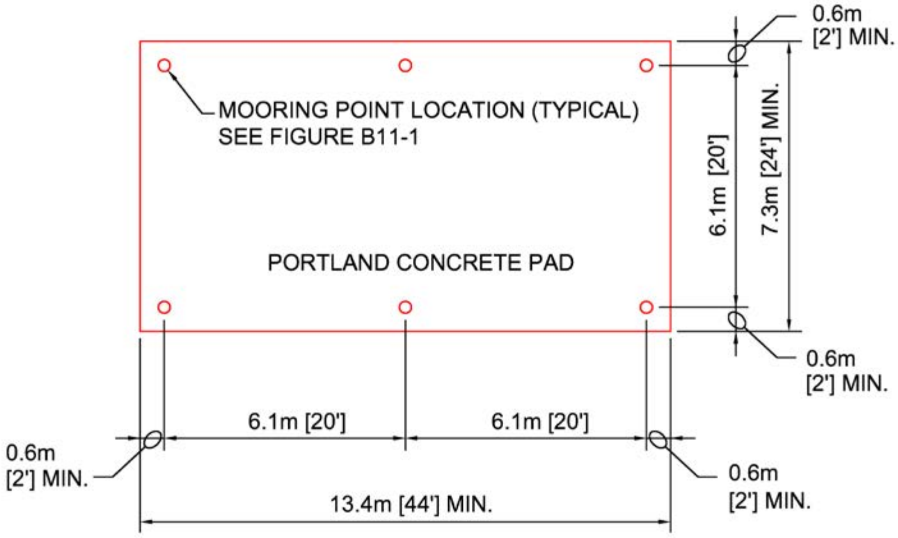
B11-2.4.3.1 Installation Option 1, Mooring Pad.

This option is the preferred installation method and allows for placement of a new concrete pad with a minimum thickness of 200 millimeters (8 inches). The size of the pad should be a minimum of 7.3 meters (24 feet) wide by 13.4 meters (44 feet) long. The length and width may be increased to match the existing concrete joint pattern. The mooring pad, with six mooring points, is illustrated in Figure B11-7. The mooring devices should be installed as illustrated in Figure B11-1 and the concrete reinforced as illustrated in Figure B11-5.

B11-2.4.3.2 Installation Option 2, Piers.

This option allows the use of individual concrete piers for each mooring point, as shown in Figure B11-8. The diameter and length of the pier must be based on the strength of the soil, as presented in Table B11-1.

Figure B11-7. Army Rotary-Wing Mooring Pad Detail

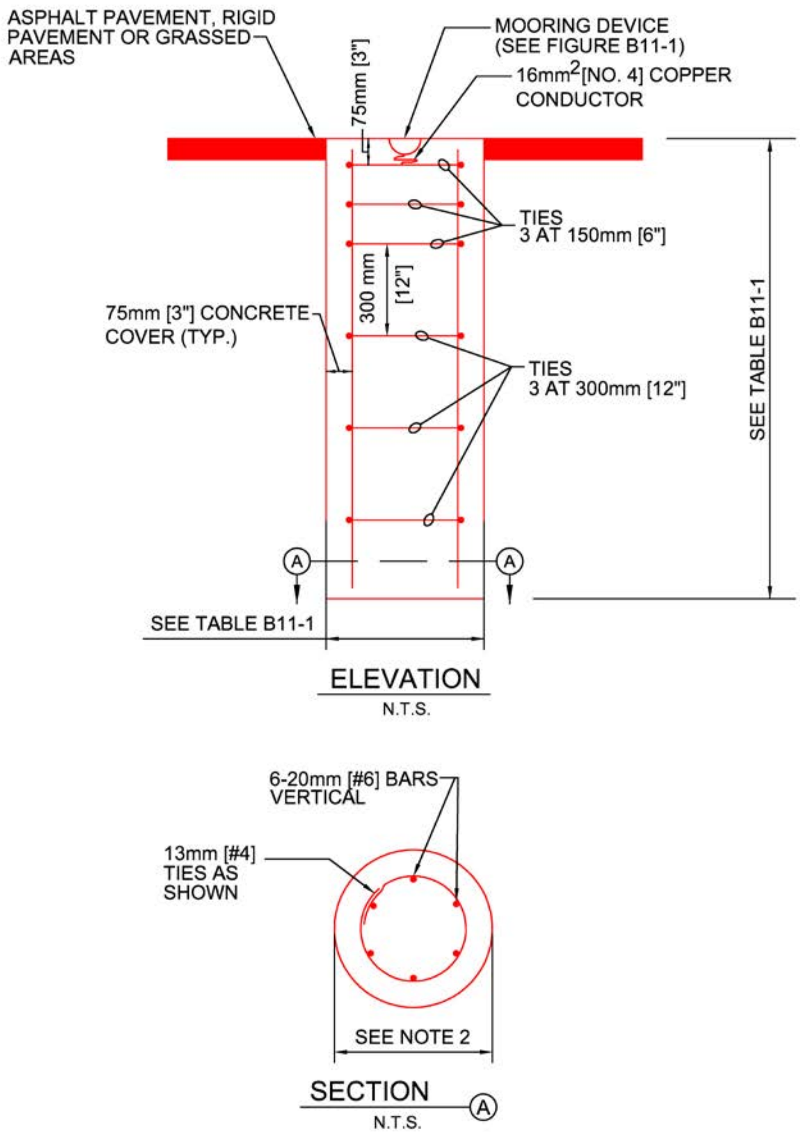


PLAN VIEW
N.T.S.

NOTES

1. THIS MOORING PAD IS THE PREFERRED METHOD OF PROVIDING MOORING POINTS IN GRASSED AREAS AND IN FLEXIBLE PAVEMENTS. FOR RIGID PAVEMENT APPLICATIONS, THE SIZE OF THE PAD SHOULD BE INCREASED TO MATCH THE EXISTING JOINT PATTERN.
2. THICKNESS OF THE PAD SHALL BE DESIGNED TO CARRY THE EXPECTED AIRCRAFT LOADS, BUT NOT LESS THAN 200mm [8"] THICK.
3. THE SLAB SHOULD BE DESIGNED AS A REINFORCED SLAB SO THAT PAVEMENT JOINTING WILL NOT BE REQUIRED. IF JOINTED PAVEMENT IS DESIRED, JOINT SPACING SHOULD BE ADJUSTED SO THAT MOORING POINTS ARE A MINIMUM OF 0.6m [2'] FROM PAVEMENT JOINTS.
4. SEE FIGURE B11-6 FOR REINFORCING ADJACENT TO MOORING DEVICE.
5. TYPICAL PREFERRED SPACING BETWEEN MOORING DEVICES IS 6.1m [20']. SEE FIGURE B11-3 FOR ALLOWABLE MOORING AND STATIC GROUND POINT SPACING.

Figure B11-8. Army Mooring Point for Grassed Areas, Flexible Pavement, or Rigid Pavement - Thickness Less Than 150 millimeters (6 inches)



NOTES

1. CORE DRILL ASPHALT PAVEMENT. FOR PIER LENGTH AND DIAMETER, SEE TABLE B11-1
2. SPIRAL REINFORCEMENT EQUIVALENT TO THE 13mm [#4] TIES MAY BE USED.
3. SEE FIGURE B11-3 FOR ALLOWABLE MOORING AND STATIC GROUND POINT SPACING

Table B11-1. Army Pier Length and Depths for Tiedowns

Cohesive Soils				
	Pier Diameter		Pier Length	
Unconfined Compressive Strength (q_u in kg/m^2 [lb/ft^2])	m	ft	m	ft
q_u < 5,000 kg/m^2 (q_u < 1,000 lb/ft^2)	600 mm	2.0 ft	1,800 mm	6.0 ft
5,000< q_u <19,500 kg/m^2 (1,000< q_u <4,000 lb/ft^2)	500 mm	1.5 ft	1,800 mm	6.0 ft
q_u >18,500 kg/m^2 (q_u >4,000 lb/ft^2)	500 mm	1.5 ft	1,200 mm	4.0 ft
Cohesionless Soils				
	Pier Diameter		Pier Length	
Friction Angle ∅ in Degrees	m	ft	m	ft
Φ < 20°	600 mm	2.0 ft	2,100 mm	7.0 ft
20° ≤ Φ ≤ 30°	600 mm	2.0 ft	1,800 mm	6.0 ft
Φ > 30°	500 mm	1.5 ft	1,800 mm	6.0 ft

B11-3 EXISTING MOORING POINTS FOR ARMY.

Existing mooring points will be tested for structural integrity and strength as detailed in Figure B11-2. If the existing mooring fails to meet the structural requirements listed herein, replacement of the mooring structure is required. If the existing mooring point has an attached ground rod, its electrical resistance value must be measured. If it fails to meet resistivity requirements, a new static ground rod is required.

B11-3.1 Evaluation of Existing Mooring Points for Structural Adequacy.

B11-3.1.1 Adequate Mooring Points.

Existing 19-millimeter (0.75-inch) -diameter bimetallic, copper-covered steel rods, 1,800 millimeters (6 feet) long are considered adequate for immediate aircraft protection, provided the following conditions are met:

- The existing rods are installed in rigid pavement.
- The existing rods do not show signs of deformation or corrosion.
- The existing rods are inspected for deformation and corrosion at least once a year and after each storm event with winds greater than 90 kilometers per hour (50 knots).

B11-3.1.2 Inadequate Mooring Points.

At Army facilities, any existing rods that exhibit deformation or corrosion will be considered inadequate and require replacement. All existing 19-millimeter (0.75-inch) -diameter, 1,800-millimeter (6-foot) -long rods in flexible (asphalt) pavement, including those with a Portland cement concrete (PCC) block at the surface, require replacement.

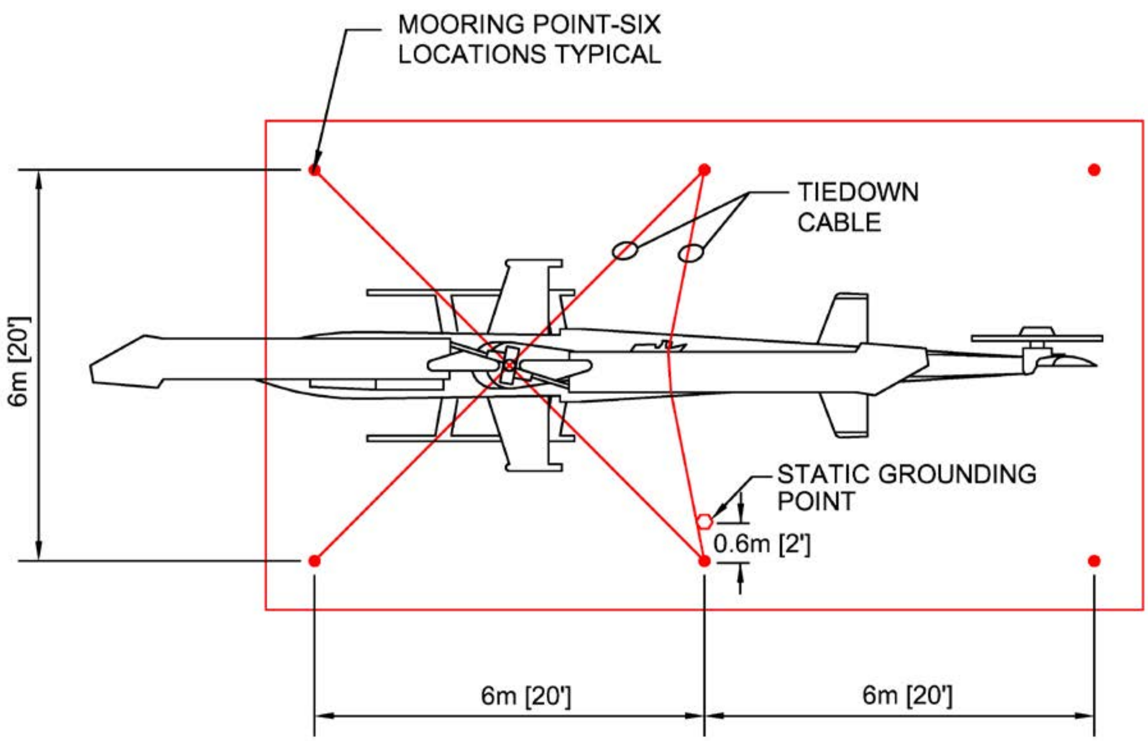
B11-3.2 Evaluation of Existing Mooring Points for Resistance.

The maximum resistance measured, in accordance with IEEE Standard 142, of existing grounding points, will not exceed 10,000 ohms under normally dry conditions. If this resistance cannot be obtained, an alternative grounding system will be designed.

B11-4 STATIC GROUNDING POINTS FOR ARMY AND AIR FORCE FIXED- AND ROTARY-WING FACILITIES.

See UFC 3-575-01 for static ground requirements. One static ground point shall be provided at each rotary-wing parking position, as shown in Figure B11-9.

Figure B11-9. Mooring and Ground Point Layout for Rotary-Wing Parking Space



B11-5 AIR FORCE TIEDOWNS.

B11-5.1 General.

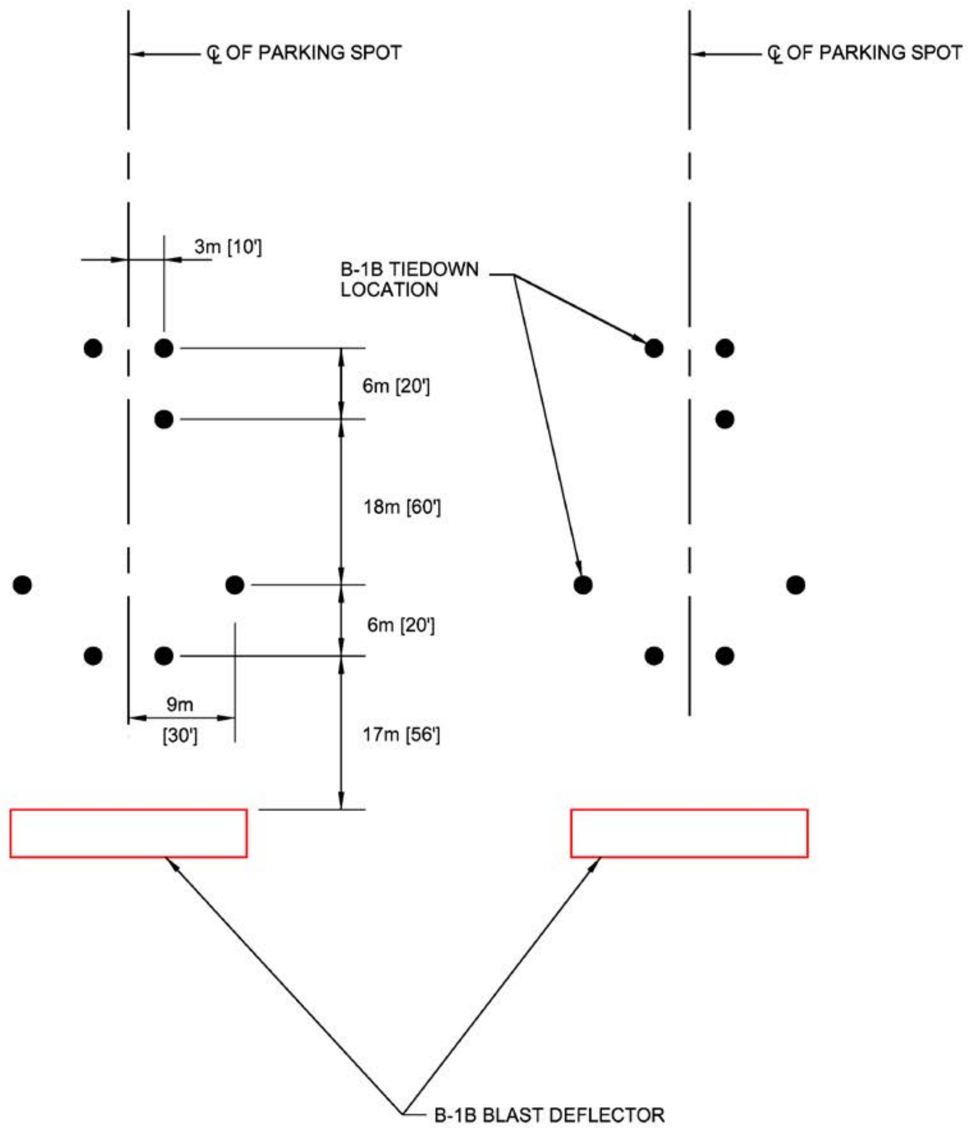
For the Air Force, tiedowns will be constructed in accordance with Figures B11-11 and B11-12 and may be used as a static ground provided they meet the requirements given in UFC 3-575-01. For maximum flexibility, they may be installed in 4.6-meter (15-foot), 6.1-meter (20-foot), or 9.1-meter (30-foot) grids, or offset grids. At minimum, place tiedowns as indicated in aircraft Technical Orders or Facility Requirements Documents. Ideally, tiedowns will be centered in slabs, but, at minimum, shall not be located less than **\1** 533 millimeters (21 inches) **/1/** from any joint.

- B11-5.1.1 If tiedowns are intended to also be used as static grounds, soil conditions may require that a ground rod be installed. When a ground rod is included, bond it to the tiedown bar.
- B11-5.1.2 See UFC 3-575-01 for static ground requirements.

B11-5.2 Layout.

Tiedowns shall be configured and spaced in accordance with the requirements of the mission aircraft and will vary from aircraft to aircraft. An example of a multiple fixed-wing aircraft tiedown layout is shown in Figure B11-10.

Figure B11-10. Example of Air Force Multiple Tiedown Layout for Fixed-Wing Aircraft



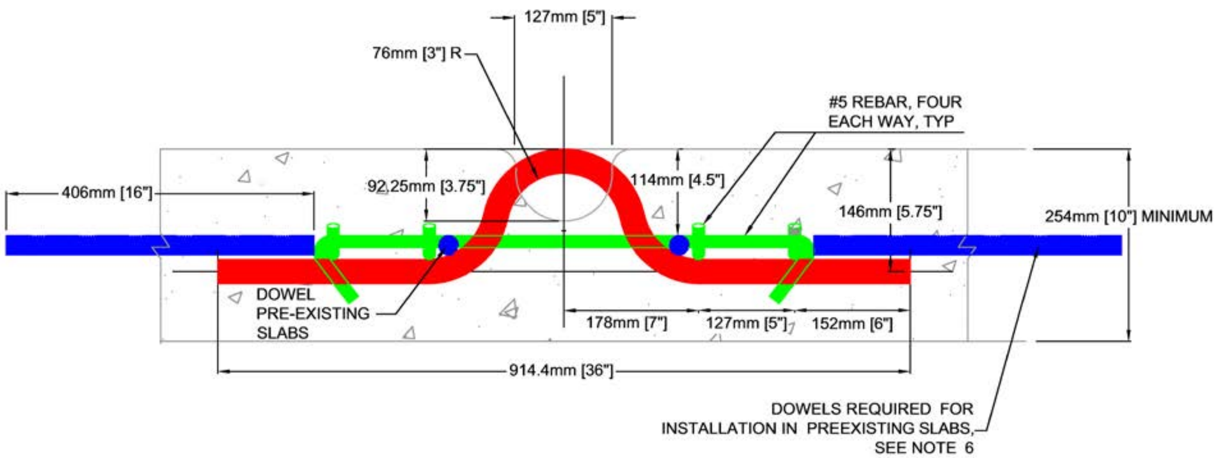
NOTE:
THIS IS AN EXAMPLE FOR ONE AIRCRAFT (B-1B). FOR SPECIFIC AIRCRAFT DIMENSIONS REFERENCE THE AIRCRAFT TECHNICAL ORDER (T.O.) (AVAILABLE FROM MAINTENANCE ASSISTANCE PROGRAM OFFICE).

B11-5.3 Installation.

B11-5.3.1 Pavement Recess Design.

The top of the static ground will be set at pavement grade or not more than 6 millimeters (0.25 inch) below grade. A smooth, rounded-edge recess 75 millimeters (3 inches) wide and not more than 150 millimeters (6 inches) long will be provided in the pavement around the eye for accessibility and attachment of grounding cables. This is shown in Figure B11-12.

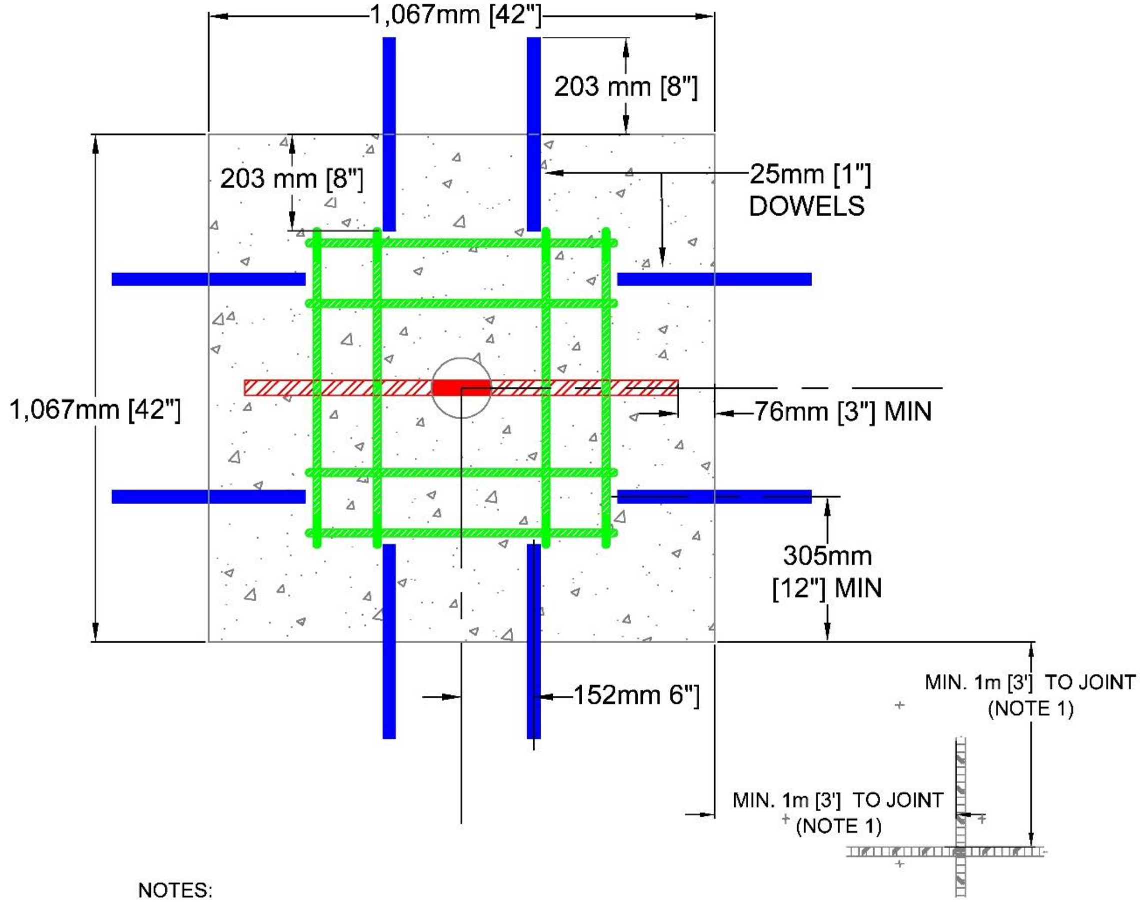
Figure B11-11. Air Force Aircraft Tiedown, Profile



NOTES:

1. PLACE TIE DOWNS AS INDICATED IN AIRCRAFT TECHNICAL ORDER OR FACILITY REQUIREMENTS DOCUMENT. IF THE TIEDOWN IS INTENDED TO ALSO BE USED AS A STATIC GROUND, SOIL CONDITIONS MAY REQUIRE THAT A GROUND ROD BE INSTALLED. WHEN A GROUND ROD IS INCLUDED, BOND IT TO THE TIEDOWN BAR.
2. MINIMUM DISTANCE FROM TIEDOWN CENTER POINT TO AN UNDOWELED JOINT IS 914 mm (3'). WHEN TIE DOWNS OCCUR 914mm [3 '] FROM A SINGLE JOINT, ORIENT BAR PARALLEL WITH THE JOINT. IF CENTER POINT OCCURS 914mm (3') FROM ADJACENT JOINTS, ORIENT BAR PARALLEL WITH EITHER JOINT.
3. BAR WILL BE NUMBER 7 (0.875") NON-DEFORMED AISI 8620H STEEL.
4. MINIMUM SLAB THICKNESS IS 254mm [10"].
5. PIER DIMENSIONS FOR ASPHALT PAVEMENTS MUST BE DESIGNED TO ACCOMMODATE ANTICIPATED UPLIFT FORCES. FOR 17,100 kg (37,700 LBS) MINIMUM PIER DIMENSIONS ARE 1.83m x 1.83m x 2.13m (6' x 6' x 7').
6. FOR INSTALLATION IN PREEXISTING SLABS, INSTALL 1" Ø x 16" DOWEL RODS CENTERED AT HALF SLAB DEPTH , ALL FOUR SIDES AS SHOWN IN THE PLAN VIEW. MINIMUM ANCHOR BLOCK DIMENSIONS IN THIS CASE ARE 254mm [10"] x 1,067mm [42"] x 1,067mm [42"].

Figure B11-12. Air Force Aircraft Tiedown, Plan



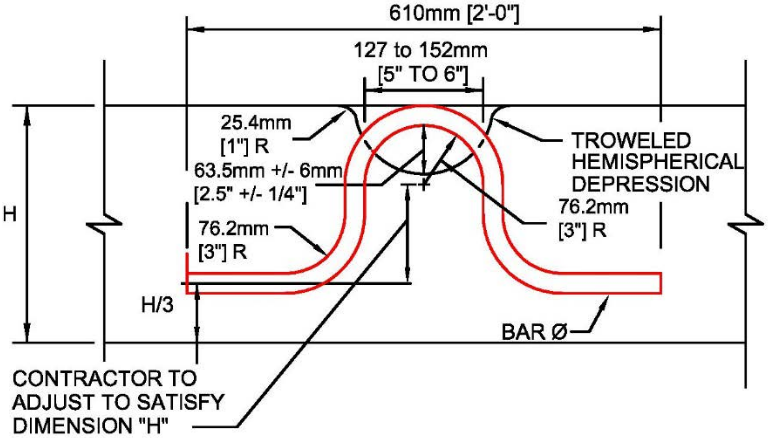
NOTES:

1. EDGE OF RETROFIT PATCH WILL BE MINIMUM 1m (3') FROM NEAREST JOINT IN BOTH DIRECTIONS TO REDUCE RISK FOR SYMPATHETIC CRACKS IN EXISTING SLAB. IF TIEDOWN MUST BE CLOSER TO JOINT, THEN EXPAND RETROFIT PATCH TO THE NEAREST JOINT.

B11-6 TIEDOWN MOORING EYES FOR NAVY AND MARINE CORPS.

Requirements, layout, and installation details for Navy and Marine Corps tiedown mooring eyes are found in Figures B11-13, B11-14 and B11-15. Requirements, layout, and installation details for Navy and Marine Corps grounding arrangements are found in UFC 3-575-01. A tiedown mooring eye must be placed at the center of every parking apron slab. For PCC with a thickness greater or equal to 254 mm (10"), the allowable uplift capacity of a T-56 tiedown is 167,698 Newtons (37,700 lbs). For PCC with a thickness greater or equal to 178 mm (7"), but less than 254 mm (10"), the allowable uplift capacity of a T-56 tiedown is 111,206 Newtons (25,000 lbs). These allowable uplift capacities assume a minimum of 40% load transfer efficiency across all doweled and non-doweled joints.

Figure B11-13. Navy and Marine Corps T-56 Mooring Eye/Tiedown Detail



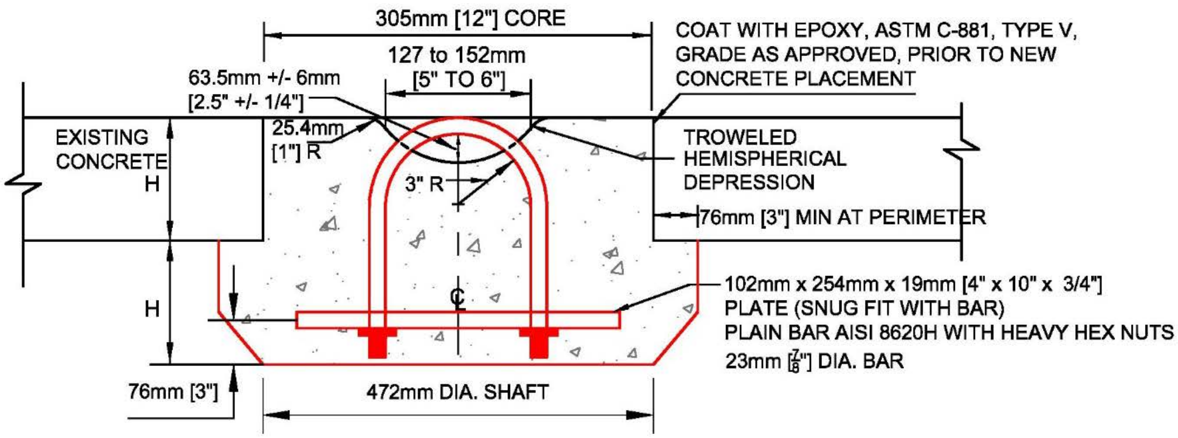
TIEDOWN/MOORING EYE-TYPE A

NOT TO SCALE

NOTES

1. PLACE MOORING EYES AS INDICATED ON PLANS.
2. WHEN REBAR FOR EYE OCCURS WITHIN 610mm (2') OF JOINT, ORIENT REBAR PARALLEL TO JOINT.
3. BAR MUST BE 23MM ($\frac{7}{8}$") NON-DEFORMED AISI 8620H STEEL (SINGLE QUENCHED AND TEMPERED (230° C (450° F)), CARBURIZED).

Figure B11-14. Navy and Marine Corps T-56 Retrofit Detail Option 1



TIEDOWN/MOORING EYE (RETROFIT) DETAIL

NOT TO SCALE

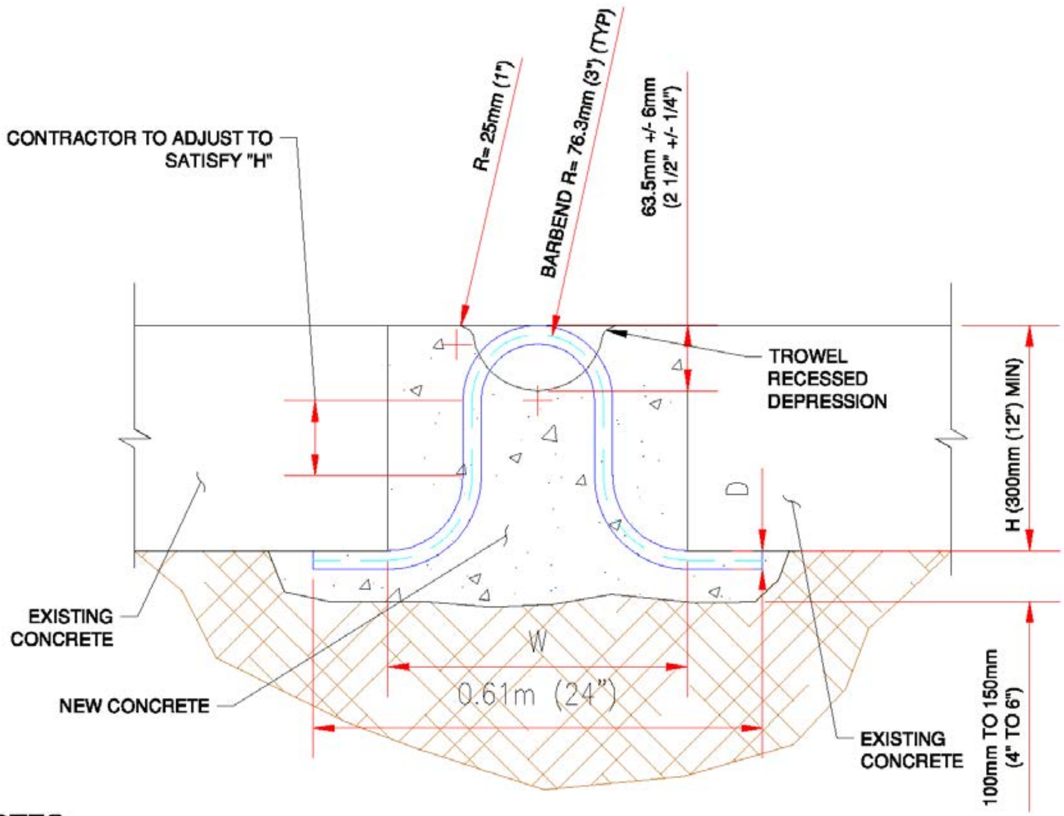
NOTES

1. PLACE MOORING EYES AS INDICATED ON PLANS.
2. DO NOT PLACE MOORING EYE WITHIN 1M [3'] OF ANY CRACK OR JOINT.
3. TIEDOWNS MUST NOT BE PLACED WITHIN 1M (3') OF ANY CONTRACTION OR CONSTRUCTION JOINT AND MUST BE ORIENTED PARALLEL TO NEAREST JOINT.
4. BAR MUST BE 23MM (7/8") NON-DEFORMED AISI 8620H STEEL (SINGLE QUENCHED AND TEMPERED (230° C (450° F)), CARBURIZED).

SEQUENCE

1. CORE PAVEMENT.
2. EXTEND SHAFT TO A MINIMUM DEPTH AND 76mm [3"] MINIMUM UNDERCUT SHOWN.
3. MAINTAIN SHAFT UNTIL PCC PLACEMENT.
4. PLACE BAR ASSEMBLY AND NEW CONCRETE (4,000 PSI MIN).

Figure B11-15. Navy and Marine Corps T-56 Retrofit Detail Option 2



NOTES

1. THIS DETAIL IS NOT INTENDED FOR USE IN PAVEMENTS LESS THAN 300mm (12") THICK.
2. SAWCUT EXISTING CONCRETE. DIMENSIONS OF SAWCUT SHALL BE 300mm (12") WIDE ("W") BY 685mm (27") LONG.
3. EXCAVATE 100mm to 150 mm (4" TO 6") BELOW BASE OF SLAB WITH HAND TOOLS AS REQUIRED TO ROTATE HAT-SHAPED BAR 90 DEGREES.
4. PLACE HAT SHAPED BAR INTO HOLE.
5. ROTATE HAT-SHAPED BAR 90 DEGREES.
6. SUSPEND TOP OF HAT-SHAPED BAR SO THAT THE TOP OF BAR IS RECESSED APPROXIMATELY 6mm (¼") BELOW TOP OF CONCRETE SLAB.
7. PLACE CONCRETE AND HAND TROWEL RECESSED DEPRESSION.
8. BAR MUST BE 23mm (⅞") NON-DEFORMED AISI 8620H STEEL (SINGLE QUENCHED AND TEMPERED (230° C (450° F)), CARBURIZED).
9. TIEDOWNS MUST NOT BE PLACED WITHIN 1m (3') OF ANY CONTRACTION OR CONSTRUCTION JOINT AND MUST BE ORIENTED PARALLEL TO NEAREST JOINT.

APPENDIX B
SECTION 12
JET ENGINE THRUST STANDOFF REQUIREMENTS FOR AIRFIELD ASPHALT EDGE PAVEMENTS

B12-1 PURPOSE.

This section presents the standoff distances from jet aircraft during engine run-up required to prevent uplift forces from causing catastrophic failure of asphalt edge pavements. This Section supersedes ETL 07-3, *Jet Engine Thrust Standoff Requirements for Airfield Asphalt Edge Pavements*.

B12-2 APPLICATION.

The requirements of this section are mandatory for Air Force Installations.

B12-2.1 Authority.

Air Force policy directive (AFPD) 32-10, *Air Force Installations and Facilities*, and Air Force instruction (AFI) 32-1023, *Design and Construction Standards and Execution of Facility Construction Projects*.

B12-2.2 Intended Users.

- Air Force MAJCOM engineers.
- Base Civil Engineers (BCE), RED HORSE (Rapid Engineers Deployable - Heavy Operations Repair Squadron Engineers) squadrons, and other units responsible for design, construction, maintenance, and repair of airfield pavements.
- U.S. Army Corps of Engineers (USACE) and Navy offices responsible for Air Force design and construction.

B12-2.3 Referenced Publications.

B12-2.3.1 Air Force.

B12-2.4 Background.

Catastrophic failure of airfield edge pavement due to uplift forces from jet engine thrust has occurred at multiple locations, resulting in damage to aircraft, vehicles, and real property. The criteria in this Section are being issued due to tangible life safety and financial concerns. This phenomenon has been observed and studied in the past. In 1988, the Air Force Engineering and Services Center (AFESC) responded to MAJCOMs' requests for engineering data on this subject by providing safe standoff distances to edge pavements for numerous aircraft. This Section encompasses and updates previous guidance.

B12-2.5 Analysis.

Past guidance was based on both mechanistic air velocity–air pressure relationships, as defined by the Bernoulli equation, and empirical observation. Based on the following Bernoulli model, the critical air velocity would be limited to 218 kilometers per hour (kph) (136 miles per hour [mph] or 199.8 feet per second [fps])

$$V = \sqrt{\frac{2g\Delta p}{\rho}}$$

$$\rho = \frac{p}{RT}$$

where:

V	=	velocity
Δp	=	1197 pascals (25 pounds per square foot [psf]) (51-millimeter [2-inch] thick asphalt mass)
g	=	9.81 meters (32.2 feet) per second•second

ρ	=	101.3 kilopascals (14.7 pounds per square inch absolute [psia]) at sea level
R	=	53.3 (ft-lb/lb) / °Rankine (°R) (gas constant, air)
T	=	985 °R (typical exhaust temperature at expected velocity and distance of interest)

However, empirical observation has indicated that the typical 51-millimeter (2-inch)-thick edge pavement can withstand velocities up to 362 kph (225 mph). This higher observed velocity was accepted as a valid basis for criteria development because the simple Bernoulli model ignored other forces which are difficult to model, such as friction, shear, and adhesion. Without being able to further refine the mechanistic model, guidance was issued based on empirical observations, with a safety factor of two applied. The active uplift force is a function of the velocity squared. Dividing the observed velocity of 362 kph (225 mph) by the square root of this safety factor yielded a threshold velocity of 257 kph (160 mph). This velocity was issued as criteria for establishing standoff distances.

B12-2.6 Standoff Distances.

Aircraft should be positioned so that jet blast velocities are below 257 kph (160 mph) at the edge of a typical 51-mm (2-in) -thick asphalt shoulder pavement. Table B12-1 lists the standoff distance aft of the aircraft tail where data indicates the engine exhaust velocity is reduced to 257 kph (160 mph). Where data indicates that the actual velocity would be lower than this threshold velocity value, a minimum standoff distance of 8 meters (m) (25 feet [ft]) is recommended. In locations where the Aircraft Tail Standoff Distance cannot be met, increasing the asphalt thickness can counteract the uplift force caused by jet blast; however, asphalt lifts must be well-bonded to each other and free of cracking to ensure jet blast cannot separate the top lift from the underlying lift(s).

Table B12-1. Safe Standoff Distances Aft of Aircraft Tail (Based on 51-mm [2-in] Asphalt Shoulder Pavement Thickness)

Table B12-1. Safe Standoff Distances Aft of Aircraft Tail			
Aircraft	**Aircraft Tail Standoff Distance**	**Jet Blast Velocity Data Source**	**Remarks**

Airbus A319	8 m (25 ft)	Airbus	See Note 3
Airbus A320	26 m (85 ft)	Airbus	
Airbus A321	8 m (25 ft)	Airbus	See Note 3
Airbus A330	76 m (250 ft)	Airbus	
Airbus A340	No jet blast data available for >102 mph		
Airbus A380	107 m (305 ft)	Airbus	
AN-124	No jet blast data available		
IL-76	No jet blast data available		

NOTES

1. If the design aircraft is not listed in Table B12-1, bases should contact their MAJCOM pavement engineer for additional guidance.
2. The information listed in the table is derived from the best information available at the time of publication. However, aircraft models and engines can change, resulting in changes to jet blast characteristics. Therefore, when designing or evaluating a site for a particular aircraft, always check for updated jet blast characteristics.
3. Data indicates jet blast velocities are less than 257 kph (160 mph) at the back of the aircraft tail. In such instances, it is recommended that a minimum 8 m (25 ft) standoff should be applied.
4. All reported distances are for maximum or takeoff engine power settings.
5. Where no specific aircraft model is listed, listed standoff distance is for the aircraft model with highest jet blast velocity.
6. Standoff distance is based on Gulfstream II jet blast data.

B12-2.7 Run-Up Pad Design.

When designing new or checking existing engine run-up pads, the following criteria should be applied:

- New and existing run-up pads should be designed/modified to provide the full standoff distance behind the tail of the aircraft, as listed in Table B12-1.
- When it is not possible or practical to meet the distances listed in Table B12-1, then a minimum 8 m (25 ft) of Portland cement concrete (PCC) pavement must be provided between the tail of the aircraft and the edge of the apron. However, be aware that damage to the asphalt shoulder pavement can be expected. To mitigate damage, PCC may be constructed in lieu of asphalt in the areas affected by jet blast.
- Consideration must be given to other objects in the jet blast wake (e.g., roads, parking lots, hangars, lights, cargo). Precautions should be taken to eliminate the potential for damage caused by flying debris.

B12-2.8 Run-Up Pad Markings.

Proper marking of engine run-up pads is critical to ensure aircraft positioning complies with required standoff distances. All markings should comply with service-specific instructions and UFC 3-260-04, *Airfield Pavement Marking*. The following guidance shall be followed on current and future run-up pad locations:

- Provide a centerline marking that runs parallel to the prevailing wind direction specific to the run-up pad.
- Provide a nose wheel stop-block marking for the primary assigned aircraft that will be using the run-up pad. If several different aircraft are assigned to the installation, provide a nose wheel stop-block marking for the most demanding aircraft. Aircraft may be parked on nose wheel stop-block markings that provide more standoff distance than required. However, aircraft must not be parked on nose wheel stop-block markings that provide less standoff distance.
- Label each nose wheel stop-block marking for the aircraft that are intended to use it. Only mark blocks for primary assigned aircraft. Transient aircraft requiring use of the run-up pad should be evaluated on a case-by-case basis.

APPENDIX B
SECTION 13
DEVIATIONS FROM CRITERIA FOR AIR FORCE AND ARMY AIRFIELD SUPPORT FACILITIES

B13-1 WAIVERABLE AIRFIELD SUPPORT FACILITIES

B13-1.1 Contents.

This section provides information for selected airfield support systems and facilities that are authorized to deviate from criteria presented in this UFC with a specific waiver from the IMSC Detachment or USAASA (USA) as applicable. See Appendix B, Section 1 for waiver processing procedures. The standard designs for these facilities and systems are not considered frangible and therefore must not be sited within the frangibility zones described within paragraph B13-2.2 and Chapter 3. See Air Force Technical Order (T.O.) 31Z3-822-2. When airfield NAVAIDs, support equipment, or weather systems are decommissioned, become obsolete, or are deactivated for other reasons, the systems and all related equipment, structures, and foundations must also be removed from the airfield environment and the grades restored to comply with criteria provided in this UFC. Unless otherwise specified, the criteria (distances) referenced in the paragraphs below are applicable to Class A and B fixed-wing runways.

B13-1.2 Navy and Marine Corps Requirements.

This section does not apply to the Navy, and Marine Corps.

B13-1.3 Fixed Base Airport Surveillance Radar (ASR) or Fixed Base Digital Airport Surveillance Radar (DASR).

Radar that displays range and azimuth typically is used in a terminal area as an aid to approach and departure control. Normally, ASR and DASR are used to identify and control air traffic within 60 nautical miles of the airfield. The antenna scans through 360 degrees to give the air traffic controller information on the location of all aircraft within line-of-sight range. The antenna, located adjacent to the transmitter or receiver shelter, is elevated to obtain the required line-of-sight distance. Fixed radar siting in the continental United States (CONUS) will be accomplished in accordance with FAA Order 6310.6.

B13-1.4 Airport Rotating Beacon.

Airport rotating beacons are devices that project beams of light, indicating the location of an air base/airfield/heliport/helipad. Detailed siting guidance is found in UFC 3-535-01.

B13-1.5 Nondirectional Radio Beacon Facilities.

Radio beacon facilities are nondirectional aids used to provide homing, fixing, and air navigation assistance to aircraft with suitable automated direction-finding equipment.

They consist of two categories: a medium-power, low-frequency beacon and a medium-power, ultrahigh-frequency beacon.

B13-1.6 Air Traffic Control Tower (ATCT).

The ATCT Control Cab must be correctly oriented so that the area to be controlled is visible from the cab. Air traffic controllers must have proper depth perception of the area under surveillance and there can be no electronic interference with equipment in the cab or with navigational equipment on the ground. A site survey must be conducted to determine the best siting. For these and other operational and technical aspects and considerations for selecting a site, consult Service-specific requirements in the early stages of planning. For Air Force installations, contact Air Force Flight Standards Agency (AFFSA), Requirements and Sustainment Directorate, HQ AFFSA/XR; or for Army installations, contact the United States Army Air Traffic Services Command (ATSCOM), Fixed Base Systems Division (AFAT-ATS-CB), Building 50301 Nevin Street, Cairns Army Airfield, Ft. Rucker, AL 36362-5265. Specific architectural, structural, mechanical, and electrical systems design requirements may be found in UFC 4-133-01, *Air Traffic Control and Air Operations Facilities*. Also, see paragraph B13-2.21.3.6 and Appendix B, Section 16, paragraph B16-4.3.

B13-2 PERMISSIBLE DEVIATIONS FROM DESIGN CRITERIA.

B13-2.1 Contents.

This section furnishes siting information for airfield support facilities that may not conform to the airfield clearance and airspace surface criteria elsewhere in this UFC. This list is not all-inclusive. Siting and design for airfield facilities and equipment must conform to these design and siting criteria, and must be necessary for support of assigned mission aircraft, or a waiver from the MAJCOM or USAASA is required. If the equipment renders satisfactory service at locations not requiring a clearance deviation, such locations should be selected to enhance the overall efficiency and safety of airfield operations. When airfield NAVAIDs, support equipment, or weather systems are decommissioned, become obsolete, or are deactivated for other reasons, the systems and all related equipment, structures, and foundations must also be removed from the airfield environment and the grades restored to comply with criteria provided in this UFC.

a. Any facilities in this chapter installed on rotary-wing runways (IFR/VFR) cannot violate the lateral clearance criteria, but is permissible within the transitional surface.

b. Clear zones are comprised of two separate areas that are treated differently. This is because initially the area known as the clear zone was defined as "the areas immediately adjacent to the ends of a runway, which have been cleared of all above ground obstructions and graded to minimize damage to aircraft that undershoot or overrun the runway." In 1974, DoD implemented a requirement for the Services to control development near military airfields to protect the safety, health and welfare of personnel on base and in the surrounding communities. This action was also intended to preserve maximum mission flexibility. To accommodate these needs, the clear zone size was expanded and the allowable uses were published within the Air Installation Compatible Use Zone (AICUZ) Program guidance, DoDI 4165.57. It is important to understand that all objects located within the expanded area of clear zones are not necessarily obstructions and there are no specific grading requirements for this area. Review current AICUZ criteria for land uses in this area before initiating development.

NOTE: For Air Force operated airfields (including those at Joint Bases): AFI 32-7063, Air Installations Compatible Use Zones (AICUZ) Program, directs that Air Force facility sitings, construction and land use must be consistent with the land use recommendations in the AFI and provides specific guidance on what is and is not allowed in the Clear Zone. Essential navigation aids and operational facilities can be located in the clear zone if there are no feasible alternatives. Due to the high potential for accidents in the CZ, facilities/equip listed in this section that are not required to be located in this area, especially those with personnel/people (i.e. facilities with classrooms or offices) should be considered for locations outside the clear zone. If they must be located within the clear zone to support the safe operation of the airfield, documents supporting the need to locate these facilities/equipment within the clear zone should be kept on file (including other locations evaluated and found unsuitable in order to communicate the decision to locate these objects within Air Force controlled areas of the Clear Zone. Any other uses within the clear zone will require a clear zone variance be completed (see AFI 32-7063).

B13-2.2 Frangibility Requirements.

All structures placed or constructed within the airfield environment must be made frangible (to the maximum extent practicable) or placed below grade unless otherwise noted in the definitions that follow or unless specifically described as exempt from frangibility requirements using the siting criteria in this UFC. This applies for any above ground construction within 76 meters (250 feet) of a fixed wing runway centerline and an extension of that dimension for 914 meters (3,000 feet) beyond the ends of the runway thresholds and within the taxiway clearance line (see Table 5-1, Item 10), but is limited to structures owned or controlled by DoD. For VFR helicopter runways/helipads (except limited use facilities) frangibility requirements apply within 30 meters (100 feet) of centerline/center of helipad and an extension of that dimension beyond the ends of the runway threshold/ approach/departure surface for 120 meters (400 feet) and within the rotary-wing taxiway clearance line (see Table 5-2, Item 5). For IFR helicopter runways/helipads (except limited use facilities) frangibility requirements apply within 53 meters (175 feet) of centerline/center of helipad. Frangibility implies that an object will collapse or fall over after being struck by a moving aircraft with minimal damage to the aircraft to the maximum extent practicable. The constructed object must not impede the motion or radically alter the path of the aircraft. Foundations for frangible structures shall be constructed flush with finished grade and the surrounding soil shall be compacted. Corrective action is required if more than 76 millimeters (3 inches) of the vertical surface of any foundation is exposed above finish grade. All structures shall be designed to allow performance of the structure to withstand wind loads less than 112 kilometers per hour (70 miles per hour). At wind speeds and icing conditions above permissible airfield operations conditions, deflections shall remain within the elastic performance of the structure. **\1** This concept does not include structures intended to house people or perimeter fencing within the MFZ. **/1/** Integral fuel tanks should be used for necessary emergency power generator sets. If auxiliary fuel tanks are required for emergency generators, or integral fuel tanks are not available, place the fuel supply system below grade with other supporting utilities.

B13-2.2.1 Types of Frangible Devices and Structures.

Essentially, there are three types of frangible devices and structures. These are normally related to the height of the structure. They are described below.

B13-2.2.1.1 Frangible Support.

A support for elevated fixtures or other devices composed of a supporting element with a fracture mechanism at its base. It is designed to present a minimum of mass and to break at the base when impacted. It is typically used when the mounting height is 2 meters (6 feet) or less above the mounting surface.

B13-2.2.1.2 Low-Impact Resistant Support.

A support for elevated fixtures or other devices designed to present a minimum mass and to break with a minimum resistance when impacted. Normally used for supporting lights or other devices between 2 meters and 12 meters (6 feet and 40 feet) above the mounting surface.

B13-2.2.1.3 Semi-Frangible Support.

A two-element support for light fixtures or other devices designed for use in applications where the mounting height is over 12 meters (40 feet) above the ground or the facility, or the device is constructed over a body of water. These type supports are comprised of a rigid base or foundation with a frangible or low-impact-resistant support used for the upper portion of the structure. The rigid portion of the structure must be no higher than required to allow performance and maintenance of the apparatus and the frangible or low-impact-resistant support.

B13-2.2.2 Frangibility Requirements.

New designs for airfield equipment, systems, and other facilities must meet the design and testing criteria given in ICAO Document 9157, *Aerodrome Design Manual*, Part 6, "Frangibility," First Edition, 2006, as well as the following guidelines for acceptance as a permissible deviation. Siting criteria provided within this UFC shall be used in lieu of the siting standards provided within Part 6 of the *Aerodrome Design Manual*. These requirements do not apply to facilities that house people.

B13-2.2.2.1 Frangible Structures.

Construction above the ground surface that will collapse or shatter upon impact. The structure must be designed using materials of minimum mass that will either break into segments or shatter without impaling the aircraft skin or becoming an obstacle to the continued movement of the aircraft.

B13-2.2.2.2 Frangible Support.

Used for mounting fixtures or equipment items less than 2 meters (6 feet) in height. The structure will be of minimum mass and will separate at the base connection when struck by a moving aircraft. Upon separation of the base connection, the support must not alter the path or impede flight of the aircraft if a segment of the structure wraps around the aircraft. The structure also must not impale the aircraft.

B13-2.2.2.3 Low-Impact-Resistant Support.

Used for supporting elevated fixtures or equipment items more than 2 meters but less than 12 meters (6 to 40 feet) above the ground surface, typically towers or poles. Upon impact by aircraft, the structure will be designed to break away at or below the impact location and collapse without wrapping around the aircraft, impaling the aircraft, or causing significant structural damage to the aircraft. If the design is such that potential exists for a portion of the structure to wrap around the aircraft, it shall not significantly alter the path or flight trajectory, nor prevent the aircraft from completing a successful takeoff or landing. Collapse of the structure may occur at a single point of failure or may be a segmented collapse. The structure shall be designed such that service of the equipment must be accomplished by lowering the equipment. The design shall not include elements that permit climbing by means of a built-in ladder or other scaling devices.

B13-2.2.2.4 Semi-Frangible Support.

Semi-frangible supports are used for those elevated fixtures or equipment items that must be higher than 12 meters (40 feet) or constructed over a body of water. The foundation shall be no higher above grade or the surface of the water than necessary to allow performance and maintenance of the apparatus and the frangible or low-impact-resistant support. The upper portion of the structure will be constructed of multiple elements of low-impact-resistant supports. The supports may be in pairs that provide directional stability or groups that provide stability to the grouping as an element. Upon impact by aircraft, each of the supporting elements will be designed to collapse as a unit or in segments independent of the grouping. The elements of the supporting structure will not impale the aircraft, wrap around the aircraft, or significantly change aircraft direction of travel upon impact. If the design is such that potential exists for a portion of the structure to wrap around the aircraft, it shall not significantly alter the path or flight trajectory, nor prevent the aircraft from completing a successful takeoff or landing. The group of elements may incorporate climb-to-service devices such as ladders, provided they comply with applicable safety criteria.

\1

B13-2.2.2.5 Airfield Perimeter Fencing within the Mandatory Frangibility Zone (MFZ).

a. The chain-link fencing within the MFZ must meet the requirements of UFC 4-022-03.

b. Fence posts must be thin wall steel, aluminum, or fiberglass composite material. Do not brace posts in the direction parallel to the direction of the runway. Gates, gate posts, corner posts, and pull posts are prohibited in the MFZ. Frangible connections at the bottom of fence posts are not required. Ensure posts are not filled with concrete or reinforced in any way. **/1/**

B13-2.3 Visual Air Navigational Facilities.

This term identifies, as a type of facility, all lights, signs and other devices located on, and in the vicinity of, an airfield that provide a visual reference to pilots for guidance when operating aircraft in the air and on the ground. These facilities supplement guidance provided by electronic aids, such as tactical air navigation (TACAN) and precision approach radar (PAR). When constructed and sited in accordance with Air Force/Army standards, these components and systems are frangible. Systems and components not designed and constructed in accordance with Air Force/Army standards must be programmed for replacement. For detailed construction and siting criteria, see **\1** AFMAN 32-1040 **/1/** and UFC 3-535-01.

B13-2.4 Radar Facilities.

Services use various fixed-base radar facilities, such as Ground Control Approach (GCA), Radar Approach Control (RAPCON) (USAF), Army Radar Approach Control (ARAC) (Army) to support local radar air traffic control operations. The radar sets are situated for the best possible coverage of air traffic operations. The radar data may be relayed many miles between the radar set and the radar facility, so the site is very often separated from the operations facility. These facilities provide air traffic controllers information on aircraft alignment, rate of descent, and relative position in the approach. See paragraph B13-1.3 for fixed airport surveillance radar (ASR) and digital airport surveillance radar (DASR) siting guidance.

B13-2.4.1 Permanent GCA/RAPCON/ARAC Facilities.

Permanent GCA/RAPCON/ARAC facilities house the radar operations center, radar equipment room, training facilities, office spaces, emergency and standby power services, and telecommunications service connections. The fixed GCA/ RAPCON/ARAC facilities are sited outside the airspace boundaries required for safe air traffic control operations.

B13-2.4.2 Mobile GCA and Mobile RAPCON Systems.

Mobile GCA and mobile RAPCON systems are designed to set up at remote deployed locations or stateside in garrison or at temporary training locations.

B13-2.4.2.1 Mobile GCA.

The GCA usually consists of two equipment shelters, one containing the precision approach and ASR and the other shelter containing the air traffic control operations center. Both shelters come with support generators, environmental control units, and remote communications equipment. The radar and operations shelters may be separated by up to 30 meters (100 feet). These units are non-frangible.

B13-2.4.2.2 Mobile RAPCON.

The mobile RAPCON usually consists of mobile ASR, mobile PAR, and one or two mobile operations shelters. The mobile ASR and the mobile PAR may be remotely located from the operations center by several miles via fiber optic cable. The siting of the mobile RAPCON system is dependent upon several factors and is determined before deployment by a survey team from the deploying unit. Each of the mobile RAPCON shelters comes with support generators, environmental control units, and communications remoting equipment. The footprint of the deployed systems is determined during pre-survey coordination meetings between the deploying unit and local airfield manager. These units are non-frangible.

B13-2.4.3 GPM-22 PAR Units.

PAR systems (AN/GPN-22) must be sited not less than 156 meters (512 feet) from the centerline of a runway to the near edge of the equipment. The reference reflector must be positioned so that the reflector and the radar antenna are parallel with runway centerline (± 0.005°), be in clear and unobstructed view of the radar antenna, and be located in an area where there are no large reflecting objects. Specific siting criteria for this system is provided in Air Force T.O. 31P5-2GPN22-12. When it is necessary to place units between parallel runways with insufficient distance to allow a 156-meter (512-foot) clearance to each runway centerline, the system shall be sited to provide the minimum distance to the centerline of the primary instrument runway and the lesser clearance to the centerline of the other runway. While it is desirable, from a safety standpoint, to keep these units as low as possible, the final elevation for the units will be determined by AFFSA ATCALS. The elevation is dependent on the necessary lines of sight between the unit and calibration reflectors and the touchdown areas of the runways. If it is necessary to change the existing ground elevation to provide a proper height for these units, follow grading requirements discussed in Chapter 3. These systems are non-frangible.

B13-2.4.4 AN/TPN-31 or ATNAVICS (Air Traffic Navigation, Integration, and Coordination System).

ATNAVICS is a highly mobile ground-controlled approach system that provides air traffic services where no operational airport control and landing system exists. It consists of an Airport Surveillance Radar (ASR), Precision Approach Radar (PAR), and Secondary Surveillance Radar (SSR).

The ATNAVICS system includes a sensor vehicle, sensor trailer with mounted generator, operations shelter, and an operations trailer with mounted generator. The near edge of the sensor vehicle and sensor trailer with mounted generator will be sited no less than 300 feet from the runway centerline. The operations shelter and operations trailer with mounted generator will be sited no less than 500 feet from the runway centerline. See B13-2.7.2 for siting of reflectors.

B13-2.4.5 AN/FPN-67 or FBPAR (Fixed Base Precision Approach Radar).

The AN/FPN-67 is a modern, solid-state, reliable, ground-based, precision approach radar in a fixed-shelter (or integrated with the ATNAVICS system). AN/FPN-67 systems must be sited not less than 156 meters (512 feet) from the centerline of a runway to the near edge of the equipment. See B13-2.7.2 for siting of reflectors.

B13-2.5 Emergency Generators, Maintenance and Personnel Facilities (Non-Frangible).

These facilities may be collocated with GCA facilities and mobile RAPCON vans as follows:

a. Trailers of standard mobile home construction or pre-engineered construction may be used for maintenance and personnel facilities. (Non-frangible)

b. The entire GCA or RAPCON complex consisting of radar vans, emergency generators, maintenance and personnel trailers must be confined to a site not to exceed 45.7 meters long by 30.5 meters wide (150 feet by 100 feet), with the long side perpendicular to the main runway. The elevation of antennas and other projections will be held to the minimum essential for proper operation. Make every effort to keep the site as small as possible and to maintain the greatest possible distance from the runway. The perimeter of the site must be clearly marked and all future requirements contained within the area. Integral fuel tanks should be used for necessary mobile emergency power generator sets. If additional tanks are required or integral fuel tanks are not available, place the fuel supply system below grade with other supporting utilities.

B13-2.6 Remote Microwave Link (Non-Frangible).

This equipment provides remote operation and control of PAR and GCA facilities and must be sited adjacent to them. In siting the antenna, make sure that the increase in size of the total complex does not exceed the specified size of the area previously given for the GCA facility and RAPCON facility.

B13-2.7 PAR Reflectors (Frangible and Non-Frangible).

B13-2.7.1 Air Force.

For the Air Force, moving target indicator (MTI) reflectors, or “target simulators,” may not be sited less than 45.7 meters (150 feet) from the near edge of a runway nor less than 38.1 meters (125 feet) from the near edge of a taxiway or apron boundary marking to the centerline of the equipment. For the Army, MTI reflectors may not be sited less than 76.2 meters (250 feet) from the near edge of a runway nor less than 38.1 meters (125 feet) from the near edge of a taxiway or apron boundary marking to the centerline of the equipment. The height of these reflectors must be held to a minimum consistent with the operational requirements of the system. MTI reflectors sited less than 152.4 meters (500 feet) from the centerline of any runway must be of frangible construction, using breakaway sections in reflector masts. Tracking reference reflectors must not be installed closer than 152.4 meters (500 feet) to the centerline of any runway, nor exceed 18.3 meters (60 feet) in height above the centerline elevation of the nearest runway at the intersection of the equipment centerline perpendicular with the runway centerline.

B13-2.7.2 Army.

For Army, at least one reflector must be located within the AN/FPN67/AN/TPN-31 PAR azimuth angle coverage area in order to provide a horizontal reference point. Reflectors may not be sited less than 45.7 meters (150 feet) from the near edge of a runway nor less than 38.1 meters (125 feet) from the near edge of a taxiway or apron boundary marking to the centerline of the equipment. Reflectors sited less than 76.2 meters (250 feet) from the runway centerline must be of frangible construction, using breakaway sections of reflector masts, nor exceed 3 meters (10 feet) in height above the centerline elevation of the nearest runway at the intersection of the equipment centerline perpendicular with the runway centerline.

B13-2.8 Airborne Radar Approach Reflectors (Non-Frangible).

Airborne radar approach reflectors may be placed not less than 99.1 meters (325 feet) from the runway edge and not less than 121.9 meters (400 feet) nor more than 228.6 meters (750 feet) from the runway centerline to the edge of the equipment in a pattern parallel to the runway.

B13-2.8.1 Army.

For Army, at least one reflector must be located within the AN/FPN67/AN/TPN-31 PAR azimuth angle coverage area in order to provide a horizontal reference point. It can be sited within 250 feet of the runway centerline with an approved waiver. Reflectors sited less than 76.2 meters (250 feet) from the runway centerline must be of frangible construction, using breakaway sections of reflector masts, nor exceed 3 meters (10 feet) in height above the centerline elevation of the nearest runway at the intersection of the equipment centerline perpendicular with the runway centerline.

B13-2.9 Instrument Landing System (ILS).

Reference FAA Order 6750.16 for siting criteria for the ILS.

B13-2.9.1 ILS Localizer Antennas (Frangible).

The localizer array should be located between 304.8 meters (1,000 feet) and 609.6 meters (2,000 feet) beyond the stop end of the runway. As a rule, siting must conform to approach-departure clearance surface criteria discussed in Chapters 3 and 4. Refer to FAA order 6750.16 if standard localizer antenna placement is not an option.

B13-2.9.1.1 Far Field Monitor (FFM) (Frangible if Mounted on Low-Impact-Resistant Supports, Non-Frangible if Mounted on Utility Poles).

The FFM is not required for CAT I ILS systems; however, it is required for CAT II and above systems. The FFM is considered part of the localizer system. However, it is sited at the opposite end of the runway from the localizer antenna array. Typical locations are 365.8 meters (1,200 feet) to 914.4 meters (3,000 feet) prior to the landing threshold. FFM antenna height is determined by line of sight to the localizer antenna array. The line of sight requirement can be relaxed if satisfactory localizer signal reception is proven with a portable ILS receiver at the proposed lower height of the FFM site. Just as with the localizer antenna array, the FFM antenna shall not penetrate the approach-departure clearance surface criteria discussed in Chapters 3 and 4. Army siting requirements are contained in FAA Order 6750.16.

B13-2.9.1.2 ILS Localizer Transmitter (Non-Frangible).

The ILS localizer transmitter is sited adjacent to the localizer antenna array. It must be located at least 76.2 meters (250 feet) from the extended runway centerline or a waiver is required. Emergency power generators must be as close to the facilities they support as practical.

B13-2.9.2 ILS Glide Slope Antenna (Non-Frangible).

The antenna mast or monitor should be located a minimum distance of 121.9 meters (400 feet) from the runway centerline to the centerline of the antenna, and should not exceed 16.7 meters (55 feet) in height above the nearest runway centerline elevation. A mast height of over 16.7 meters (55 feet) is permitted if the minimum distance from the runway centerline is increased by 3.1 meters (10 feet) for each 305 millimeters (1 foot) the mast exceeds 16.7 meters (55 feet). When the mast cannot, for technical or economic reasons, be located at a minimum distance of 121.9 meters (400 feet) from the runway centerline, the minimum distance may be reduced to not less than 76.2 meters (250 feet) from the centerline, provided the basic mast height of 16.7 meters (55 feet) is reduced 305 millimeters (1 foot) for each 1.5 meters (5 feet) it is moved toward the runway from the 121.9-meter (400-foot) point. Glide slope monitor units are considered part of the parent equipment. Emergency power generators must be as close to the facilities they support as practical, but no closer than the glideslope main facility.

B13-2.9.2.1 ILS End Fire Glide Slope Antenna (Frangible).

Site in accordance with FAA Order 6750.16. For the end-fire glide slope, the antenna array typically extends to 25 feet from the runway edge. This is allowed due to antenna frangibility.

B13-2.9.3 Marker Beacons (Non-Frangible).

Marker beacons support instrument approach procedures. They are located on the runway centerline extended as noted.

B13-2.9.3.1 Outer Marker (OM) Beacon.

The OM beacon marks the point where the aircraft should intercept the glide slope. When the OM beacon cannot be located at this point, it is located between this point and the landing threshold, as close to this point as possible.

B13-2.9.3.2 Middle Marker (MM) Beacon.

B13-2.9.3.3 The MM beacon is located from 609.6 meters to 1,828.8 meters (2,000 to 6,000 feet) from the instrument runway threshold. Inner Marker (IM) Beacon.

The IM beacon is located to mark the point where the glide slope angle intersects the DH point of a CAT II ILS. An inner marker beacon is not used on a CAT I ILS. Marker beacons must not penetrate airspace clearance surfaces defined in this UFC.

B13-2.10 Microwave Landing System (MLS) and Mobile Microwave Landing System (MMLS) (Non-Frangible).

Use FAA Order 6830.5 for selecting MLS sites. Criteria for siting MMLS are provided within AFI 11-230. All installations should be sited the maximum distance from the runway centerline allowed by operational requirements but not less than 60.96 meters (200 feet). MMLS may be required to be sited as near as 45.72 meters (150 feet). Additionally, if the MMLS will be required to remain in service for more than 30 days, the antenna and associated operational equipment should be removed from the trailer and installed on a small foundation that is placed so that the surface is no higher than 76 millimeters (3 inches) above grade. The anchors used to secure the equipment should be the minimum size required to meet local requirements.

B13-2.11 Mobile Navigational Aids and Communication Facilities (Non-Frangible).

These units (including UAS TALS) follow the same general siting criteria as their fixed facility counterpart and the same deviations from standard clearance criteria are permissible. Power generators for these facilities will be located as close to the equipment and in as small a site configuration as possible.

B13-2.12 Mobile Air Traffic Control Towers (MATCT)/Mobile Tower System (MOTS) (Non-Frangible).

At least a 152.4-meter (500-foot) distance must be maintained between the centerline of any runway and the near edge of the tower. Power generators may be located in positions adjacent to the MATCT/MOTS. Communication antennas to be used with these towers, which are not mounted on the facility, require the same separation from the runway centerline as the parent equipment, fixed or mobile.

B13-2.13 Terminal Very High Frequency Omnirange (TVOR) Facility and Very High Frequency Omnirange (VOR) Facility (Non-Frangible).

TVOR and VOR facilities may be located not less than 152.4 meters (500 feet) for Air Force (76.2 m or 250 ft for Army) from the centerline of any runway to the edge of the facility, nor less than 61 meters (200 feet) for Air Force (45.72 m or 150 ft for Army) from the centerline of a taxiway.

B13-2.14 Tactical Air Navigation (TACAN) Facility and Very High Frequency Omnidirectional Radio Range (VORTAC) Facility (Non-Frangible).

When used as terminal navigational aids, the TACAN, VOR, and VORTAC facilities may be sited not less than 152.4 meters (500 feet) from the centerline of any runway to the edge of the facilities, provided the elevation of the antenna does not exceed 15.2 meters (50 feet) above the highest point of the adjacent runway centerline. For an on-base installation, the maximum angle of convergence between the final approach course and the runway centerline is 30 degrees (30°). The final approach course should be aligned to intersect the extended runway centerline 3,000 feet (914.4 meters) outward from the runway threshold. When an operational advantage can be achieved, this point of intersect may be established at any point between the threshold and a point 5,200 feet (1584.96 meters) outward from the runway threshold. Also, where an operational advantage can be achieved, a final approach course which does not intersect the runway centerline or intersects at a point greater than 5,200 feet (1,584.96 meters) outward from the runway threshold may be established, provided that such a course lies within 500 feet (152.4 meters) laterally of the extended runway centerline at a point 3,000 feet (914.4 meters) outward from the runway threshold.

B13-2.15 Non-Directional Beacon (NDB) (Non-Frangible).

When used as terminal navigational aid for the Army, the facility may be sited not less than 76.2 meters (250 feet) from the centerline of any runway to the edge of the facilities, provided the elevation of the antenna does not exceed 7.62 meters (25 feet) above the highest point of the adjacent runway centerline.

B13-2.16 Tactical Automated Landing System (TALS) (Non-Frangible).

This paragraph provides siting information for UAS support facilities that do not conform to the airfield clearance and airspace surface criteria elsewhere in this document. The MQ-1C Tactical Automated Landing System (TALS) and supporting equipment shall be sited at a maximum distance from the runway centerline allowed by operational requirements but not less than 250 feet. When the TALS is required to be sited within 250 feet it must meet frangibility requirements and have an approved waiver IAW Appendix B, Section 1. All other supporting equipment shall be sited not less than 250 feet from the runway centerline. Under no conditions will the TALS be sited closer than 150 feet from the runway centerline. If line-of-sight is the basis of the waiver request then the waiver request will have a line-of-sight analysis justifying the operational distance from the runway centerline. Additionally, if the Tactical Automated Landing System-Tracking System (TALS-TS) will be required to remain in service for more than 30 days, the equipment should be installed on a small concrete foundation. No part of the TALS-TS foundation and any remaining structure attached to it will extend three inches or more above grade after the frangible connections fail.

B13-2.17 Runway Supervisory Unit (RSU) (Non-Frangible) (USAF Only).

An RSU is a transportable or permanent all-weather, control tower type facility used to control or monitor aircraft movement. The RSU complex, consisting of the facility and all support equipment, must be confined to a site not to exceed 15.2 meters (50 feet) long by
15.2 meters (50 feet) wide. A minimum distance of 76.2 meters (250 feet) must be maintained between the runway centerline and the RSU facility and support equipment. Integral fuel tanks should be used for necessary mobile emergency power generator sets. If additional tanks are required or integral fuel tanks are not available, place the fuel supply system below grade with other supporting utilities.

B13-2.18 Fixed Base Weather Observing Systems (Non-Frangible).

A permanently installed automated FBWOS (e.g., AN/FMQ-19, AN/FMQ-22, AN/FMQ-23, or ASOS) consists of a suite of weather sensors and processors capable of collecting, measuring or calculating and reporting a myriad of weather elements. These elements include, but are not limited to, wind direction and speed, prevailing visibility, present weather and visibility obstructions, cloud coverage and cloud base height, temperature, dew point, atmospheric pressure, lightning, and precipitation amounts. The observing system's primary sensor suite contains the majority of the sensors. Many locations also have additional discontinuity sensor suites. The discontinuity suite contains fewer sensors than the primary suite and is sited at the runway's roll out, midfield, or in the case of a multi-runway configuration, at an adjacent site along a parallel or intersecting runway in order to provide critical weather element readings that are representative of the respective location. Selecting appropriate locations to install sensor groups is a critical consideration for flight operations safety as well as to ensure the weather elements collected are representative of the meteorological conditions affecting flight operations. The primary and discontinuity sensor groups will be aligned parallel to the runway and must be not less than 300 feet (Class A/Rotary-Wing Runways) or 400 feet (Class B) from centerline of the runway as close as possible to the touchdown point (between 1000 and 3000 feet down from the runway threshold). Fixed base weather systems are mounted on concrete footings or foundations and may vary in dimension depending on type of system suite. The top surface of these concrete structures will be flush with the surrounding surface grade. For siting criteria of a FBWOS near taxiways and parking aprons on airfields and heliports, use Tables 5-1, 5-2, and 6-1 in this manual. In cases where real-estate and/or terrain do not permit siting according to the UFC's direction, a waiver with supporting justification is required by Air Force IMSC Detachment or Garrison Commander at Army locations.

B13-2.19 Wind Direction Indicators (Frangible and Non-Frangible).

B13-2.19.1 Wind Cones.

See UFC 3-535-01 for appropriate siting.

B13-2.19.2 Landing Direction Indicator (Landing “T” or Tetrahedron) (Non-Frangible).

A landing “T” or tetrahedron must be located at least 83.82 meters (275 feet) from the edge of a runway to the centerline of the equipment.

B13-2.20 UAS Support Equipment (Frangible and Non-Frangible).

UAS support equipment is mobile and moved around the base to meet mission requirements. Equipment must be frangible whenever feasible. Acceptable runway centerline offset for support equipment is 250 ft. Acceptable taxiway centerline offset is 100 ft. Minimum 50 ft taxiway wingtip clearance is required for any non-local aircraft.

B13-2.20.1 Ground Data Terminal (GDT).

Line of Sight (LOS) Antenna that controls aircraft within LOS. The GDT must be elevated to avoid LOS signal interruption.

B13-2.20.2 GDT Towers.

Towers (mobile and fixed) that elevate the GDT above potential LOS interference.

B13-2.20.3 Ground Control Station (GCS).

Container/facility from where the Pilot and Sensor Operator control aircraft

B13-2.20.4 Satellite Antenna (PPSL).

Satellite antenna dish that controls aircraft beyond LOS.

B13-2.20.5 HVAC.

Equipment for cooling.

B13-2.20.6 UHF/VHF Antennas.

radio antenna to communicate with Tower and Crew Chiefs.

B13-2.20.7 Concrete Pads.

Concrete pads set in the turf or pavement for parking mobile equipment. Pads must be constructed flush with the surrounding grade.

B13-2.21 General Information for Operational and Maintenance Support Facilities.

Detailed siting information is furnished in this section, where appropriate.

B13-2.21.1 Operational Facilities.

B13-2.21.1.1 Aircraft Arresting Systems and Barriers (Net Engaging Systems) (Non-Frangible).

A series of components used to engage an aircraft and absorb the forward momentum of a routine or emergency landing (or aborted take-off). See **\1** AFMAN 32-1040 **/1/** or NAVAIR 51-5-31 for detailed siting criteria and other information and requirements.

a. Current aircraft arresting systems installed under previous criteria and standards may continue in service without waiver if they do not impair operational safety. The BCE's representative should identify such systems to flight safety and operations through the airfield manager, determine the proper risk mitigation, and program these systems for replacement. This should be done annually in conjunction with the annual waiver review. Such systems are: BAK-12 with two-roller deck sheave-type runway edge sheaves; BAK-12 systems with two-roller fairlead beam runway edge sheaves; on-grade BAK-12 systems installed before 1 July 1977 that are sited less than 76.2 meters (250 feet) from runway centerline (see grandfather allowance in **\1** AFMAN 32-1040 **/1/**); BAK-9 systems with two-roller deck-sheave runway edge sheaves; and BAK-13 systems; E-28 Arresting Gear Systems for Navy runways.

b. BAK-12 energy absorbers installed on-grade may not be sited less than 83.82 meters (275 feet) from runway centerline. Slopes over tape tubes for all types of installations must comply with criteria for shoulder grading provided in Chapter 3. Fairlead and three-roller deck sheave foundations must be constructed in accordance with Air Force Typical Installation Drawings 67F2013A, applicable to three-roller fairlead beams (e.g., sloped 30H to 1V). Protective shelters constructed for on-grade installations must be constructed from lightweight framing materials and sheathing using connections that will allow the structure to break away and collapse if struck by an aircraft wing. The overall height of the structure must be kept to the absolute minimum to meet mission requirements. See Typical Installation Drawing 67F2013A for suggested sources. For structures that must be constructed to resist high wind or snow loads, consider internal bracing that can be quickly and easily installed when such weather events are forecast, rather than concrete masonry or heavy steel designs.

c. BAK-15 barrier masts and hydraulic system components may be sited within 3 meters (10 feet) of the overrun edge. This is necessary to minimize the mast height needed to maintain the centerline height of the net. Foundations must be constructed flush with grade or grading surrounding the foundations shall be shaped to comply with the grading allowances provided for shoulders in Chapter 3, Table 3-4, Items 5 and 6.

d. Textile brake aircraft arresting systems may be sited adjacent to the runway or overrun edges, whether in a paved or unpaved surface. Cable pretensioning devices should be sited as far from the overrun or runway edge as possible. All foundations shall be flush with grade except the leading edge of the module foundations which have a 76.2-millimeter (3-inch) or less vertical drop to provide jet blast protection for the modules. Unidirectional models of this system, such as the MB 60.9.9, are not sited between the thresholds.

e. When aircraft arresting systems are decommissioned and removed from the airfield environment with no intent of replacement in the existing location, all related structures and foundations must be demolished and removed from the airfield. Grades in the area must be restored to comply with criteria provided in this UFC, as appropriate.

B13-2.21.1.2 Warm-up or Holding Pad.

The warm-up or holding pad is a paved area adjacent to the taxiway and the runway end. It provides a means of bypassing aircraft being held at the runway end for various reasons. For detailed design and siting criteria, see Chapter 6.

B13-2.21.1.3 Arm/Disarm Pad.

Arm/disarm pads are used for arming aircraft just before takeoff and for disarming weapons retained or not expended upon the aircraft's return. For detailed siting criteria and other information, see Chapter 6. When a personnel shelter is required, it is considered a part of the arm/disarm complex and must be sited to provide minimum wingtip/rotor clearance for the adjacent pavement type (taxiway or taxilane) and according to explosives quantity-distance criteria as discussed in Appendix B, Section 9 and AFMAN 91-201/DA PAM 385-64 for Air Force and Army respectively. Also see paragraph B13-2.21.2.8.

B13-2.21.1.4 Helicopter Autorotation Lanes (Also Called "Slide Areas" or Skid Pads").

Such lanes may be sited on or between active runways without a waiver. Ensure they are sited to prevent conflicts in operations (safety clearance zones must not overlap operational areas that will be used simultaneously).

B13-2.21.1.5 Vehicle Control Signs and Traffic Lights (Frangible and Non-Frangible).

These signs and lights provide drivers with guidance on traffic routes, service yard areas, and similar places. They provide warning information at runway and taxiway crossings and other hazardous points. Vehicle control signs and traffic lights may be located on the airfield movement area (including apron) without a waiver to criteria. However, a traffic engineering study should be accomplished and coordinated with civil engineers, airfield management, and safety before traffic control devices are selected and installed. (Refer to Army Military Traffic Management Command [MTMC] Pamphlet 55-14 for information on obtaining assistance with traffic engineering studies.) In siting vehicle controls signs and traffic lights, make sure that they do not obstruct taxiing or towed aircraft. Incorporate frangibility into existing designs to the maximum extent practicable by saw-cutting wood posts on opposing sides to a depth of approximately one-third the cross-section of the post, or chain-drilling metal posts to provide an intended break point near the base. Modifications of this type must be made at a point no more than 76.2 millimeters (3 inches) above grade. Incorporate more precise frangible designs as these devices are replaced. See paragraph B13-2.2.2 for further guidance.

B13-2.21.1.6 Runway Distance Remaining (RDR) Signs (Frangible).

These signs are required for runways used by jet aircraft and are recommended for runways used by propeller-type aircraft. For detailed siting and design guidance, see **\1** AFMAN 32-1040 **/1/** and UFC 3-535-01.

B13-2.21.1.7 Aircraft Security System (Frangible and Non-Frangible).

If a security system or fence is approved by the Air Force for airfield security, such as the microwave fence sensor or similar system as required by AFI 31-101, approval of the siting by the AFIMSC Detachment operation and safety offices will allow siting the system without waiver. No fence shall be allowed to penetrate the primary or approach-departure clearance surfaces without a waiver.

a. Flightline security sensor supports originally developed for the tactical area security system (TAAS) were tested and qualified as acceptable frangible mounting supports for various types of security sensors. These supports may be used over the entire airfield if sited to comply with the following guidelines.

- **Taxiways.** Conformance with criteria for taxiway signs must be met (distance and height).
- **Aprons.** TAAS security sensor mounts will be allowed on aprons, provided minimum taxilane wingtip clearance (as described in Chapter 6 for peripheral, through, and interior taxilanes) is maintained. There is no height restriction for supports up to 3 meters (10 feet) tall.
- **Runway/Overrun.** The closest distance from runway and paved overrun edge will be 30 meters (100 feet); closest distance to threshold (longitudinally) within the CZ will be 300 meters (1,000 feet). No penetrations of the approach-departure clearance surface will be allowed.

B13-2.21.1.8 Defensive Fighting Positions (Non-Frangible).

Although primarily used at deployed locations, base defense plans may require temporary defensive fighting positions (DFP) during base operational readiness exercises or increased force protection levels. DFPs are allowed to be sited within the primary surface and land use control area of the clear zone; however, they must not penetrate the approach-departure clearance surface or the runway/taxiway mandatory zone of frangibility. When temporary DFPs are not in use or are no longer required, they must be removed from the airfield and grades restored.

B13-2.21.2 Maintenance Facilities.

B13-2.21.2.1 Jet Blast Deflectors (Non-Frangible).

Jet blast deflectors are installed where continual jet engine run-up interferes with the parking or taxiing of aircraft, the movement of vehicles, the activities of maintenance personnel, or where it causes the erosion of pavement shoulders. To provide maximum efficiency, jet blast deflectors must be positioned at their optimum distance from the aircraft. They should be located to maintain nominal aircraft taxiing clearance distance as described in Table 6-1.

B13-2.21.2.2 Floodlights (Non-Frangible).

Floodlights illuminate aprons, alert stubs, specialized pads and other paved areas used for aircraft maintenance, loading/unloading, area security, and other reasons. Floodlights may be located on or near the apron, but must provide the minimum aircraft wingtip clearance in Table 6-1. They are not, however, exempt from the vertical restriction imposed by the transitional surface. Any deviation from this restriction must be waived, as discussed in Appendix B, Section 1.

B13-2.21.2.3 Fire Hydrants (Non-Frangible).

Fire hydrants may be installed within the apron clearance distances discussed in Chapter 6, provided the height is no more than 762 millimeters (30 inches) above the ground, and not more than 610 millimeters (24 inches) above the elevation of the adjacent load-bearing pavement. Hydrants must also be sited at least 25.6 meters (84 feet) from taxilane centerline. This is to provide the minimum clearance required by AFI 11-218 and is based on the geometry of a KC-135 aircraft positioned off taxilane centerline toward the hydrant, but with the outermost main gear still on the load-bearing pavement. Fire hydrants that violate the apron or taxiway lateral clearances will be completely painted with reflective paint or have a minimum 4" wide retro-reflective tape or paint surrounding stripe to ensure visibility during night operations. Normally bollards are not required for hydrants located adjacent to aprons. Per UFC 3-600-01, they are required only for hydrants located near roads, streets, and parking lots. If unique circumstances dictate that bollards be installed to protect hydrants located adjacent to the apron, they must be sited at the minimum distance and maximum height provided above. For aprons not intended to support the KC-135, this distance must be computed for the most critical aircraft that will use the apron taxilane. In cases where hydrants were sited prior to the date of publication of this UFC and are found to be sited too close to the peripheral taxilane centerline, the painted taxilane centerline and apron boundary marking or the fire hydrant locations should be adjusted to provide a minimum of 3 meters (10 feet) from the hydrant or bollard to the nearest point on the most demanding aircraft that will use the apron, with the outermost main gear positioned at the edge of the load-bearing pavement. For additional siting criteria and other information on the location of fire hydrants, see UFC 3-600-01.

B13-2.21.2.4 Explosives Safety Barricades (Non-Frangible).

When barricades are an element in an aircraft alert complex, they may be located on or near the apron, but must be sited to provide minimum wingtip clearance distances in Table 6-1. For information on explosives safety standards, see AFMAN 91-201/DA PAM 385-64 for Air Force and Army respectively.

B13-2.21.2.5 Ground Support Equipment (Mobile) (Non-Frangible).

Mobile ground support equipment may be located on aprons, but must be positioned to provide minimum wingtip clearance distances prescribed in Table 6-1 for all aircraft other than those being serviced with the equipment. Examples of ground support equipment exempt under this category are: aerospace ground equipment; electrical carts; forklifts; tow bar trailers; fire extinguisher carts; material-handling equipment; flightline maintenance stands; stair trucks; and portable floodlights. Similar equipment may be included in this category. When such equipment is not in use, it must be removed from the aircraft parking area and stored in areas that do not violate aircraft clearance requirements for normal operating routes (marked taxilanes or taxiways) or other imaginary surfaces. For the purpose of this UFC, equipment in use is defined as support equipment in place not more than three hours before aircraft arrival or three hours after aircraft departure. Support equipment may remain on the ramp in an Ops Group approved location indefinitely. These locations should be marked on the pavement to ensure equipment is stored to meet aircraft wingtip clearance and any other operational criteria to provide for safe operations.

B13-2.21.2.6 Flightline Vehicles (Non-Frangible).

Motor vehicles are allowed, based on approved operational/mission requirements, to operate on or near the flight line, including runways, taxiways, aprons, and service roads, in accordance with the provisions of TC 21-305-20, Chapter 20, *Operation of Motor Vehicles on Flight Lines*, and applicable Service airfield/flightline driving regulations/guidelines. When not required, these vehicles are relocated away from the vicinity of the parked aircraft.

B13-2.21.2.7 Ground Support Equipment (Stationary) (Non-Frangible).

Stationary ground support equipment and the associated safety and security components are necessarily sited on and near aprons, but must be sited to provide the minimum wingtip clearance prescribed in Table 6-1, defined by the wingtip trace of the most demanding aircraft that will use the apron. This type of equipment should not be sited in a way that will require any part of the aircraft to overhang the equipment unless the components are located below grade and the access points meet applicable grading criteria and are designed to withstand wheel loads and jet blast as defined within Chapter 6 of this UFC and Appendix B, Section 7. Fuel safety shut-off switches may be sited in accordance with the siting criteria for fire hydrants or in accordance with siting criteria for airfield signs if they incorporate a frangible coupling at the base (see UFC 3-535-01). Examples of stationary ground support equipment are centralized aircraft support systems and pantograph refueling systems. This also includes markers for petroleum, oil, and lubricant (POL) supply lines, communications and utility lines, and property demarcation. Ensure proper lighting and fire safety features are included.

B13-2.21.2.8 Crew Chief Shack (Non-Frangible).

This facility, sometimes identified as an airfield maintenance unit, is a trailer or permanent prefabricated structure that may be located at the end of the runway, close to the arm/disarm pad or the apron edge. It may also be located on the apron, but must meet wingtip clearance requirements provided in Table 6-1. Although these shelters are allowed in the graded area of the clear zone, no shelter shall penetrate the approach-departure clearance surface, nor the runway or taxiway mandatory zone of frangibility.

Explosive quantity distance criteria in AFMAN 91-201/DA PAM 385-64 applies to Air Force and Army respectively.

B13-2.21.2.9 Service Roads.

Service roads may be located on the perimeter of alert aprons, around specialized aircraft parking pads, or for access to NAVAIDs, aircraft arresting systems, weather sensors, and other similar areas on the airfield. Service roads are not permitted in the runway (graded) clear zones, unless access is controlled by air traffic control (Tower). In locating these roads, the wing overhang and appropriate safe clearance distance for the largest aircraft using the facility must be taken into account, and they must be marked or signed to identify VFR and instrument holding positions, to prevent encroachment into NAVAID critical areas or violation of the approach-departure clearance surface. The distance from the peripheral taxilane on an apron to the edge of the road is computed from the centerline of the aircraft's path, plus the minimum wingtip clearance given in Table 6-1, items 4, 5, and 6 (except at intersections with operational pavement). See UFC 3-260-04 for placement of runway holding positions and instrument landing system (ILS) or precision approach radar (PAR) critical areas. Ensure service roads are appropriately marked to control vehicular movement along and within the roadway. Markings shall be in accordance with **\1** AFMAN 32-1040 **/1/** and the *Manual on Uniform Traffic Control Devices* (MUTCD), published by the Department of Transportation, Federal Highway Administration.

B13-2.21.2.10 Fencing and Barricades (Jersey Barriers) (Frangible and Non-Frangible, respectively).

Fencing and barricades are erected on airfields for a variety of purposes. They may be located on the perimeter of alert aprons, around specialized aircraft parking pads or NAVAIDs, and other similar areas on the airfield when necessary for security or force protection. When siting fences or barricades, the wing overhang and appropriate safe clearance distance for the largest aircraft using the facility must be taken into account. The distance from the nearest taxilane on an apron to the fence or barricade is computed from the centerline of the aircraft's path, plus the minimum wingtip clearance given in Table 6-1, items 4, 5, and 6. **\1\ Exception:** Barricades may not be located within the Mandatory Zone of Frangibility for runways or taxiways without a waiver and fences constructed within these areas must meet wingtip clearance requirements and the requirements of paragraph 13-2.2.2.5. No fence or barricade shall penetrate the primary or approach-departure clearance surfaces or the graded area of the Clear Zone. Installation perimeter fencing shall not be sited within the graded area of the Clear Zone (305 meters [1000 feet]) but may be sited outside of it in the land-use area of the Clear Zone/Mandatory Zone of Frangibility to comply with required installation boundary security/force protection requirements. Fencing within the MFZ must meet the requirements of paragraph 13-2.2.2.5 or it requires a waiver. **/1/** Penetrations to the 7:1 transitional surface are allowed without waiver for base boundary (property line) fences if they have no impact to existing or planned instrument procedures (TERPS). Barricades located on aprons within the primary surface must be marked and lighted as obstructions unless they are shielded by other obstructions that are marked and lighted, or are located on the outer periphery of the apron away from the runway, behind an aircraft parking area with an exempt status or approved waiver.

a. **Snow Fencing**. This type of structure may be installed within the Runway Primary Surface or Transitional Surface(s) however it must be located outside of the Mandatory Frangibility Zone. Fencing will be of a sturdy yet non-permanent construction, of a height not exceed 6 feet tall and all fencing components will be removed during the season(s) when snow is not probable. Snow fencing location(s) will be selected in coordination with the installation Flight Safety and Airfield Management office concurrence. Snow fencing is not permitted in any location that will violate aircraft wing-tip clearances criteria or that will interfere with NAVAIDs or METNAV devices

B13-2.21.2.11 Wildlife Control Devices.

Various devices such as propane cannons, sirens, and traps may require siting within the airfield environment for wildlife control. Ensure these devices are sited at least 30.5 meters (100 feet) from the near edge of runways and overruns. When sited along taxiways and aprons, ensure these devices do not pose a hazard to taxiing or towed aircraft and, as a minimum, conform to distance and height criteria for airfield signs (see UFC 3-535-01). For guidelines on wildlife control fences, see paragraph B13-2.21.2.10 above.

B13-2.21.2.12 Bird Aircraft Strike Hazard (BASH) Radar Systems.

Aircraft bird-strike avoidance radar systems should be sited off the airfield when possible. However, when no alternatives exist, these facilities are authorized as permissible deviations to airfield criteria, provided they are sited so they do not impact existing or planned instrument procedures (TERPS). They also must not be sited within 122 meters (400 feet) of runway centerline, the graded area of the clear zone, as a penetration to the approach-departure clearance surface, nor within any of the mandatory frangibility zones (see Tables 3-2 and 3-5). These areas include taxiway clearance distances and taxilane wingtip clearance distances (see Tables 5-1 and 6-1). Care must also be taken to ensure they are sited so they will not interfere with NAVAID critical areas or other airfield radar systems. Coordinate with the METNAV shop and communications to ensure these requirements are met.

B13-2.21.2.13 Fuel Hydrants.

Fuel hydrants may be installed within the apron clearance distances discussed in Chapter 6, provided the height is no more than 762 millimeters (30 inches) above the ground, and not more than 610 millimeters
(24 inches) above the elevation of the adjacent load-bearing pavement. Fuel Hydrants must also be sited at least 25.6 meters (84 feet) from taxilane centerline. This is to provide the minimum clearance required by AFI 11-218 and is based on the geometry of a KC-135 aircraft positioned off taxilane centerline toward the hydrant, but with the

outermost main gear still on the load-bearing pavement. Normally bollards are not required for hydrants located adjacent to aprons. If unique circumstances dictate that bollards be installed to protect hydrants located adjacent to the apron, they must be sited at the minimum distance and maximum height provided above. For aprons not intended to support the KC-135, this distance must be computed for the most critical aircraft that will use the apron taxilane. In cases where hydrants were sited prior to the date of publication of this UFC and are found to be sited too close to the peripheral taxilane centerline, the painted taxilane centerline and apron boundary marking or the fuel hydrant locations should be adjusted to provide a minimum of 3 meters (10 feet) from the hydrant or bollard to the nearest point on the most demanding aircraft that will use the apron, with the outermost main gear positioned at the edge of the load-bearing pavement.

B13-2.21.3 Miscellaneous.

B13-2.21.3.1 Telephone and Fire Alarm Systems.

Telephone and fire alarm system boxes may be located on or in the vicinity of aprons, provided the height of the structure does not constitute an obstruction to the most demanding aircraft that will use the apron.

B13-2.21.3.2 Trash Collection Containers.

Dumpsters and similar equipment may be located in the vicinity of an apron, provided appropriate wingtip clearance requirements given in Table 6-1, items 4, 5, and 6 are provided, and the location does not constitute a hazard to pedestrian or vehicular traffic from the debris.

B13-2.21.3.3 Landscaping Around Flightline Facilities.

Shrubs and other landscaping should conform to the height restriction discussed in paragraph B13-2.21.3.1 or must be located to provide the minimum wingtip clearances provided in Chapter 6.

B13-2.21.3.4 Other Apron Facilities.

Facilities other than those previously mentioned within this section may require siting near or on aprons due to their function and purpose. In these cases, ensure wingtip clearance shown in Table 6-1 is provided. Some examples of these type facilities are hangars, aircraft sunshades, wash racks, taxi-through alert shelters, air passenger terminals, movable passenger access platforms (jetways), base operations facilities, squadron operations facilities, airfield maintenance unit facilities, fire stations, fuel or groundwater recovery systems, material-handling equipment storage facilities, airfreight terminals, and weather shelters for sentries. Facilities must not penetrate imaginary surfaces without an approved waiver.

B13-2.21.3.5 Utility Access Points.

Utility handholes and manholes should be constructed flush with grade. These utility access points do not require a waiver if the drop-off at the edge of the top surface is 76 millimeters (3 inches) or less.

B13-2.21.3.6 Air Traffic Control Towers.

Air Traffic Control Towers may be considered permissible deviations to the transitional surface if it meets the siting criteria given in Appendix B, Section 16. For Army, Air Traffic Control Towers are not considered permissible deviations.

B13-2.21.3.7 Runway Ice Detection System (RIDS).

RIDS consists of four functional elements: in-pavement sensors; supporting power supply/signal processor units; terminal data processing units; and data display units/printers. The components sited within the airfield environment are authorized as a permissible deviation to airfield criteria provided in this UFC when sited as follows:

a. The in-pavement sensors are installed in the runway pavement flush with and in the plane of the pavement surface. The head surface texture shall be similar to that of the surrounding pavement surface and approximate the flow and pooling characteristics of water on the surrounding pavement. The remote field units that provide power to the in-pavement sensor head, processes raw surface condition input data, collect air temperature and related atmospheric data, and transmit the processed data to the terminal data processing unit are fixed by function and must be sited on the airfield.

b. Where practical, these units should be collocated with other air navigational aids outside the mandatory frangibility zone (MFZ) so they do not conflict with other electronic and visual air navigational aids. If collocation is not possible, the units must be equipped with obstruction lights and shall be sited along the runway and taxiway, outside the MFZ but not within the last 304 meters (1,000 feet) of the runway. The height must be kept to the minimum practicable and the units must be equipped with a frangible coupling at the base. See FAA AC 150/5220-13 for more detailed information on these systems.

B13-2.21.3.8 Utility Risers.

Utility risers located near runways, taxiways and aprons supporting facilities listed as permissible deviations in this Section are authorized. Utility risers within the MFZ must be frangible. Utility riser must be lower than 4-ft tall. Utility riser shall have obstruction light installed when required per UFC 3-535-01.

APPENDIX B
SECTION 14
CONSTRUCTION PHASING PLAN AND OPERATIONAL SAFETY ON AIRFIELDS DURING CONSTRUCTION

B14-1 CONTENTS.

A construction phasing plan must be included in the contract documents. The purpose of a phasing plan is to establish guidelines and constraints the contractor must follow during construction. It is recommended that the construction phasing plan be submitted for coordination and review at the concept and design stage. At minimum, the plan must be coordinated with airfield management, airfield operations, communications, ground and flight safety, environmental, security forces, contracting and logistics.

B14-2 NAVY AND MARINE CORPS REQUIREMENTS.

This section does not apply to the Navy and Marine Corps.

B14-3 INFORMATION TO BE SHOWN ON THE CONSTRUCTION PHASING PLAN.

The phasing plan will include, but is not necessarily limited to, the following:

B14-3.1 Phasing.

All construction activities will be separated into phases. The phasing plan will show or describe the sequence of construction activity for each phase. The phasing plan will be incorporated into the contractor's management plan and reflected in the progress schedule. The work area limits (to define required aircraft and worker safety and security clearances), barricades, maximum equipment height, and temporary fencing requirements will be clearly delineated for each phase. The work area limits will include identification of restricted areas requiring escorts and free zones with secure areas.

B14-3.2 Aircraft Operational Areas.

The phasing plan will identify active aircraft operational areas and closed pavement areas for each phase.

B14-3.3 Additional Requirements.

If required, the location of flagmen, security guards, and other personnel should be shown. These locations should be supplemented in the specifications.

B14-3.4 Temporary Displaced Thresholds.

Temporary displaced thresholds and temporary displaced threshold lighting requirements should be shown. These details will be presented in the drawings and supplemented in the specifications.

B14-3.5 Access.

Construction vehicle access roads, including access gates and haul routes, will be shown.

B14-3.6 Temporary Marking and Lighting.

Temporary pavement marking and lighting details will be presented on the phasing plan. Marking and lighting details are presented in UFC 3-260-04, UFC 3-535-01, and applicable FAA guidance.

B14-3.7 Safety Requirements and Procedures.

The construction phasing plan must include a section outlining safety requirements and procedures for activities on the airfield during the planned period of construction.

B14-3.8 FOD Checkpoints.

Location of foreign object debris (FOD) checkpoints, when required, should be included in the phasing plan.

B14-4 OTHER ITEMS TO BE SHOWN IN THE CONTRACT DRAWINGS.

The following items are not necessarily a part of the phasing plan, but will be included in the contract documents.

B14-4.1 Storage.

The contractor's equipment and material storage locations.

B14-4.2 Parking.

The contractor's personnel vehicle parking area and access routes to the work area.

B14-4.3 Buildings.

Location of the contractor's offices and plants.

B14-4.4 Designated Waste and Disposal Areas.

Off-site disposal should be included in the specifications.

B14-5 MAXIMUM EQUIPMENT HEIGHT.

The maximum height of construction equipment expected to be in use during construction must be included in the contract documents, the work order project requirements checklist, or other project guidance documents. This information must also be included on FAA Form 7460-1, *Notice of Proposed Construction or Alteration*. This form must be submitted to the FAA 30 days before the start of construction if the maximum equipment height penetrates any of the surfaces described in FAR Part 77.

B14-6 OPERATIONAL SAFETY ON THE AIRFIELD DURING CONSTRUCTION.

This section provides the minimum risk mitigation standards for Army and Air Force airfield construction projects and guidelines concerning operational safety on airfields during construction. This information is intended to assist civil engineers, airfield management, and safety personnel in maintenance of a safe operating environment. The principal guidelines provided here were taken from FAA AC 150/5370-2, latest version, but have been modified to better relate to Army and Air Force needs and terminology. Construction activity is defined as the presence and movement of personnel, equipment, and materials in any location that could infringe upon the movement of aircraft. Normal maintenance activities are exempt from these requirements. Some examples of exempt maintenance activities are grass cutting, minor pavement repairs, inspection, calibration, and repair of NAVAIDs and weather equipment, aircraft arresting systems maintenance, and snow removal operations.

B14-6.1 General Requirements.

Construction activities on the airfield, in proximity to, or affecting aircraft operational areas or navigable airspace, must be coordinated with all airfield users before initiating such activities. In addition, basic responsibilities must be identified and assigned and procedures developed and disseminated to instruct construction personnel in airport procedures and for monitoring construction activities for conformance with safety requirements. These and other safety considerations must be addressed in the earliest stages of project formulation and incorporated in the contract specifications, the work order project requirements checklist, and/or other project guidance documents developed for in-house construction projects. Construction areas located within the aircraft movement area requiring special attention by the contractor or in-house construction activity must be clearly delineated on the project plans. The quality assurance personnel, airfield manager, and contract administrator should closely monitor construction activity throughout its duration to ensure continual compliance with safety requirements. At minimum, comply with the requirements in paragraphs B14-6.1.1 through B14-6.1.4. Otherwise, alternative safety mitigation plans must be developed and included in the construction waiver request for the installation commander's approval.

B14-6.1.1 Runways.

Activities within the graded areas of the clear zone will require threshold displacement sufficient to protect the approach-departure clearance surface, and adjustment to the departure runway end location to provide a minimum 305-meter (1,000-foot) safety area between the stop end of the runway and construction activities. Construction activities must not be conducted within a distance equal to the normal VFR holding position distance from the near edge of any active segment of a runway.

B14-6.1.2 Taxiways, Taxilanes and Aprons.

Construction activity setback lines must be located at a distance to provide the minimum wingtip clearance required in Table 6-1, items 5 or 6, as appropriate, for the largest aircraft that will use the taxiway, taxilane or apron.

B14-6.1.3 Jet Blast.

You must also consider jet blast effects on personnel, equipment, facilities, and other aircraft. Maintain a distance behind aircraft sufficient to dissipate jet blast to 56 kilometers per hour (35 miles per hour) and temperatures to a maximum of 38 degrees Celsius (100 degrees Fahrenheit), or ambient, whichever is more, or provide jet blast protection with a deflector.

B14-6.1.4 Marking and Lighting.

Threshold displacements and runway end relocation must be marked and lighted in accordance with UFC 3-260-04, and UFC 3-535-01. Additionally, alternate temporary taxi routes on taxiways or aprons must be marked either with temporary paint markings or with frangible edge markers. They must also be lighted if they will be used during periods of darkness or during instrument flight rule operations. Closed taxiways or taxilanes on aprons must be marked or barricaded and normal lighting circuits disabled. Temporary obstructions, such as cranes, must be marked and lighted in accordance with FAA AC 70/7460-1. All hazardous areas (such as excavations or stockpiled materials) on the airfield must be delineated with lighted barricades on all exposed (visible or accessible) sides.

B14-6.2 Formal Notification of Construction Activities.

Any entity, including the military, proposing any kind of construction or alteration of objects that may affect navigable airspace, including military airspace, as defined in FAR Part 77, is required to notify the FAA. FAA Form 7460-1 is used for this purpose.

B14-6.3 Safety Considerations.

The following is a partial list of safety considerations which experience indicates will need attention during airport construction.

a. Minimum disruption of standard operating procedures for aeronautical activity.

b. Clear routes from firefighting and rescue stations to active airport operations areas.

c. Chain of notification and authority to change safety-oriented aspects of the construction plan.

d. Initiation, currency, and cancellation of Notice to Airmen (NOTAM).

e. Suspension or restriction of aircraft activity on affected airport operations areas.

f. Threshold displacement and appropriate temporary lighting and marking.

g. Installation and maintenance of temporary lighting and marking for closed or diverted aircraft routes and disabling the normal lighting circuits for closed runways, taxiways, and taxilanes.

h. Revised vehicular control procedures or additional equipment and manpower.

i. Marking/lighting of construction equipment.

j. Storage of construction equipment and materials when not in use.

k. Designation of responsible representatives of all involved parties and their availability.

l. Location of construction personnel parking and transportation to and from the work site.

m. Marking/lighting of construction areas.

n. Location of construction offices.

o. Location of contractor's plants.

p. Designation of waste areas and disposal.

q. Debris cleanup responsibilities and schedule.

r. Identification of construction personnel and equipment.

s. Location of haul roads.

t. Security control on temporary gates and relocated fencing.

u. Noise pollution.

v. Blasting regulation and control.

w. Dust control.

x. Location of utilities.

y. Provision for temporary utilities and/or immediate repairs in the event of disruption.

z. Location of power and control lines for electronic/visual navigational aids.

aa. Additional security measures required if AFI 31-101 is impacted (relocation or reconstruction of fences or security sensors).

bb. Marking and lighting of closed airfield pavement areas.

cc. Coordination of winter construction activities with the snow removal plan.

dd. Phasing of work.

ee. Shutdown, relocation and/or protection of airport electronic and or visual navigational aids.

ff. Smoke, steam, vapor, and extraneous light controls.

gg. Notification to crash/fire/rescue and maintenance personnel when working on water lines.

hh. Provide traffic directors/wing walkers, etc., as needed to assure clearance in construction areas.

B14-6.4 Examples of Hazardous and Marginal Conditions.

Analyses of past accidents and incidents identified many contributory hazards and conditions. A representative list follows:

a. Excavation adjacent to runways, taxiways, and aprons.

b. Mounds or stockpiles of earth, construction material, temporary structures, and other obstacles near airport operations areas and approach zones.

c. Runway surfacing projects resulting in excessive lips greater than 25.4 millimeters (1 inch) for runways and 76.2 millimeters (3 inches) for edges between old and new surfaces at runway edges and ends.

d. Heavy equipment, stationary or mobile, operating or idle near airport operations areas or in apron, taxiway, or runway clearance areas.

e. Proximity of equipment or material which may degrade radiated signals or impair monitoring of navigational aids.

f. Tall but relatively low-visibility units such as cranes, drills, and the like in critical areas such as aprons, taxiways, or runway clearance areas and approach zones.

g. Improper or malfunctioning lights or unlighted airport hazards.

h. Holes, obstacles, loose pavement, trash, and other debris on or near airport operations areas.

i. Failure to maintain fencing during construction to deter human and animal intrusions into the airport operation areas.

j. Open trenches alongside operational pavements.

k. Improper marking or lighting of runways, taxiways, and displaced thresholds.

l. Attractions for birds such as trash, grass seeding, or ponded water on or near the airfield.

m. Inadequate or improper methods of marking temporarily closed airport operations areas, including improper and unsecured barricades.

n. Obliterated markings on active operational areas.

o. Encroachments to apron, taxiway, or runway clearance areas, improper ground vehicle operations, and unmarked or uncovered holes and trenches in the vicinity of aircraft operating surfaces are the three most recurring threats to safety during construction.

B14-6.5 Vehicles on the Airfield.

Vehicular activity on the airfield movement areas should be kept to a minimum. Where vehicular traffic on airfield operational areas cannot be avoided, it should be carefully controlled. A basic guiding principle is that the aircraft always has the right-of-way. Some aspects of vehicle control and identification are discussed below. It should be recognized, however, that every airfield presents different vehicle requirements and problems and therefore needs individualized solutions so vehicle traffic does not endanger aircraft operations. Personnel required to drive on the airfield must be knowledgeable of and comply with the procedures outlined in the installation airfield driving program.

B14-6.5.1 Visibility.

Vehicles which routinely operate on airport operations areas should be marked and/or flagged for high daytime visibility and, if appropriate, lighted for nighttime operations. Vehicles which are not marked and lighted may require an escort by one that is equipped with temporary marking and lighting devices. (See Air Force T.O. 36-1-191 and FAA AC 150/5210-5.)

B14-6.5.2 Identification.

It is usually desirable to be able to visually identify specific vehicles from a distance. It is recommended that radio-equipped vehicles which routinely operate on airfields be permanently marked with identifying characters on the sides and roof. Vehicles needing intermittent identification could be marked with tape or magnetically attached markers. Such markers are commercially available. However, select markers that can perhaps be mounted inside the vehicle or tethered to the vehicle so they do not fall off during vehicle operation and present potential foreign object damage (FOD) to aircraft.

B14-6.5.3 Noticeability.

Construction vehicles and equipment should have automatic signaling devices to sound an alarm when moving in reverse.

B14-6.5.4 Movement.

The control of vehicular activity on airfield operations areas is of the highest importance. Airfield management is responsible for developing procedures and providing training regarding vehicle operations to ensure aircraft safety during construction. This requires coordination with airfield users and air traffic control. Consideration should be given to the use of two-way radio, signal lights, traffic signs, flagman, escorts, or other means suitable for the particular airfield. The selection of a frequency for two-way radio communications between construction contractor vehicles and the Air Traffic Control Tower (ATCT) must be coordinated with the ATC tower chief. At non-tower airfields, two-way radio control between contractor vehicles and fixed-base operators or other airport users should avoid frequencies used by aircraft. It should be remembered that even with the most sophisticated procedures and equipment, systematic training of vehicle operators is necessary to achieve safety. Special consideration should be given to training intermittent operators, such as construction workers, even if escort service is being provided.

B14-6.6 Inspection.

Frequent inspections should be made by the airfield manager, civil engineering contract inspectors, and other representatives during critical phases of the work to ensure the contractor is following the prescribed safety procedures and there is an effective litter control program.

B14-6.7 Special Safety Requirements during Construction.

Use the following guidelines to help develop a safety plan for airfield construction.

B14-6.7.1 Runway Ends.

Construction equipment will not penetrate the approach-departure clearance surface.

B14-6.7.2 Runway Edges.

Construction activities normally will not be permitted within 30 meters (100 feet) of the runway edge. However, construction may be permitted within 30 meters (100 feet) of the runway edge on a case-by-case basis with a temporary waiver approved by the installation commander.

B14-6.7.3 Taxiways and Aprons.

Normally, construction activity setback lines will be located at a distance to provide the minimum wingtip clearance required from Table 6-1, items 5 or 6, as appropriate, plus one-half the wingspan of the largest predominant aircraft that will use the taxi route from the centerline of the active taxiway or apron. However, construction activity may be permitted up to the taxiway and aprons in use, provided the activity is approved by the installation commander and NOTAMs are issued; marking and lighting provisions are implemented; and it is determined the height of equipment and materials is safely below any part of the aircraft using the airfield operations areas which might overhang those areas. Alternate taxi routes and procedures for wing-walkers should be included in the safety plan if adequate wingtip clearance cannot be provided.

B14-6.7.4 Excavation and Trenches.

Excavations and open trenches may be permitted along runways up to 30 meters (100 feet) from the edge of an active runway, provided they are adequately signed, lighted and marked. In addition, excavation and open trenches may be permitted within 30 meters (100 feet) of the runway edge on a case-by-case basis; that is, cable trenches, pavement tie-ins, etc., with the approval of the installation commander. Along taxiways and aprons, excavation and open trenches may be permitted up to the edge of structural taxiway and apron pavements, provided the drop-off is adequately signed, lighted and marked.

B14-6.7.5 Stockpiled Materials.

Extensive stockpiled materials should not be permitted within the construction activity areas defined in the preceding four paragraphs.

B14-6.7.6 Maximum Equipment Height.

FAA Form 7460-1 shall be submitted when equipment is expected to penetrate any of the surfaces described in Appendix B, Section 5, FAR Part 77.9.

B14-6.7.7 Proximity of Construction Activity to Navigational Aids.

Construction activity in the vicinity of navigational aids requires special considerations. The effect of the activity and its permissible distance and direction from the aid must be evaluated in each instance. A coordinated evaluation by the airfield manager, civil engineer, safety, and communications personnel is necessary. Particular attention needs to be given to stockpiling materials as well as to the movement and parking of equipment which may interfere with line-of-sight from the tower or interfere with electronic emissions.

B14-6.7.8 Proximity of Construction to Explosives QD Arc.

Wing Explosive safety must obtain a waiver for any construction falling inside an explosives QD Arc.

B14-6.8 Construction Vehicle Traffic.

With respect to vehicular traffic, aircraft safety during construction is likely to be endangered by four principle causes: increased traffic volume; nonstandard traffic patterns; vehicles without radio communication and marking; and operators untrained in airfield procedures. Because each construction situation differs, airfield management must develop and coordinate a construction vehicle traffic plan with airfield users, air traffic control and the appropriate construction engineers and contractors. The plan, when signed by all participants, should become a part of the contract, the work order project requirements checklist, and/or other project guidance documents developed for in-house projects. Airfield management, quality assurance, and safety are responsible for coordinating and enforcing the plan.

B14-6.9 Limitation on Construction.

Open-flame welding or torch cutting operations are prohibited unless adequate fire and safety precautions are provided and have been approved by the fire chief. All vehicles are to be parked and serviced behind the construction restriction line and/or in an area designated by the contract, the work order project requirements checklist, and/or other project guidance documents developed for in-house projects. Open trenches, excavations, and stockpiled material at the construction site should be prominently marked with orange flags and lighted with flashing red or yellow light units during hours of restricted visibility and/or darkness. Under no circumstances are flare pots to be near aircraft operating areas. Stockpiled material should be constrained in a manner to prevent dislocation that may result from aircraft jet blast or wind. Material should not be stored near aircraft operating areas or movement areas.

B14-6.10 Marking and Lighting Closed or Hazardous Areas on Airfields.

To ensure adequate marking and lighting is provided for the duration of the project, the construction specifications, the work order project requirements checklist, and/or other project guidance documents must include a provision requiring the contractor or other construction activity to have a person on-call 24 hours a day for emergency maintenance of airport hazard lighting and barricades. See **\1** AFMAN 32-1040 **/1/**, UFC 3-260-04 and UFC 3-535-01 for marking and lighting requirements for closed pavement areas.

B14-6.11 Temporary Runway Threshold Displacement.

Identification of temporary runway threshold displacements must be provided as indicated in UFC 3-260-04, and UFC 3-535-01. The extent of the marking and lighting should be directly related to the duration of the displacement as well as the type and level of aircraft activity. Temporary visual aids must be placed to provide an unobstructed approach-departure clearance surface with a 3-meter (10-foot) buffer between the surface and the tallest equipment in the construction zone, and a 304.8-meter (1,000-foot) -long overrun safety area beyond the departure end of the runway. Runway threshold displacements must be coordinated with the TERPS office as the displacement will require discontinuation of precision instrument procedures and may affect landing minima for non-precision procedures. Departure procedures will also have to be evaluated to determine the effects of the runway threshold displacements.

APPENDIX B
SECTION 15
ARMY AND AIR FORCE AIRCRAFT TRIM PAD AND THRUST ANCHOR FOR 267 KILONEWTONS (60,000 POUNDS) AND 445 KILONEWTONS (100,000 POUNDS) THRUST

B15-1 PURPOSE.

This Section presents design details for two aircraft trim pad anchoring systems designed to support working loads of 267 kN (60,000 lb) and 445 kN (100,000 lb) of thrust. This Section supersedes Air Force ETL 01-10, *Design and Construction of High-Capacity Trim Pad Anchoring Systems*.

B15-2 BACKGROUND.

A thrust anchor is constructed by embedding a steel anchor block trim pad into a large reinforced concrete block tie to the surrounding anchor concrete slab, and used to constrain fighter aircraft during power checks and routine engine maintenance procedures. Many existing aircraft anchor blocks were designed to withstand loads associated with F-4 operations and 267 kN (60,000 lb) thrust; however, the newer generation of fighter aircraft employs engines with much greater thrusts. At locations supporting those aircraft, the 445 kN (100,000 lb) anchor block must be used. At locations where only aircraft with lower thrust loads, smaller anchor blocks may be designed. **All anchors shall be clearly labeled with the design load rating**.

B15-3 ANALYSIS AND VISUAL INSPECTIONS.

Analyses of anchor block designs have concluded that the likely mode of failure will be rupture of the metal link; however, other modes could occur. Therefore, the critical areas for routine visual inspection should include the surface at the steel-concrete interfaces, the top of the weld between the curved bar and the web plate, and the weld on the metal link. Observable permanent deformation of the steel bar would indicate that appreciable plastic stains have occurred and that the strength of the anchor block system should be reviewed more carefully.

B15-4 CONSTRUCTION.

B15-4.1 Materials and Manufacturing.

The anchor steel shall be high-strength alloy with a yield strength of at least 689.5 MPa (100 kips per square inch). A high strength alloy must be used to keep the thickness of the bar to a diameter than can be bent 180-degrees at an inside radius of 101 mm (4 inches). Also, a thicker bar would make connection design more difficult.

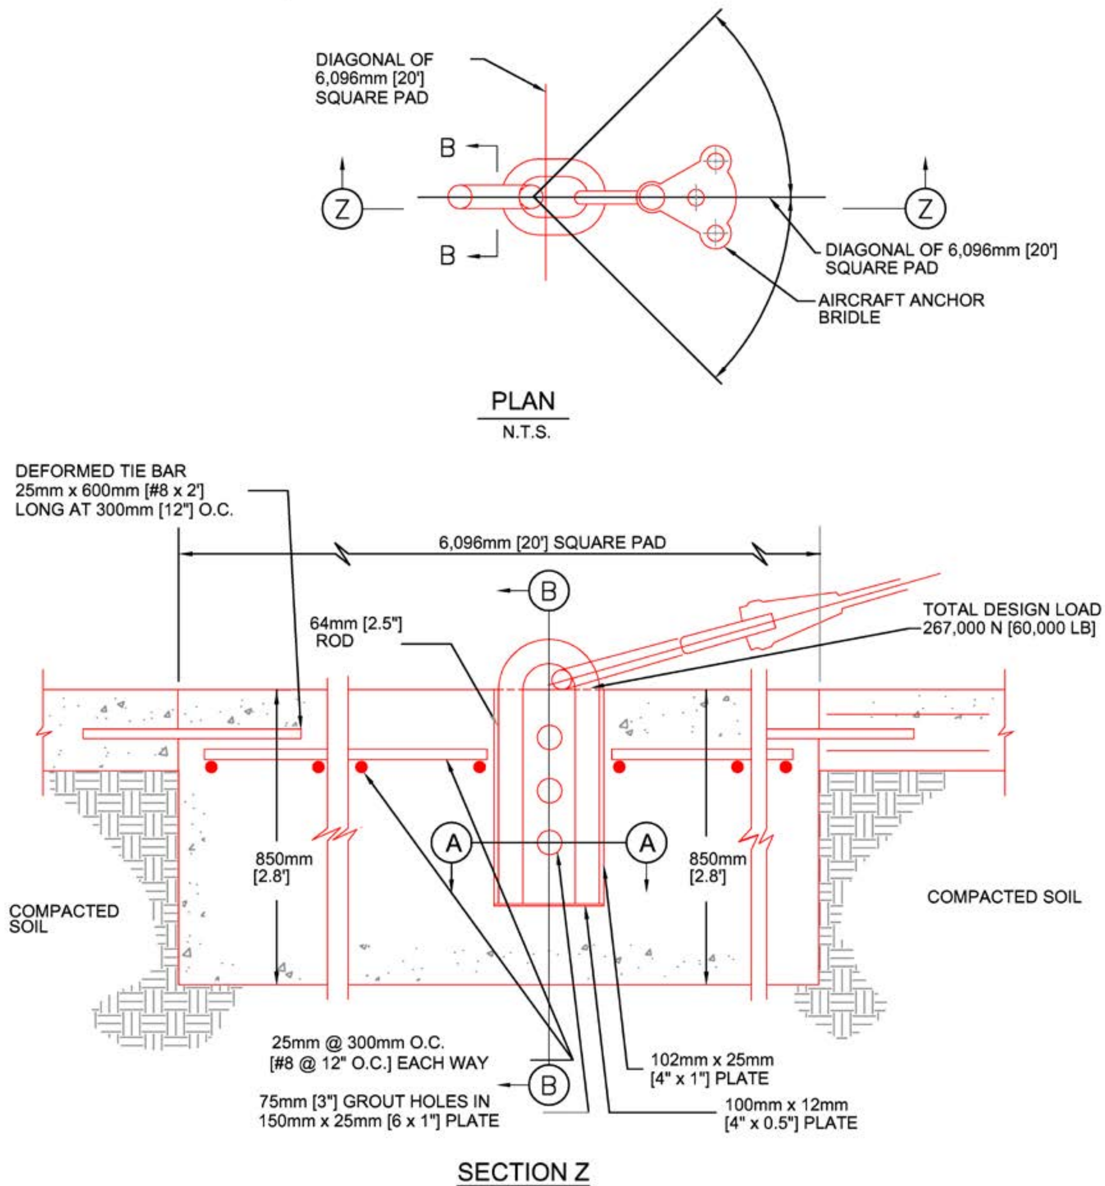
B15-4.2 Placement of Rebar.

For the 445 kN (100,000 lb) anchor block, the rebar is designed so that pulling out the steel anchor would require pulling out the top layer of rebar. The top layer of rebar is set over the 63-millimeter (2.5-inch) steel dowels that go through the web of the steel anchor. A minimum cover of 203 millimeters (8 inches) should be provided and checked before the concrete is poured.

B15-4.3 Pouring and Finishing Concrete.

Approximately 15,300 liters (20 yards) of concrete is needed for the 445 kN (100,000 lb) anchor block. Concrete must be placed evenly on both sides of the anchor so the anchor will not move while pouring. Minimum 34.4-megapascal (5000-psi) compressive strength concrete shall be used in anchor blocks.

Figure B15-1. Example of 267 kN (60,000 LB) Square Aircraft Anchor Block and Cross Section

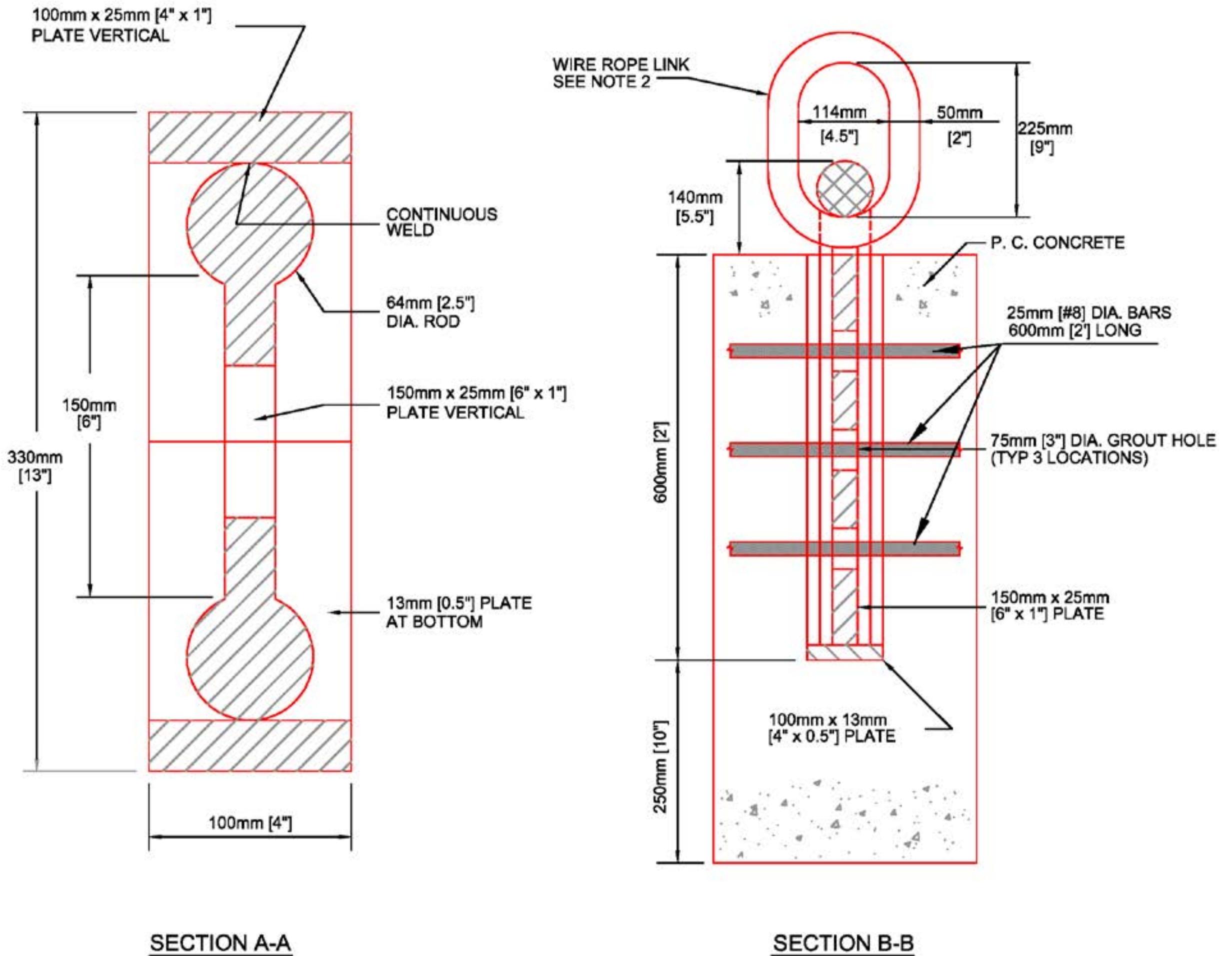


STANDARD 267 kN (60,000 lb) AIRCRAFT ANCHOR BLOCK
N.T.S.

NOTES

1. THIS DESIGN IS FOR UP TO 267,000 N [60,000 LB] THRUST AND WILL ACCOMMODATE FIGHTER AIRCRAFT UP TO AND INCLUDING F-15E. THE DESIGNER MUST VERIFY STRUCTURAL DESIGN FOR THRUST OF DIFFERENT AIRCRAFT AND ENGINE TYPES.
2. DESIGN MAY BE SCALED DOWN TO MEET MISSION AIRCRAFT THRUST LOAD REQUIREMENTS. IF SCALED DOWN, THE ANCHOR MUST BE LABELED WITH THE MAXIMUM THRUST IT IS DESIGNED TO HOLD.
3. SEE FIGURE B15-2 FOR SECTION VIEW.

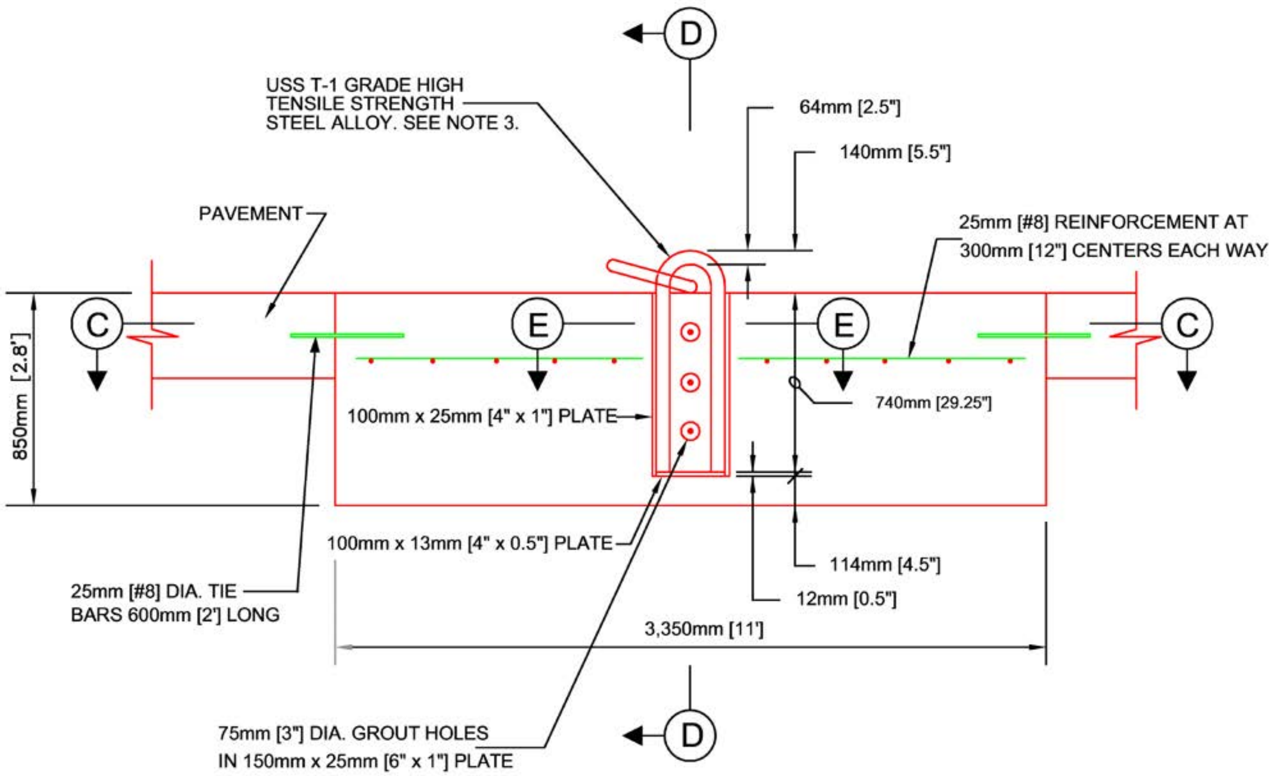
Figure B15-2. Example of 267 kN (60,000 lb) Square Anchor Block, Cross Section A-A and B-B



NOTES

1. THIS DESIGN IS FOR UP TO 267,000 N [60,000 LB] THRUST AND WILL ACCOMMODATE FIGHTER AIRCRAFT UP TO AND INCLUDING F-15E. THE DESIGNER MUST VERIFY STRUCTURAL DESIGN FOR THRUST OF DIFFERENT AIRCRAFT AND ENGINE TYPES.
2. DESIGN MAY BE SCALED DOWN TO MEET MISSION AIRCRAFT THRUST LOAD REQUIREMENTS. IF SCALED DOWN, THE ANCHOR MUST BE LABELED WITH THE MAXIMUM THRUST IT IS DESIGNED TO HOLD.
3. WIRE ROPE LINK TO BE CONSTRUCTED OF HIGH-STRENGTH ALLOY WITH MINIMUM YIELD OF 100 KSI, OR USE A LOAD-CERTIFIED COMMERCIAL SHACKLE. ONE SOURCE FOR LOAD-CERTIFIED SHACKLES IS THE CROSBY GROUP INC.
4. ALL STEEL COMPONENTS USED ARE ASTRALLOY V WITH 1,000 MEGAPASCALS [145,000 PSI] YIELD AND 360 MIN BRINELL HARDNESS EXCEPT FOR SHACKLES AND REINFORCING STEEL.
5. ANCHOR ROD SHOULD HAVE A MINIMUM YIELD OF 100 KSI, BE CORROSION RESISTANT, BENDABLE TO THE SPECIFIED RADIUS WITHOUT LOSS OF STRENGTH, HAVE CONSTANT ENGINEERING PROPERTIES TO 537° C, AND POSSESS GOOD FATIGUE CHARACTERISTICS.

Figure B15-3. Example of 267 kN (60,000 lb) Octagonal Anchor Block



NOTES

1. THIS DESIGN IS FOR UP TO 267,000 N [60,000 LB] THRUST AND WILL ACCOMMODATE FIGHTER AIRCRAFT UP TO AND INCLUDING F-15E. THE DESIGNER MUST VERIFY STRUCTURAL DESIGN FOR THRUST OF DIFFERENT AIRCRAFT AND ENGINE TYPES.

2. SEE FIGURE B15-4 FOR SECTION VIEWS.

3. ANCHOR ROD SHOULD HAVE A MINIMUM YIELD OF 100 KSI, BE CORROSION RESISTANT, BENDABLE TO THE SPECIFIED RADIUS WITHOUT LOSS OF STRENGTH, HAVE CONSTANT ENGINEERING PROPERTIES TO 537° C, AND POSSESS GOOD FATIGUE CHARACTERISTICS.

APPENDIX B
SECTION 16
AIR TRAFFIC CONTROL TOWER SITING CRITERIA

B16-1 GENERAL INFORMATION.

The Air Traffic Control Tower (ATCT) is the focal point for flight operations within the designated airspace of the installation and for controlling aircraft and vehicles on the airport movement area. Locating and siting an ATCT is a complex procedure that involves many operational and technical requirements. The tower cab must be correctly oriented. The area to be controlled must be visible from the cab. The air traffic controller must have proper depth perception of the area under surveillance, and there can be no electronic interference with equipment in the cab or with navigational equipment on the ground. For these considerations and other operational and technical aspects of selecting a site, consult UFC 4-133-01, *Air Traffic Control and Air Operations Facilities* for Service-specific requirements in the early stages of planning. A site survey will be conducted to determine the best siting for the proposed ATCT. For accurate planning and design considerations, the site survey should be conducted within five (5) years of the projected ATCT construction completion date. See UFC 4-133-01 for specific architectural, structural, mechanical, electrical, and other systems design requirements.

B16-2 SITING CRITERIA.

ATCT siting and height determination requires sound engineering principles and close coordination with the host base. Siting project engineers must consider factors that relate to the economics of each candidate site, such as accessibility to utilities, subsoil and ground water conditions, expansion possibilities, as well as selecting a site requiring a tower of the minimum height necessary to meet the specific requirements. The following specific guidelines must be followed:

B16-2.1 Unobstructed View.

The air traffic controllers operating this facility must have a clear, unobstructed, and direct view to all operating positions of the airport traffic area; to the approach end of the primary instrument runway; and all other active runways, taxiways, parking aprons, test pads, and similar areas. The ATCT should be located close to runway midpoints and equidistant from other airfield areas to the greatest extent possible.

B16-2.2 Site Area Requirements.

The site must provide sufficient area to accommodate the initial building and any planned expansions, including vehicle parking, fuel storage tanks, and exterior transformers.

B16-2.3 Quantity Distance Criteria.

See Chapter 1, Paragraph 1-4.1 and Appendix B, Section 9 for additional siting and facility requirements.

B16-2.4 Obstruction Clearance.

As a minimum, the site must conform to ground system and obstruction clearance criteria for Category II Instrument Landing Operations (see FAA Handbook [FAAH] 7110.65 and AFI 11-230).

B16-2.5 Siting Effects on NAVAIDS.

The ATCT must be sited where it will not detract from the performance of existing or planned electronic air navigational facilities (terminal very high frequency omnirange [TVOR], airport surveillance radar [ASR], and tactical air navigation [TACAN]). There are no criteria that establish minimum distances from electronic air navigational facilities. However, the facilities most likely to be affected are the TVOR, TACAN, and ASR. The ATCT should be no closer than 450 meters (1,500 feet) from these three facilities. Other electronic air navigation facilities (e.g., precision approach radar, ILS) are not as likely to be affected because their usage is more directed along the runway's major axis. However, care should be taken in siting the ATCT so it does not conflict with proper operation of these facilities.

B16-2.6 Siting for Proper Depth Perception.

Sufficient depth perception of all surface areas to be controlled must be provided. This is the ability to differentiate the number and type of grouped aircraft and ground vehicles and to observe their movement and position relative to the airfield surface areas. Proper depth perception is provided when the controller's line-of-sight is perpendicular or oblique to the line established by aircraft and ground vehicle movement, and where the line-of-sight intersects the airfield surface at a minimum vertical angle of 35 minutes, with an objective target of 48 minutes vertical angle. Required eye level elevation is determined using the following formula:

$$E_e = E_{as} + D \tan (VA + G s)$$

Where:

E_e = Eye-level elevation (1.5 m [5 ft] above control cab floor).

E_{as} = Average elevation for section of airfield traffic surface in question.

D = Distance from proposed tower site to section of airfield traffic surface in question.

G_s = Angular slope of an imaginary line from the surface of the airfield to the base of the tower, determined by the difference in elevation and the distance between, measured in minutes) (negative value if slope is downward towards the tower, positive value if slope is upward towards the tower).

VA = Line of Sight Vertical Angle. 35 minutes minimum, 48 minutes optimum.

B16-2.7 Compliance with Airfield Standards.

Siting should conform to airfield and airspace criteria in Chapter 3. Deviations should only be considered when they are absolutely necessary. Any siting deviations that would normally require a waiver must be subjected to a TERPS analysis performed by the appropriate service specific office. If the analysis reveals that the ATCT will not adversely affect instrument procedures, the ATCT siting may be considered a permissible deviation with proper service-specific coordination per Chapter 1, Paragraph 1-7.

B16-2.8 Orientation of the Control Cab.

Siting should provide an acceptable orientation of the ATCT Control Cab. The preferred Cab orientation in relation to the runway is obtained when the long axis of the equipment console is parallel to the primary runway. The reason for this orientation is to allow controllers to face the runway and the ATCT instrument panel without frequently turning their heads to observe events on the runway. Preferred direction should be north (or alternatively, east, south, or west, in that order of preference) when sited in the Northern Hemisphere. Locations that place the runway approach in line with the rising or setting sun should be avoided.

B16-2.9 Extraneous Lighting.

Siting should be such that visibility is not impaired by external lights such as floodlights on the ramp, rotating beacons, reflective surfaces, and similar sources.

B16-2.10 Weather Phenomena.

Siting should consider local weather phenomena to keep visibility restriction due to fog or ground haze to a minimum.

B16-2.11 Exhaust Fumes and other Visibility Impairments.

Siting should be in an area relatively free of jet exhaust fumes and other visibility impairments such as industrial smoke, dust, and fire training areas.

B16-2.12 Avoid Sources of Extraneous Noise.

The ATCT should be sited in an area where exterior noise sources are minimized. Special efforts should be made to separate the ATCT from aircraft engine test cells, engine run-up area, aircraft parking areas, and other sources of noise.

B16-2.13 Personnel Access Considerations.

Efforts should be made to site the ATCT so that access can be gained without crossing areas of aircraft operations.

B16-2.14 Compliance with the Comprehensive Plan.

Siting should be coordinated as much as possible with the base comprehensive plan. Particular attention should be given to future construction (including additions or extensions) of buildings, runways, taxiways, and aprons to preclude obstructing controller visibility at a future date.

B16-2.15 Consider the Effects on Meteorological and Communications Facilities.

The ATCT should be sited so it is free of interference from or interference with existing communications-electronics meteorology or non-communications-electronics meteorology facilities. If an acceptable location is not otherwise obtainable, consider relocating these facilities.

Figure B16-1. Runway Profile and New Control Tower

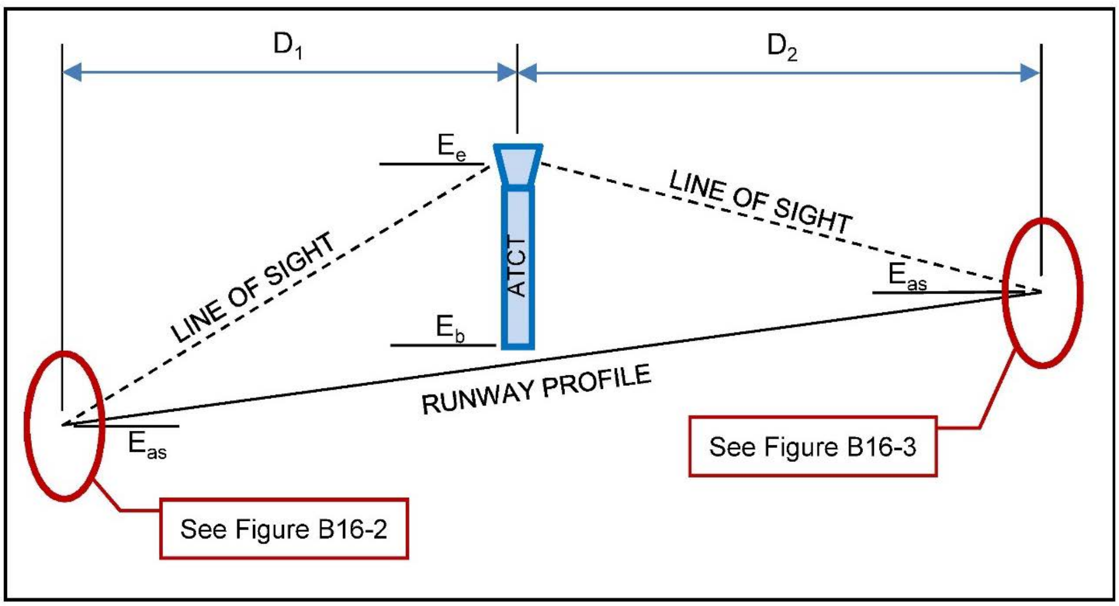

Figure B16-2. Minimum Eye-Level Determination – Tower Higher than Runway End

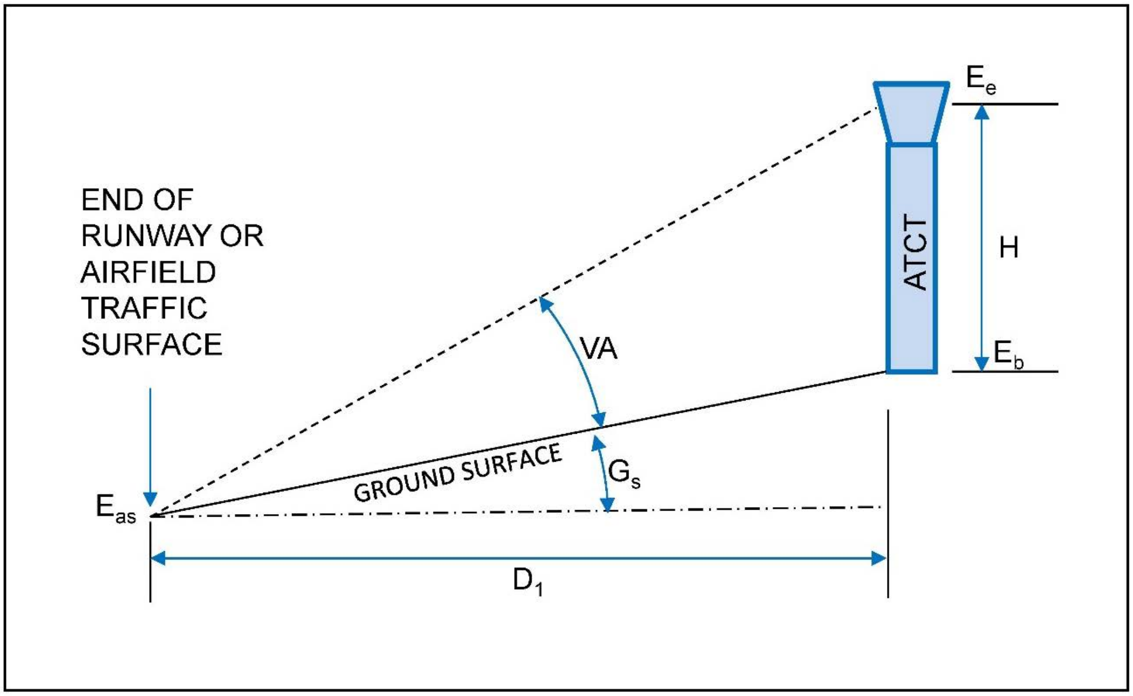


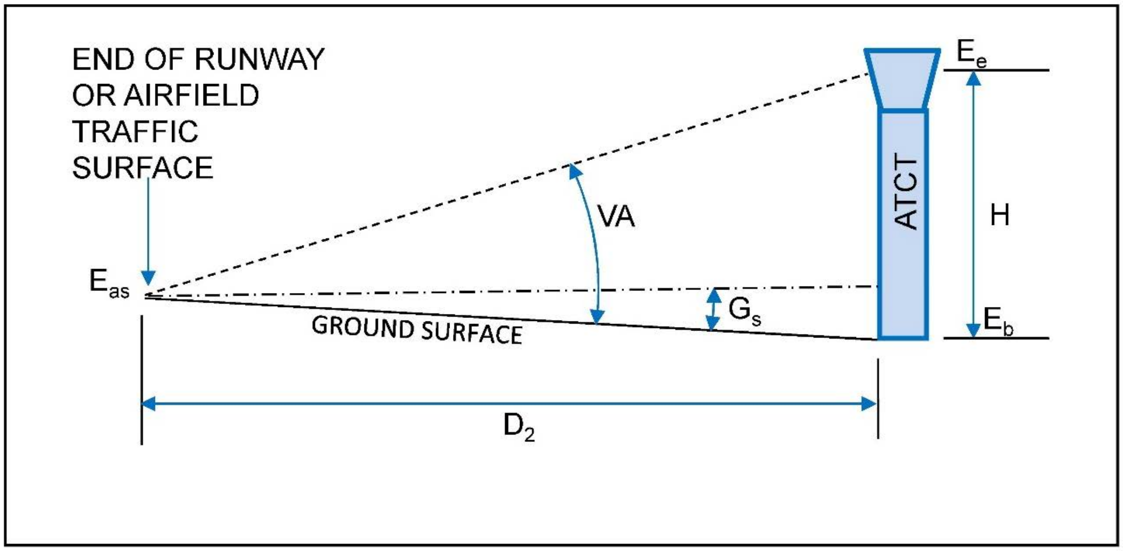
Given: E_{as} = 30.5 m (100') MSL E_b = 32.3 m (106') MSL
D_1 = 1,828.8 m (6,000')
G_s = +2 min
VA = 35 minutes (to reflect minimum requirement)

Find E_e :

E_e = 30.5 m (100') + H
= 30.5 m (100') + (1,828.8 m (6,000') x tan (35 min + 2 min))
= 30.5 m (100') + (1,828.8 m (6,000') x 0.01076)
= 30.5 m (100') + 19.7 m (64.6')
= 50.2 m (164.6') MSL

Minimum Required Eye Level Height = E_e - E_b = 50.2 m (164.6') - 32.3 m (106.0') = 17.9 m (58.6')

Figure B16-3. Minimum Eye-Level Measurement – Tower Lower than Runway End



Given: E_{as} = 33.5 m (110') MSL E_b = 32.3 m (106.0') MSL
D_2 = 1,828.8 m (6,000')
G_s = - 2 min
VA = 35 minutes (to reflect minimum requirement)

Find E_e :

E_e = 33.5 m (110') + H
= 33.5 m (110') + (1,828.8 m (6,000') x tan (35 min - 2 min))
= 33.5 m (110') + (1,828.8 m (6,000') x 0.0096)
= 33.5 m (110') + 17.6 m (57.6')
= 51.1 m (167.6') MSL

Minimum Required Eye Level Height = E_e - E_b = 51.1 m (167.6') - 32.3 m (106.0') = 18.8m (61.6')

CONCLUSIONS:

a. 18.8 m (61.6') height is larger and therefore controls.

b. Eye height to cab ceiling is 2.1 m (7'); therefore, the overall height is 2.1 m (7') + 18.8 m (61.6') = 20.9 m (68.6').

c. In this case, minimum tower height of 20.4 m (67') will not satisfy requirements (see Figure B16-3). Therefore, in order to meet the minimum 35-minute depth perception requirement, an additional floor must be added to increase the overall height of the proposed control tower.

B16-3 MINIMUM REQUIRED FLOOR LEVELS.

See UFC 4-133-01, *Air Traffic Control and Air Operations Facilities* for specific architectural, structural, mechanical, electrical and other systems design requirements.

B16-4 SITING PROCEDURES

The project siting engineer, in determining the site recommendation, should fix the ATCT siting and height to the cab floor with assistance from and concurrence of base communications (plans and programs), base airfield operations flight (control tower and airfield management), and base civil engineering offices. The project engineer for support equipment installation will establish internal ancillary equipment requirements based on an assessment of operational needs. Suggested procedures for selecting an ATCT site are in paragraphs B16-4.1 and B16-4.2.

B16-4.1 Office Study by Siting Engineers.

a. Using elements of the most up-to-date base comprehensive plan, make tentative site selections. Using elements of the base comprehensive plan and the 35-minute depth perception requirements, determine the approximate ATCT height for each tentative site selected.

b. Analyze more than one tentative site if appropriate.

B16-4.2 Field Study by Siting Engineers.

a. Conduct field review of the office-selected tentative sites plus other sites that merit consideration based on discussions with base organizations and the on-location surveys. Consider both siting requirements and siting considerations previously discussed.

b. Consider in the survey of each site the availability and cost of access roads, utility extensions, and communications cable relocations. Also, evaluate each site to determine the adequacy of ground conditions for structural support of the ATCT, drainage characteristics, and availability of utilities.

c. Use profile drawings and shadow maps to determine areas of visibility restrictions due to other structures.

d. If available and practical, obtain panoramic pictures taken at the proposed ATCT Control Cab eye level at each tentative site. Photographs should be in color and oriented to true north to allow precise interpretation of the surfaces and objects viewed and for complete 360-degree horizontal plane around the site. Suggested methods of taking pictures are from a helicopter, cherry picker, or crane boom.

e. Consider the environmental impact of each site. The Environmental Impact Analysis Process (EIAP) is accomplished through the local installation.

B16-4.3 TERPS Analysis.

To determine if a new ATCT will be an obstruction factor, TERPS shall evaluate the proposed ATCT location and final elevation and determine its effect on all existing or planned instrument procedures. Penetrations of the transitional surface may not necessarily affect instrument procedures.

NOTE: ATCTs will not be sited within the primary surface from a runway centerline except at locations required to operate under International Civil Aviation Organization (ICAO) standards. At these locations, the ATCT must be located at least 228.6 meters (750 feet) from the runway centerline.

B16-5 SITE RECOMMENDATIONS.

On completing the field study, siting participants should evaluate each alternative location and should recommend a site. The project siting engineer should then compile all siting data, comparisons, and determinations (including the siting recommendation) in a Statement of Intent (SOI). If practical, the SOI should be signed by all participating personnel, the base communications officer, and the base commander. If practical, the SOI must be completed and signed by appropriate personnel before completing the field study. The SOI should include the following:

- Siting recommendation: location, orientation, and height.
- Data comparisons and determinations made during field study.
- Reasons for deviations, if any, from siting requirements.
- Panoramic pictures, if available.
- Economic evaluations, if applicable.
- Major construction requirements to support communications-electronic (C-E) equipment, if applicable.
- Other special considerations.

B17-6 SOI DISTRIBUTION.

The SOI should be distributed to all signatories. Copies should be retained by the appropriate installation planning, communications, and airfield operations flight offices. Copies should be sent to the appropriate Service program authorities. After agreement to a siting recommendation, the host base submits the siting plan to the appropriate Service program authorities for approval. A sample of an SOI is shown below.

B17-7 SAMPLE SOI.

This is a Statement of Intent (SOI) between (enter name of Service program authority) and (enter name of appropriate installation entity) as it pertains to the (enter date) Site Survey for the proposed new Air Traffic Control Tower at (enter appropriate installation).

The purpose of this SOI is to reserve the area required for this project, to note the major allied support requirements needed for later installation of the project equipment, and to serve as a source document for preparation of the planning documents.

This survey considers (enter appropriate number) possible ATCT locations:

- Site No. 1: (describe location)
- Site No. 2: (describe location)
- Site No. 3: (describe location)

B16-7.1 Site Numbers.

(Insert appropriate numbers) were rejected for the following reasons:

Site No. _________: (Insert reasons for rejection)

Site No. _________: (Insert reasons for rejection)

Based on the results of this survey, it is recommended that Site Number ______ be selected for the new ATCT location. The following rationale supports this recommendation: (Insert rationale.)

The ATCT will be designed using the ________________________ ATCT as a guide. The height of the control ATCT will be (insert height in meters [feet]). See attached sketch. This height is necessary to provide adequate visibility for taxiways/runways and to provide the minimum angle of 35 minutes for depth perception to the farthest aircraft traffic surface on the airdrome.

B16-7.2 Allied Support Requirements

B16-7.3 Utilities.

Electrical power shall be (insert appropriate voltage and frequency), plus or minus 10 percent, three-phase, four wire to the ATCT. Other electrical utility power for mechanical systems shall be (insert appropriate voltage and frequency) to support requirements.

B16-7.3.1 Environmental Requirements.

Environmental control is required in the ATCT Control Cab and the electronic equipment rooms in order to sustain effective and continuous electronic equipment operation. The operational limits and the amount of heat dissipated by the equipment are as follows:

Room Heat Dissipated Temp/Humidity

ATCT Control Cab ______BTU _______/_______

Upper Equipment Room ______BTU _______/_______

Lower Equipment Room ______BTU _______/_______

Other Equipment Room ______BTU _______/_______

B16-7.3.2 Field Lighting Panel.

A field lighting panel, connected to the night lighting vault, will be required for this new structure.

B16-7.3.3 Communications.

All existing communication lines/circuitry for NAVAID monitors and radio transmitters/receivers now terminated in the existing ATCT shall be provided to the new ATCT.

B16-7.3.4 Underground Duct.

The existing base duct system must be extended to the proposed ATCT site for the field lighting cables, primary power cables, control cables, telephone cables, and meteorological cables.

a. After the ATCT project has become a firm MCP item, programming action should be initiated by the base Communications department to relocate the electronic equipment from the existing ATCT to the new ATCT.

b. Points of contact concerning the survey are __________________.

APPENDIX B
SECTION 17
GUIDELINES FOR ESTABLISHING BUILDING RESTRICTION LINE AT AIR FORCE BASES

B17-1 OVERVIEW.

In January 2000, the Chief of Staff directed formation of an Air Force tiger team to address reducing the number of airfield obstructions. To facilitate this effort, the Deputy Chiefs of Staff for Operations, Safety, and Civil Engineering directed that the MAJCOMs provide a listing of airfield obstructions at their bases, along with a cost estimate to remove them. Because many of the obstructions listed were high-cost facilities that were constructed under previous less-stringent standards, and therefore exempt from compliance with current standards, HQ USAF/XOO and ILE issued a policy memorandum directing that all bases must establish building restriction lines (BRL) at the predominant line and height of flight-line facilities. This policy memorandum also authorized further development within the boundaries established by the BRLs without waiver. The guidelines they established for creating the BRLs are provided below to establish a record of the rationale used to accomplish this work and the policy for continued growth within the exempt area. Policy for future modification of BRLs was added to these guidelines for publication within this UFC. See paragraph B17-7.

B17-1.1 General Information.

The BRL is defined as "a line which identifies suitable building area locations on airports." For civilian airports, it is described in FAA AC 150/5300-13. For Air Force installations, the BRL will have the same meaning; however, it will be established at a different location than at civilian airports. Generally, the distance from the runway centerline will be greater. However, in some cases, it may be slightly less than it would be if established in accordance with civil standards.

B17-1.2 Purpose.

The purpose in establishing BRLs on Air Force bases is to identify the area where facilities were constructed under previous standards (exempt facilities) and eliminate waivers for other facilities constructed within this area after the lateral clearance distance standards changed in 1964. (Facilities constructed under previous standards that were consciously omitted from the confines of the BRL must be carried as waivers.) This clarifies existing policy for exempt facilities and creates new policy for new construction and land use to allow continued but controlled development without waiver. This will significantly reduce the administrative burden imposed by the airfield waiver program without increasing risk to flight or ground safety. It will allow continued growth at bases with land constraints and will continue to protect existing airspace. Use the following information to establish the BRL.

B17-2 ESTABLISHING THE BRL AT A BASE.

Establish the BRL laterally from the runway centerline at the predominant line of facilities. The lateral line may have right angles that form indentations or pockets but must exclude all objects and/or facilities that affect existing or planned Terminal Approach and Departure Procedures (TERPS) criteria for your runway, and the 914-meter by 914-meter (3,000-foot by 3,000-foot) clear zone area. See Figure B17-1 for a plan view of a typical BRL. Using the same methodology as described above, establish an elevation control line at the predominant roofline of the facilities within the area formed between the lateral BRL and the lateral clearance distance boundary or the transitional surface, as applicable. The longitudinal slope of the elevation control line should match the slope of the primary surface. This elevation control line will terminate laterally at its intersection with the transitional surface, or at the base boundary, whichever occurs first. See Figure B17-2 for a profile view of a typical BRL.

B17-3 STATUS OF EXISTING AND FUTURE FACILITIES AND OBSTRUCTIONS WITHIN THE AREA.

All facilities beyond and beneath the control lines will be exempt from waiver and obstruction marking and lighting requirements. However, it is imperative that obstruction lighting be maintained along the periphery of the BRL control line. Therefore, maintain obstruction marking and lighting on the facilities used to form the BRL. New facilities constructed at the outer or uppermost limits of the BRL must also be marked and lighted, and appurtenances that extend above the elevation control line must be marked and lighted as obstructions, regardless of their location. Waivers must be maintained for facilities or obstructions that affect instrument procedures (TERPS) and these obstructions must be marked and lighted in accordance with **\1** AFMAN 32-1040 **/1/** and UFC 3-535-01. Obstacles that are behind and beneath the facilities may not need obstruction lights if they are shielded by other obstacles.

B17-4 FUTURE DEVELOPMENT OF AREA WITHIN BRL CONTROL LINES.

B17-4.1 Future Construction.

Future construction within this area is allowed, but only for flightline-related facilities within the following category groups:

- 11, Airfield Pavements
- 12, Petroleum Dispensing and Operating Facilities
- 13, Communications, Navigational Aids, and Airfield Lighting
- 14, Land Operations Facilities
- 21, Maintenance Facilities
- 44 and 45, Storage Facilities Covered, Open and Special Purpose
- 61, Administrative Facilities

- 73, Personnel Support
- 85, Roadway Facilities
- 86, Railroad Trackage
- 87, Ground Improvement Structures.

Utilities and ancillary systems for these types of structures are authorized. See AFH 32-1084 for additional information.

B17-4.2 Existing Facilities.

Existing facilities that are not within the category groups listed above may remain within the exempt zone created by establishing the BRL control lines. However, they must be relocated outside of this area when the facility is replaced.

B17-5 FUTURE MODIFICATION TO BRL.

BRLs may not be modified after they are established except to remove them from the airfield obstruction map if and when all exempt facilities are eventually relocated or to reduce the size of the area encompassed by the BRL as buildings are relocated.

MALS—medium-intensity approach lighting system

MALSR—medium-intensity approach lighting system with runway alignment indicator lights

MATCT—mobile air traffic control tower

max—maximum

MCA—military construction, Army

MDA—minimum descent altitude

METNAV—meteorological NAVAIDS detachment

MFZ—mandatory frangibility zone

MHz—megahertz

MILCON—military construction

MIL-HDBK—military handbook

min—minimum

min—minute

MIRL—medium-intensity runway edge lights

MLG—Main Landing Gear

MLS—microwave landing system

mm—millimeter

MM—middle marker

MMLS—mobile microwave landing system

MOA—military operating area

MOB—main operating base

MOG—maximum on ground

MOTS—Mobile Tower System

mph—miles per hour

MQ—Multi-role unmanned aircraft system

MSL—mean sea level

MTI—moving target indicator

MTMC—Military Traffic Management Command

MUTCD—Manual on Uniform Traffic Control Devices

N/A—not applicable

NAFIG—Navy Flight Information Group

NATO—North Atlantic Treaty Organization

NAVAID or NavAIDS—navigational aids

NAVAIR—Naval Air Systems Command

NAVFAC—Naval Facilities Engineering Command

NAVFACENGCOM—Naval Facilities Engineering Command

NAVFACINST—Naval Facilities Engineering Command instruction

NAVFAC P—Naval Facilities Engineering Command publication

NAVFIG—Naval Flight Information Group

NAVSEA OP—Naval Sea Operations Command operating instruction

NDB—non-directional beacon

NEPA—National Environmental Policy Act

NFPA—National Fire Protection Association

NGB—National Guard Bureau

NLG—Nose Landing Gear

NOTAM—Notice to Airmen

N.T.S.—not to scale

NVG—night vision goggles

O&M—operations and maintenance

OCONUS—outside the continental United States

ODALS—omnidirectional approach lighting system

OH—observation helicopter

OIS—obstacle identification surfaces

OLF—outlying field

OLS—optical landing system

OM—outer marker

OPNAVINST—operations naval instruction

OPR—office of primary responsibility

PACAF/CD—Pacific Air Forces Deputy Commander

PAPI—precision approach path indicator

PAR—precision approach radar

PCASE—Pavement-Transportation Computer Aided Structural Design and Evaluation

PCC—Portland cement concrete

pci—pound per cubic inch

PCN—Pavement Classification Number

PES—potential explosive site

PGCS—portable ground control station

PGDT—portable ground data terminal

PI—point of intersection

PJHTC—plain jointed high temperature concrete

PJPCC—plain jointed Portland cement concrete

PPSL—Predator primary satellite link

POL—petroleum, oil, lubricants

Prime BEEF—Prime Base Engineer Emergency Force

psf—pounds per square foot

psi—pounds per square inch

psia—pounds per square inch absolute

psig—pound per square inch gauge

PUD—planned unit development

Q-D—quantity-distance

°R —degree Rankine

RAIL—runway alignment indicator lights

RAPCON—radar approach control

RCR—runway condition reading

RDO—runway duty officer

RDT&E—research, development, testing, and evaluation

RED HORSE—Rapid Engineers Deployable Heavy Operations Repair Squadron

REIL—runway end identifier light

RF—radio frequency

RIDS—runway ice detection system

RNM—rotorcraft noise model

ROD—record of decision

RPLANS—real property planning and analysis system

RQ—Reconnaissance unmanned aircraft system

RSU—runway supervisory unit

RSZ—refueling safety zone

RVL—rolling vertical landing

RVR—runway visual range

RWOS—representative weather observation station

SALS—short approach lighting system

SI—International System of Units

SLUCM—Standard Land Use Coding Manual

SOI—statement of intent

SPAWARS—Space and Naval Warfare Systems Center

SPAWARSYSCEN—Space and Naval Warfare Systems Center

SPR—single-point receptacle

SSALR—simplified short approach lighting system with runway alignment indicator lights

SSR—Secondary Surveillance Radar

STO—short take-off

STOVL—short take-off, vertical landing

STT—Special Tactics Team

T.O.—technical order

TAAS—tactical area security system

TACAN—tactical air navigation

TALS—Tactical Automated Landing System

TALS-TS—Tactical Automated Landing System – Tracking System

TDA—tables of distribution and allowances

TDZ—touchdown zone

TDP—touchdown point

TERPS—terminal instrument procedures

TM—technical manual

T/O—Take-Off

TO&E—tables of organization and equipment

TSC—Transportation Systems Center

TVOR—terminal very high frequency omnidirectional range

UAS—Unmanned Aircraft System(s)

UPS—uninterruptible power supply

UFC—unified facilities criteria

UH—utility helicopter

UHF—ultra high frequency

US—United States

USA—United States Army

USAASA—US Army Aeronautical Services Agency

USAASDE—United States Army Aeronautical Services Detachment, Europe

USACC—U.S. Army Communication Command

USACE—U.S. Army Corps of Engineers

USACE TSC—U.S. Army Corps of Engineers Transportation Systems Center

USACRC—US Army Combat Readiness/Safety Center

USAF—United States Air Force

USAFEI—United States Air Forces in Europe Instruction

USG—United States Government

USMC—United States Marines Corps

USN—United States Navy

USTRANSCOM—U.S. Transportation Command

VAP—visual aid panel

VASI—visual approach slope indicator

VCSA—Vice Chief of Staff of the Army

VF—fixed-wing fighter

VFR—visual flight rules

VGSI—visual glide slope indicator

VHF—very high frequency

VID—visual identification

VIP—very important person

VL—vertical landing

VLZMP—visual landing zone marker panel

VMC—visual meteorological conditions

VOR—very high frequency omnidirectional range (radio)

VORTAC—very high frequency omnidirectional range (radio) and tactical air navigation

V/STOL—Vertical/Short Take-Off and Landing

VTOL—Vertical Takeoff and Landing

Terms

Aborted Takeoff—An unsuccessful takeoff operation due to power or other mechanical failures.

Accident Potential Zone I (APZ I)—The area beyond the clear zone that possesses a significant potential for accidents.

Accident Potential Zone II (APZ II)—The area beyond APZ I that has a measurable potential for accidents.

AICUZ (Air Installations Compatible Use Zones)—A DoD program designed to promote compatible development around military airfields and to protect the integrity of the installation's flying mission.

Air Traffic—Aircraft in operation anywhere in the airspace and within that area of an airfield or airport normally used for the movement of aircraft.

Aircraft—Fixed-wing (F/W) (airplane) and rotary-wing (R/W) (helicopter).

Aircraft, Class A—Aircraft listed under Class A Runways in Table 3-1 of this manual.

Aircraft, Class B—Aircraft listed under Class B Runways in Table 3-1 of this manual.

Aircraft Arresting Barrier—A device, not dependent on an aircraft hook, used to engage and absorb the forward momentum of an emergency landing or an aborted takeoff.

Aircraft Arresting Cable—That part of an aircraft arresting system which spans the runway surface or flight deck landing area and is engaged by the aircraft arresting gear.

Aircraft Arresting Gear—A device used to engage hook-equipped aircraft to absorb the forward momentum of a routine or emergency landing or aborted takeoff.

Aircraft Arresting System—A series of components used to engage and absorb the forward momentum of a routine or emergency landing or an aborted takeoff.

Aircraft Operating Area—For the purpose of this manual, the aircraft movement area is defined as that area of the airfield encompassed by the primary surface and the clear zones, as well as all apron areas and taxiways, regardless of their location. See paragraph 3-16.1 for the specific use of this term.

Aircraft Wash Area—A specially designed paved area for washing and cleaning aircraft.

Aircraft Wash Rack—Paved areas provided at all facilities to clean aircraft in conjunction with periodic maintenance.

Aircraft Rinse Facility—Paved areas provided at facilities to clean aircraft returning from flight and en route to the parking area.

Airfield—Area prepared for the accommodation (including any buildings, installations, and equipment), of landing and takeoff of aircraft.

Airfield Elevation—Established elevation, in terms of the nearest 300 mm (1 ft) above mean sea level, of the highest point of the usable landing area.

Airfield Reference Point—Designated geographical location of an airfield. It is given in terms of the nearest hundredth of a second of latitude and longitude. The position of the reference point must be as near to the geometric center of the landing area as possible, taking future development of the airfield into account.

Airport—Refers to a civil or municipal airfield.

Airside Facilities—Facilities associated with the movement and parking of aircraft. These include runways, taxiways, apron areas, associated navigational aids and imaginary surfaces.

Airspace—Space above ground or water areas which is or is not controlled, assigned, and/or designated.

Airspace Boundaries—The limits of imaginary surfaces.

Air Traffic Navigation, Integration and Coordination System (ATNAVICS/AN/TPN-31) — Provides air traffic control services for the rapid deployment of troops and equipment to remote locations where no operational airport control and landing system exists. Often deployed on Army airfields for training purposes.

Alert Aircraft Parking—Exclusive paved area for armed aircraft to park and have immediate, unimpeded access to a runway.

Alert Pad—Small paved areas provided for single alert aircraft parking.

Approach Control—Service established to control flights, operating under instrument flight rules (IFR), arriving at, departing from, and operating in the vicinity of airports by direct communication between approach control personnel and aircraft operating under their control.

Approach-Departure Clearance Surface—Inclined plane or combined inclined and horizontal planes arranged symmetrically about the runway centerline extended. The first segment or the beginning of the inclined plane is coincident with the ends and edges of the primary surface, and the elevation of the centerline at the runway end. The surfaces flare outward and upward from these points. See Chapter 3 for fixed-wing ADCS, Chapter 4 for rotary-wing ADCS and Chapter 7 for LZ ADCS dimensions.

Apron—A defined area, on an airfield, intended to accommodate aircraft for the purposes of loading or unloading passengers or cargo, refueling, parking or maintenance.

Apron, Aircraft Access—See Apron, Hangar Access.

Apron, Alert—A designated area for multiple alert aircraft parking.

Apron Edge—See Edge of Apron.

Apron, Hangar Access—Hangar access aprons are paved areas connecting hangars with adjacent aircraft aprons when the hangar is located at the outer boundary of the apron clearance distance. Hangars located beyond the apron clearance distance may be connected to the main apron with a taxiway or a towway.

Apron, Holding (Engine Run up Area)—A paved area adjacent to the taxiway near the runway ends where final preflight warm-up and engine and instrument checks are performed.

Apron, Parking—Parking apron is a designated paved area on an airfield intended to accommodate fixed-and rotary-wing aircraft for parking.

Arming and Disarming—Loading and unloading of missiles, rockets, and ammunition in aircraft.

Arrestment Capable Aircraft—Aircraft whose flight manual specifies arrestment procedures.

Autorotation Lane—A helicopter landing lane or designated area on a runway used for practicing landings under simulated engine failure or certain other emergency conditions. Also known as a slide area when designed specifically for skid-type helicopters.

Aviation Facility—Combination of land, airspace, pavements and buildings which are needed to support an aviation movement or action. An aviation facility can be an airfield, heliport, or helipad. The aviation facility includes “airside” and “landside” facilities.

Aviation Intermediate Maintenance (AVIM)—For Army, units that provide mobile, responsive "one-stop" maintenance and repair of equipment to return to user.

Aviation Movement or Action—An aviation movement or action includes but is not limited to: the landing and takeoff of aircraft; readiness of aircraft; flight training of pilots; loading and unloading of aircraft; and the maintenance and fueling of aircraft.

Aviation Unit Maintenance (AVUM)—For Army, activities staffed and equipped to perform high frequency "on aircraft" maintenance tasks required to retain or return aircraft to a serviceable condition.

Avigation Easement—A legal right obtained from a property owner to operate aircraft over that property and to restrict the height of any construction or growth on that property.

Beam Wind Component—Wind velocities perpendicular to the axis of the runway centerline used to measure the degree by which a runway pattern covers incident wind.

Blast Protective Area—Area at the ends of the runways and taxiways protected by pavement construction against jet blast erosion.

Circling Approach Area—Area in which aircraft circle to land under visual conditions.

Clear Zone—Surface on the ground or water beginning at the runway end and symmetrical about the runway centerline extended.

Compass Calibration Pad—A paved area in an electromagnetically quiet zone where an aircraft's compass is calibrated.

Compass Rose—A graduated circle, usually marked in degrees, indicating directions and printed or inscribed on an appropriate medium.

Conical Surface—An imaginary surface that extends from the periphery of the inner horizontal surface outward and upward at a slope of 20 horizontal to one for a horizontal distance of 2,133.6 m (7,000 ft) to a height, 152.4 m (500 ft) above the established airfield elevation. The conical surface connects the inner horizontal surface with the outer horizontal surface. It applies to fixed-wing installations only.

Construction Waiver—A temporary airfield waiver used to identify, coordinate, and approve construction activity on or near the airfield. The installation commander, or equivalent, is the construction waiver approval authority. Construction waivers apply to airfield systems, facilities, and on-base facilities where construction will require equipment or stockpile areas that may adversely affect flying operations. For more information about construction waivers, see Appendix B, Section 1.

Controlling Obstacle—Highest obstacle relative to a prescribed plane within a specified area. In precision and non-precision approach procedures where obstacles penetrate the approach surface, the controlling obstacle is the one which results in the requirement for the highest decision height (DH) or minimum descent altitude (MDA). For departure procedures, the obstacle that drives the highest climb gradient to the highest climb to altitude.

Correctable Obstruction—An obstruction to aircraft operations or air navigation that can be removed, modified, or relocated to comply with airfield safety criteria with a reasonable level of effort as determined by the MAJCOM or USAASA as applicable.

Crosswind Runway—A secondary runway that is required when the primary runway orientation does not meet crosswind criteria (see Appendix B, Section 4.).

Decision Height (DH) / Decision Altitude (DA)— Specified for a precision approach, at which a missed approach procedure must be initiated if the required visual reference has not been established. Decision altitude (DA) is referenced to mean sea level (MSL) and decision height (DH) is referenced to the threshold elevation.

Displaced Threshold—A runway threshold that is not at the beginning of the full-strength runway pavement. Displacement of a threshold reduces the length of runway available for landings. The portion of the runway behind a displaced threshold may be available for takeoffs and, depending on the reason for the displacement, may be available for takeoffs and landings from the opposite direction.

Edge of Apron—Boundary of an apron, marked by painted stripe in accordance with pavement marking manual.

Exemption (Air Force only)—A facility or other item constructed under a previous standard. Exemptions must be programmed for replacement away from the airfield environment at the end of their useful life cycle. Also, see Chapter 1.

Fixed-Wing Aircraft—A powered aircraft that has wings attached to the fuselage so that they are either rigidly fixed or swing-wing, as distinguished from aircraft with rotating wings, like a helicopter.

Flight Path—Line connecting the successive positions occupied, or to be occupied, by an aircraft, missile, or space vehicle as it moves through air or space.

Fuel Servicing Safety Zone (FSSZ)—The FSSZ is the area required for safety around pressurized fuel carrying servicing components; i.e. servicing hose, fuel nozzle, single point receptacle (SPR), hydrant hose car, ramp hydrant connection point, etc. and around aircraft fuel vent outlets. The fuel servicing safety zone is established and maintained during pressurization and movement of fuel.

Full Stop Landing—Touchdown, rollout, and complete stopping of an aircraft to zero speed on runway pavement.

Grade—Also Gradient—A slope expressed in percent. For example, a 0.5 percent grade means a 0.5-meter (-foot) slope in 100 meters (feet). All grades may be positive or negative unless otherwise specifically noted.

Ground Point of Intercept (GPI)—A point in the vertical plane of the runway centerline or center of a helipad at which it is assumed that the straight line extension of the glide slope (flight path) intercepts the approach surface base line (TM 95-226).

Hardstand—A term used synonymously with Apron. See Apron definition.

Helicopter—Aircraft deriving primarily elements of aerodynamic lift, thrust and control from one or more power driven rotors rotating on a substantially vertical axis.

Helicopter(Light)— Helicopters with a gross weight of 2,722 kg (6,000 lb) or less.

Helicopter(Medium)— Helicopters with a gross weight of 2723 to 5,443 kg (6,001 to 12,000 lb).

Helicopter(Heavy)— Helicopters with a gross weight over 5,443 kg (12,000 lb).

Helicopter Parking Space, Type 1 (Army Only)—In this configuration, rotary-wing aircraft are parked in a single lane, which is perpendicular to the taxilane.

Helicopter Parking Space, Type 2 (Army Only)—In this configuration, rotary-wing aircraft are parked in a double lane, which is parallel to the taxilane.

Helicopter Runway—A prepared surface used for the landing and takeoff of helicopters requiring a ground run.

Helipad—A prepared area designated and used for takeoff and landing of helicopters (includes touchdown and hoverpoint.)

Helipad, IFR—Helipad designed for IFR. IFR design standards are used when an instrument approach capability is essential to the mission and no other instrument landing facilities, either fixed-wing or rotary-wing, are located within an acceptable commuting distance to the site.

Helipad, Limited Use—A VFR rotary-wing facility for use by AH, OH, HH and UH helicopters. These type helipads support only occasional operations at special locations such as hospitals, headquarters facilities, missile sites, and other similar locations. They may also be located on airfields where one or more helipads are required to separate operations of helicopters such as OH, UH, HH and AH) from fixed-wing or other helicopter operations.

Heliport—A facility designed for the exclusive operating, basing, servicing and maintaining of rotary-wing aircraft (helicopters). The facility may contain a rotary-wing runway and/or helipads.

Heliport or Helipad Elevation—Established elevation, in terms of the nearest 300 mm (1 ft) above mean sea level, based on the highest point of the usable landing area.

High-Speed Taxiway Turnoff—A taxiway leading from a runway at an angle which allows landing aircraft to exit a runway at a high speed.

Holding Position—A specified location on the airfield, close to the active runway and identified by visual means, at which the position of a taxiing aircraft is maintained in accordance with air traffic control instructions.

Horizontal Surfaces, Fixed-Wing:

Inner Horizontal Surface—An imaginary plane 45.72 m (150 ft) above the established airfield elevation. The inner boundary intersects with the approach-departure clearance surface and the transitional surface. The outer boundary is formed by scribing arcs with a radius 2,286.0 m (7,500 ft) from the centerline of each runway end, and interconnecting those arcs with tangents.

***Outer Horizontal Surface*—**An imaginary plane 152.4 m (500 ft) above the established airfield elevation extending outward from the outer periphery of the conical surface for a horizontal distance of 9,144.0 m (30,000 ft).

Horizontal Surface, Rotary-Wing—An imaginary plane at 45.72 m (150 ft) above the established heliport or helipad elevation. The inner boundary intersects with the approach-departure clearance surface and the transitional surface. The outer boundary is formed by scribing an arc at the end of each runway, and connecting the arcs with tangents, or by scribing the arc about the center of the helipad. See Chapter 4 for dimensions.

Hover—A term applied to helicopter flight when the aircraft: (1) maintains a constant position over a selected point (1 to 3 m (3 to 10 ft) above ground), and (2) is taxiing (airborne) (1 to 3 m (3 to 10 ft) above ground) from one point to another.

Hoverlane—A designated aerial traffic lane for the directed movement of helicopters between a helipad or hoverpoint and the servicing and parking areas of the heliport or airfield.

Hoverpoint—Prepared and marked surface at a heliport or airfield used as a reference or central point for arriving or departing helicopters.

Imaginary Surfaces. Surfaces in space established around airfields in relation to runway(s), helipad(s), or helicopter runway(s) that are designed to define the obstacle free airspace around the airfield. The imaginary surfaces for DoD airfields are the primary surface, the approach-departure clearance surface, the transitional surface, the graded area of the clear zone, the inner horizontal surface, the conical surface (fixed-wing only), and the outer horizontal surface (fixed-wing only).

Ingress/Egress, Same Direction—One approach-departure route to and from the helipad exists. The direction from which the rotary-wing aircraft approaches the helipad (ingress) is the only direction which the rotary-wing aircraft departs (egress) from the helipad. Typically, the helipad is surrounded by obstacles on three sides which make approaches from other directions impossible. For example, if the rotary-wing aircraft approaches from the southwest, it must also depart to the southwest.

Ingress/Egress, Two Direction—Rotary-wing aircraft can approach and depart the helipad from two directions (one direction and the opposite direction). (See also Ingress/Egress, Same Direction.)

Instrument Runway—Runway equipped with electronic navigation aids for which a precision or non-precision approach procedure is approved.

Instrument Flight Rules (IFR)—Rules that govern the procedure for conducting instrument flight. Also see Instrument Meteorological Conditions.

Instrument Landing System—System of ground equipment designed to provide an approach path for exact alignment and descent of an aircraft on final approach to a runway. The ground equipment consists of two highly directional transmitting systems and, along the approach, three (or fewer) marker beacons. The directional transmitters are known as the localizer and glideslope transmitters.

Instrument Meteorological Conditions—Meteorological conditions expressed in terms of visibility, distance from cloud, and ceiling; less than minimums specified for visual meteorological conditions.

Intermediate Area—Area between runways and between runways and taxiways that is graded or cleared for operational safety.

Joint/Shared Use Airfield—Airports that are shared by a civilian DoD agency covered under the *Airports and Airway Improvement Act of 1982* (Public Law 97-248, Sep 3, 1982, 49 USC, APP 2201). Only those facilities (i.e., runways/taxiways) that are used by both civilian and DoD agencies are considered shared/joint use. All other facilities (parking ramps, hangars, terminals, and so forth) are the sole property of the using agency. An installation where agreements exist among the DoD, civil, and host nation authorities for joint use of all or a portion of airfield facilities.

Landing Area—See Takeoff and Landing Area.

Landing Field—Any area of land consisting of one or more landing strips, including the intermediate area, that is designed for the safe takeoff and landing of aircraft.

Landing Lane—A defined lane on the airfield used for simultaneous takeoff and landings of multiple (up to four at one time) helicopters. Landing lanes are used at airfields or heliports when a high density of helicopters are parked on an apron or in the process of takeoff and landings.

Landing Rollout—Distances covered in stopping the aircraft, when loaded to maximum landing weight, following touchdown using standard operation and braking procedures on a hard, dry-surfaced, level runway with no wind.

Landing Strip—Portion of an airfield that includes the landing area, the end zones, and the shoulder areas; also known as a flight strip.

Landing Zone (LZ)—A prepared or semi-prepared (unpaved) airfield used to conduct operations in an airfield environment similar to forward operating locations. LZ runways are typically shorter and narrower than standard runways.

Landside Facilities—Landside facilities are facilities not associated with the movement and parking of aircraft but are required for the facilities' mission. These include aircraft maintenance areas, aviation support areas, fuel storage and dispensing, explosives and munitions areas and vehicular needs.

Large Transport Aircraft—Transport aircraft with a wing span of 33.5 m (110 ft) or greater.

Light Bar—Set of lights arranged in a row perpendicular to the light system centerline.

Line Vehicle—Vehicle used on the landing strip, such as a crash fire truck or tow tractor.

Localizer—Directional radio beacon which provides to an aircraft an indication of its lateral position relative to a predetermined final approach course.

Localizer Type Directional Aid (LDA)—A NAVAID used for non-precision instrument approaches with utility and accuracy comparable to a localizer but which is not part of a complete ILS. The LDA is not aligned with the runway. The alignment is greater than 3 degrees (3°) and less than 30 degrees (30°) from the runway centerline.

Magnetic North—Direction indicated by the north-seeking pole of a freely suspended magnetic needle, influenced only by the earth's magnetic field.

Magnetic Variation—At a given place and time, the horizontal angle between the true north and magnetic north measured east or west according to whether magnetic north lies east or west of true north.

Magnetically Quiet Zone—A location where magnetic equipment, such as a compass, is only affected by the earth's magnetic forces.

Non-Precision Approach—Approach flown by reference to electronic navigation aids in which glideslope information is not available.

Non-Instrument Runway—Runway intended for operating aircraft under VFR.

Obstacle—An existing object, natural growth, or terrain, at a fixed geographical location, or which may be expected at a fixed location within a prescribed area, with reference to which vertical clearance is or must be provided during flight operations. *Fixed Obstacles* include man-made or natural features such as buildings, trees, rocks and terrain irregularities. *Mobile Obstacles* include parked aircraft, parked and moving vehicles, railroad cars and similar equipment. Taxiing aircraft are exempt from this restriction. Vehicles in performance of official duties, such as emergency vehicles, maintenance vehicles and inspection vehicles, are exempt from this restriction only when authorized by Airfield Management and operating the vehicle in accordance with local driving rules and regulations.

Obstacle Clearance—Vertical distance between the lowest authorized flight altitude and a prescribed surface within a specified area.

Obstruction—Natural or man-made object that violates airfield or heliport clearances or projects into imaginary airspace surfaces. Navy and Marine Corps see UFC 2-000-05N.

Overrun Area—Area the width of the runway plus paved shoulders extending from the end of the runway to the outer limit of the end zone. This portion is a prolongation of the runway which is the stabilized area.

Parking, Aircraft Undergoing Maintenance—Apron parking space is provided for parking aircraft which must undergo maintenance.

Parking, Alert Aircraft—Parking for aircraft that must be in flight upon short notice.

Parking, Operational Aircraft—Parking for operational aircraft assigned to a particular installation.

Parking, Transient Aircraft—Parking for transient aircraft (non-operational) at the installation, but not assigned there.

Parking, Transport Aircraft—Parking for transport aircraft carrying cargo and personnel which must be loaded and unloaded.

Pass—The movement of an aircraft over a specific spot or location on a pavement feature.

Pavement (Paved Surface)—A durable weather and abrasion resistant surface made from a prepared or manufactured material placed on an established base. General categories of pavements are flexible and rigid.

Permanent Waiver—See **Waiver, Permanent**.

Permissible Deviation (Air Force and Army only)—Airfield support facilities that are not required to meet airfield clearance criteria; however, they must meet siting criteria specified in Appendix B, Section 13, of this UFC.

Power Check—Full power test of an aircraft engine while the aircraft is held stationary.

Power Check Pad—Aircraft power check pad is a paved area, with an anchor block in the center, used to perform full-power engine diagnostic testing of aircraft engines while the aircraft is held stationary.

Precision Approach—Approach in which azimuth and glideslope information are provided to the pilot.

Primary Surface (Fixed-Wing Runways)—An imaginary surface symmetrically centered on the runway, extending 60.96 m (200 ft) beyond each runway end. The width varies depending upon the class of runway and coincides with the lateral clearance distance. The elevation of any point on the primary surface is the same as the elevation of the nearest point on the runway centerline.

Primary Surface (Rotary-Wing Runways and Landing Lanes)—Imaginary surface symmetrically centered on the runway, extending beyond the runway ends. The width and length depends upon whether the runway/landing lane is to accommodate VFR or IFR operations. The lateral clearance distance coincides with the width of the primary surface. The elevation of any point on the primary surface is the same as the elevation of the nearest point on the runway centerline.

Relocated Threshold-- A threshold that is located at a point on the runway other than the beginning of the full-strength pavement and the paved area between the former threshold and the relocated threshold is no longer used for landing or takeoff of aircraft, but may be used for taxiing aircraft.

Runway—A defined rectangular area of an airfield or heliport, with no curves or tangents, prepared for the landing and takeoff run of aircraft along its length.

Runway (Class A)—Class A runways are primarily intended for small light aircraft. Ordinarily, these runways have less than 10 percent of their operations involving aircraft in the Class B category. These runways are normally less than 2,440 m (8,000 ft).

Runway (Class B)—Class B runways are all fixed-wing runways that accommodate normal operations of Class B Aircraft.

Runway End—As used in this manual, the runway end is where the normal threshold is located. When the runway has a displaced threshold, the responsible airfield authority will evaluate each individual situation and, based on this evaluation, will determine the point of beginning for runway and airspace imaginary surfaces.

Runway Exit—Taxiway pavement provided for turnoffs from the runway to a taxiway either at normal or high speed.

Runway, Parallel—Two or more runways at the same airport whose centerlines are parallel. In addition to runway number, parallel runways are designated as L (left) and R (right) or, if three parallel runways exist, L (left), C (center), and R (right).

Runway, Rotary-wing— Runway for rolling landings and takeoff of rotary-wing aircraft. The rotary-wing runway allows for a helicopter to quickly land and roll to a stop compared to the hovering stop used during a vertical helipad approach.

Runway Threshold—A line perpendicular to the runway centerline designating the beginning of that portion of a runway usable for landing.

Runway Visual Range—The maximum distance in the direction of takeoff or landing from which the runway, or the specified lights or markers delineating it, can be seen from a position above a specified point on its centerline at a height corresponding to the average eye-level of pilots at touchdown.

Service Point—Receptacle, embedded in certain airfield pavements, containing outlets for utilities required to service aircraft.

Short Takeoff And Vertical Landing (STOVL)— a fixed-wing aircraft capable of clearing a 15 m (50 ft) obstacle within 450 m (1,500 ft) of commencing take-off run, and capable of landing vertically. This term only applies to F-35B aircraft.

Shoulder—Prepared (paved or unpaved) area adjacent to the edge of an operational pavement.

Slide Area, Helicopter—Specially prepared but usually unpaved area used for practicing helicopter landings under simulated engine failure or certain other emergency conditions. VFR Helicopter runway criteria apply to these type facilities. (Also known as a Skid Pad.)

Slope Ratio—Slope expressed in meters (feet) as a ratio of the horizontal to the vertical distance. For example, 50:1 means 50 m horizontal to 1 m vertical (50 ft horizontal to 1 ft vertical).

Standard VFR Helipad—Helipad designed to VFR. VFR design standards are used when no requirement exists or will exist in the future for an IFR helipad.

Standby Parking Pad—At individual helipad sites where it is necessary to have one or more helicopters on standby, an area adjacent to the helipad, but clear of the landing approach and transitional surfaces.

Sunshade—A cover, usually semi-circular in shape, to protect aircraft from the sun's ultraviolet rays. For Air Force, see AFI 21-136 *Aircraft Sunshade Management*.

Suppressed Power Check Pad—Enclosed power check pad, referred to as a "hush house," where full power checks of jet engines are performed.

Takeoff and Landing Area—Specially prepared or selected surface of land, water, or deck designated or used for takeoff and landing of aircraft.

Takeoff Safety Zone—Clear graded area within the approach-departure zone of all VFR rotary-wing facilities. The land use of this area is comparable to the clear zone area applied to fixed-wing facilities.

Taxilane—Designated path marked through parking, maintenance or hangar aprons, or on the perimeter of such aprons to permit the safe ground movement of aircraft operating under their own power.

Taxilane, Interior (secondary taxi routes)—Taxilane which provides a secondary taxi route to individual parking positions or a hangar and is not intended or used as a primary taxi route for through traffic.

Taxilane, Peripheral—Taxilane located along the periphery of an apron that may be considered a primary or a secondary taxi route. Provide wing tip clearance commensurate with the intended use. See Taxilane, Interior; Taxilane, Through; and Table 6-1, Items 5 and 6.

Taxilane, Through (primary taxi routes)—A taxilane providing a route through or across an apron which is intended as a primary taxi route for access to other taxilanes, aprons, taxiways or the runway.

Taxitrak—A specially prepared or designated path, on an airfield other than mass parking areas, on which aircraft move under their own power to and from taxiways to dispersed platforms.

Taxiway—A specially prepared or designated path, on an airfield or heliport other than apron areas, on which aircraft move under their own power to and from landing, service and parking areas.

Taxiway, Apron Entrance—Taxiway which connects a parallel taxiway and an apron.

Taxiway, End Turnoff (Entrance Taxiway) (Connecting Taxiway) (Crossover Taxiway)—A taxiway located at the end of the runway that serves as both an access and departure location for aircraft at the runway thresholds.

Taxiway, High-Speed Turnoff (High-Speed Exit) (Acute-angled Exit Taxiway)—A taxiway located intermediate of the ends of the runway and "acute" to the runway centerline to enhance airport capacity by allowing aircraft to exit the runways at a faster speed than normal turnoff taxiways allow. Aircraft turning off runways at high speeds (maximum 100 km/h (55 knots)) require sufficient length for a high-speed turnoff taxiway to decelerate to a full stop before reaching the parallel taxiway.

Taxiway, Normal Turnoff (Ladder Taxiway) (Intermediate Taxiway) (Exit Taxiway)—A taxiway located intermediate of the end of the runway, typically perpendicular to the runway centerline that allows landing aircraft to exit and clear runways as soon as possible.

Taxiway, Parallel—Taxiway which parallels the runway. The curved connections to the end of the runway permit aircraft ground movement to and from the runway and are considered part of the parallel taxiway when there are no other taxiway exits on the runway.

Taxiway Turnoff—A taxiway leading from a runway to allow landing aircraft to exit and clear the runway after completing their initial landing roll.

Temporary Waiver—See **Waiver, Temporary**.

Threshold Crossing Height—Height of the straight-line extension of the guide slope above the runway at the threshold.

Tie-down Anchor—A device, installed in certain airfield pavements, to which lines tying down an aircraft are secured. Electrical grounding may be provided. This is not to be confused with the aircraft trim pad and thrust anchor shown in Appendix B, Section 15.

Touchdown Point—Designated location on a landing lane, taxiway, or runway for permitting more rapid launch or recovery of helicopters in a high-density area.

Towway—Paved surface over which an aircraft is towed.

Transitional Surface— An imaginary surface that extends outward and upward at right angles to the runway centerline and the runway centerline extended at a slope ratio of 7H:1V. The transitional surface connects the primary and the approach-departure clearance surfaces to the inner horizontal, the conical, and the outer horizontal surfaces.

Transitional Surfaces (Rotary-Wing)—The imaginary plane which connect the primary surface and the approach-departure clearance surface to the horizontal surface, or extends to a prescribed horizontal distance beyond the limits of the horizontal surface. Each surface extends outward and upward at a specified slope measured perpendicular to the runway centerline or helipad longitudinal centerline (or centerlines) extended.

True North—Direction from an observer's position to the geographic North Pole. The north direction of any geographic meridian.

Unsuppressed Power Check Pad—A power check pad without an enclosure or other type of noise suppressor. It is generally used as a backup or interim facility to a suppressed power check pad. The unsuppressed power check pad, in its simplest form, is a paved area on which full power engine diagnostic testing can be performed without noise or jet blast limitations.

Visual Flight Rules (VFR)—Rules that govern the procedures for conducting flight under visual conditions. Also see Visual Meteorological Conditions.

Visual Meteorological Conditions (VMC)—Weather conditions in which visual flight rules apply; expressed in terms of visibility, ceiling height, and aircraft clearance from clouds along the path of flight. When these criteria do not exist, instrument meteorological conditions prevail and IFR must be complied with. Also see Visual Flight Rules.

Vertical Sight Distance—The longitudinal distance visible from one location to another. Usually, a height above the pavement surface is also defined.

Vertical/Short Takeoff and Landing (V/STOL)—A tilt-rotor vertical takeoff and landing aircraft that has the ability to operate as either a fixed- or rotary-wing aircraft. This applies to V-22 and AV-8 aircraft.

Waiver, Construction—A temporary airfield waiver used to identify, coordinate and approve construction activity on or near the airfield. The installation commander is the approval authority for construction waivers. See Appendix B, Section 1, for additional information.

Waiver, Permanent (Army)—An airfield waiver established for violations that cannot be reasonably corrected and pose little or no risk to flying operations. Such violations are typically caused by natural topographic features. See Appendix B, Section 1 for approval authority.

Waiver, Permanent (Air Force)— Permanent waivers are established for criteria violations that cannot be reasonably met. See Paragraph B1-2.1.2 for details.

Waiver, Temporary (Army)—An airfield waiver established to address safety mitigation for correctable obstructions or violations of other airfield criteria such as grades. See Appendix B, Section 1 for approval authority.

Waiver, Temporary (Air Force)— Temporary waivers are established for criteria violations that can be corrected within eight years. See Section B1-2.1.3 for details.

Wind Rose—A diagram showing the relative frequency and strength of the wind in correlation with a runway configuration and in reference to true north. It provides a graphic analysis to obtain the total wind coverage for any runway direction.

Wind Direction—Direction from which the wind is blowing in reference to true north.

This UFC supersedes TM 5-818-2/AFM 88-6, Chap 4, dated January 1985; TM 5-822-2/AFM 88-7, Chap 5, dated July 1987; TM 5-822-13/AFJMAN 32-1018, dated October 1994; TM 5-822-5/AFM 88-7, Chap 1, dated June 1992; TM 5-5-824-1/AFM 88-6, Chap 1, dated June 1987; TM 5-825-2/AFM 88-6, Chap 2/DM 21.3, dated August 1978; TM 5-825-2-1/AFM 88-6, Chap 2, Sec A, dated November 1989; TM 5-825-3/AFM 88-6, Chap 3, dated August 1988; and TM 5-825-3-1/AFM 8-6, Chap 3, Sec A, dated September 1988.

FOREWORD

\1\
The Unified Facilities Criteria (UFC) system is prescribed by MIL-STD 3007 and provides planning, design, construction, sustainment, restoration, and modernization criteria, and applies to the Military Departments, the Defense Agencies, and the DoD Field Activities in accordance with USD(AT&L) Memorandum dated 29 May 2002. UFC will be used for all DoD projects and work for other customers where appropriate. All construction outside of the United States is also governed by Status of forces Agreements (SOFA), Host Nation Funded Construction Agreements (HNFA), and in some instances, Bilateral Infrastructure Agreements (BIA.) Therefore, the acquisition team must ensure compliance with the more stringent of the UFC, the SOFA, the HNFA, and the BIA, as applicable.

UFC are living documents and will be periodically reviewed, updated, and made available to users as part of the Services' responsibility for providing technical criteria for military construction. Headquarters, U.S. Army Corps of Engineers (HQUSACE), Naval Facilities Engineering Command (NAVFAC), and Air Force Civil Engineer Support Agency (AFCESA) are responsible for administration of the UFC system. Defense agencies should contact the preparing service for document interpretation and improvements. Technical content of UFC is the responsibility of the cognizant DoD working group. Recommended changes with supporting rationale should be sent to the respective service proponent office by the following electronic form: Criteria Change Request (CCR). The form is also accessible from the Internet sites listed below.

UFC are effective upon issuance and are distributed only in electronic media from the following source:

- Whole Building Design Guide web site http://dod.wbdg.org/.

Hard copies of UFC printed from electronic media should be checked against the current electronic version prior to use to ensure that they are current.

CHAPTER 1

INTRODUCTION

1. PURPOSE. This document establishes general concepts and criteria for the design of airfield pavements for the U.S. Army, Navy, Air Force, and Marine Corps.

2. SCOPE. This document prescribes procedures for determining the thickness, material, and density requirements for airfield pavements in nonfrost and frost areas. It includes criteria for the California Bearing Ratio (CBR) procedure and elastic layered analysis for flexible pavements and the Westergaard Analysis and elastic layered analysis for rigid pavements. The elastic layered analysis for rigid pavements covers only plain concrete, reinforced concrete, and concrete overlay pavements.

3. REFERENCES. Appendix A contains a list of references used in these instructions.

4. UNITS OF MEASUREMENT. The unit of measurement system in this document is the International System of Units (SI). In some cases inch-pound (IP) measurements may be the governing critical values because of applicable codes, accepted standards, industry practices, or other considerations. Where the IP measurements govern, the IP values may be shown in parenthesis following a comparative SI value or the IP values may be shown without a corresponding SI value.

5. PAVEMENT. A pavement as used in this document is a surfaced area designed to carry aircraft traffic and includes the entire pavement system structure above the subgrade. All slabs on grade required to support aircraft loadings, whether interior (hangar floors) or exterior, are to be considered airfield pavements.

a. Flexible Pavement. Flexible pavements are so designated due to their flexibility under load and their ability to withstand small degrees of deformation. The design of a flexible pavement structure is based on the requirement to limit the deflections under load and to reduce the stresses transmitted to the natural subsoil. The principal components of the pavement include a bituminous concrete surface, graded crushed aggregate base course, stabilized material, drainage layer, separation layer, and subbase courses. A bituminous concrete surface course is hot mixed bituminous concrete designed as a structural member with weather and abrasion resisting properties. It may consist of wearing and binder or intermediate course. Figure 1-1 illustrates the components and the terminology used in flexible pavements. Examples of all bituminous concrete pavements (ABC) and flexible pavements utilizing stabilized layers are shown in Figures 1-2 and 1-3. Not all layers shown in the figures are required in every pavement.

b. Rigid Pavement. A rigid pavement is considered to be any pavement system that contains portland cement concrete as one element. Rigid pavements transfer the load to the subgrade by bending or slab action through tensile forces as opposed to shear forces. The principal components of a rigid pavement are the concrete slab, base course, drainage layer, and separation layer. However, a stabilized layer may be required based on site conditions. Figure 1-4 illustrates the components of a rigid pavement. The drainage and separation layer will normally serve as the base course. The following pavements are considered to be rigid pavements:

(1) Plain concrete pavement is a nonreinforced jointed rigid pavement.

(2) Reinforced concrete pavement is a jointed rigid pavement that has been strengthened with deformed bars or welded wire fabric.

(3) Continuously reinforced concrete pavement is a rigid pavement that is constructed without joints and uses reinforcing steel to maintain structural integrity across contraction cracks that form in the pavement.

(4) Fibrous concrete pavement is a rigid pavement that has been strengthened by the introduction of randomly mixed, short, small-diameter steel fibers. Nonsteel fibers have been used in portland cement concrete (PCC) to control shrinkage cracking, but their use is not covered in this TI.

(5) Prestressed concrete pavement is a rigid pavement that has been strengthened by the application of a significant horizontally applied compressive stress during construction.

(6) Rigid overlay pavement is a rigid pavement used to strengthen an existing flexible or rigid pavement.

(7) Nonrigid overlay pavement is either all-bituminous or bituminous with base course used to strengthen an existing rigid pavement.

6. USE OF FLEXIBLE PAVEMENTS. The use of flexible pavements on airfields must be limited to those pavement areas not subjected to detrimental effects of fuel spillage, severe jet blast, or parked aircraft. Jet blast damages bituminous pavements when the intense heat is allowed to impinge in one area long enough to burn or soften the bitumen so that the blast erodes the pavement. Hot-mix asphaltic concretes generally will resist erosion at temperatures up to 150 degrees Celsius (300 degrees Fahrenheit). Temperatures of this magnitude are produced only when aircraft are standing and are operated for an extended time or with afterburners operating. Fuel spillage leaches out the asphalt cement in asphaltic pavements. In an area subject to casual minor spillage, the leaching is not serious, but where spillage is repeated in the same spot at frequent intervals, the leaching will expose loose aggregate. Flexible pavements are generally satisfactory for runway interiors, secondary taxiways, shoulders, paved portions of overruns, or other areas not specifically required to have a rigid pavement surfacing.

7. USE OF RIGID PAVEMENTS. The following pavements will be rigid pavement: all paved areas on which aircraft or helicopters are regularly parked, maintained, serviced, or preflight checked, on hangar floors and access aprons; on runway ends (305 meters (1,000 feet)) of a Class B runway; areas that may be used from the runway end to 90 meters (300 feet) past the barrier to control hook skip; primary taxiways for Class B runways; hazardous cargo, power check, compass calibration, warmup, alert, arm/disarm, holding, and washrack pads; and any other area where it can be documented that flexible pavement will be damaged by jet blast or by spillage of fuel or hydraulic fluid. Navy aircraft arresting gear pavement protection shall be designed in accordance with NAVFAC design definitive #1404521 and 1404522 shown in NAVFAC P-272. The 2 meters (6.56 feet) of pavement on both the approach and departure sides of the arresting gear pendent shall be PCC for Navy and Marine Corps. Rigid pavements shall also be used at pavement intersections where aircraft/vehicles have a history of distorting flexible pavements and where sustained operations of aircraft/vehicles with tire pressures in excess of 2.06 MPa (300 psi) occur. Continuously reinforced concrete pavement will be used in liquid oxygen (LOX) storage and handling areas to eliminate the use of any organic materials (joint sealers, asphalt pavement, etc.) In those areas. The type of pavement to be used on all other paved areas will be selected on the basis of life cycle costs.

8. SOIL STABILIZATION. Soils used in pavements may be stabilized or modified through the addition of chemicals or bitumens. A stabilized soil is one which has improved load-carrying and durability characteristics through the addition of admixtures. The principal benefits of stabilization include a reduction in pavement thickness, provision of a construction platform, decreased swell potential, and reduction of the susceptibility to pumping as well as the susceptibility to strength loss due to moisture. Lime, cement, and fly ash, or any combination of these, and bitumen are the commonly used additives for soil stabilization. A modified soil is one which has improved construction characteristics through the use of additives. However, the additives do not improve the strength and durability of the soil sufficiently to qualify as a stabilized soil with a subsequent reduction in thickness. Criteria for the design of stabilized soils is contained in TM 5-822-14/AFMAN 32-1019. Additional discussion of soil stabilization is found in TM 5-818-1/AFM 88-3, Chapter 7.

9. DESIGN ANALYSIS. The outlines in Appendixes B and C will be used to prepare design analyses for all projects under design. All pertinent items and computational details will be included showing how design results were obtained.

10. WAIVERS TO CRITERIA. Each DoD Service component is responsible for setting administrative procedures necessary to process and grant formal waivers. Waivers to the criteria contained in this manual will be processed in accordance with Appendix D.

11. COMPUTER PROGRAMS. Computer programs have been developed for the design of pavements. The computer programs may be obtained electronically from the following:

a. Word Wide Web (WWW) address: http://pcase.com.

b. FTP Anonymous Site: pavement.wes.army.mil.

Disks may also be obtained from the U.S. Army Corps of Engineers, Transportation Systems Center, 215 North 17th Street, Omeha, NE 68102-4978.

CHAPTER 2

ARMY AIRFIELD/HELIPORT REQUIREMENTS

1. ARMY AIRFIELD/HELIPORT CLASSES. Army airfields are divided into six classes referred to as Class I (heliports-helipads with aircraft 11,340 kilograms (25,000 pounds) or less), Class II (heliports-helipads with aircraft over 11,340 kilograms (25,000 pounds)), Class III (airfields with Class A runways), Class IV (airfields with Class B runways), Class V contingency (theater of operations) heliports or helipads supporting Army assault training missions, and Class VI assault landing zones for contingency (theater of operations) airfields supporting Army training missions.

2. ARMY AIRFIELD AND HELIPORT LAYOUT. The layout for all Class I, II, III, and IV Army airfields, heliports, and helipads will be designed in accordance with the tri-service manual UFC 3-260-01. All Class V and VI Army contingency (theater of operations) airfield, heliport, and helipad layouts shall be designed in accordance with FM 5-430-00-2/AFJPAM 32-8013, Vol. II. Class VI airfields used for Army contingency training missions shall be designed in accordance with AF ETL 98-5. Any deviations from these criteria must be submitted through the installation MACOM to the U.S. Army Aeronautical Services Agency (USAASA) for waiver approval.

3. TRAFFIC AREAS FOR ARMY AIRFIELD PAVEMENTS. Construction of primary taxiways, runways, and apron taxi lanes with keel sections (alternating variable thickness) as indicated by traffic will not be authorized for Army aircraft operational surfaces. Uniform pavement section thicknesses will be used.

a. Class I and II Heliports. These heliport classes have only one traffic area, Type B.

b. Class III Airfields. These airfields contain three traffic areas, Types A, B, and C. Type A traffic areas consist of the primary taxiways and the first 152 meters (500 feet) of runway ends. Type B traffic areas consist of parking aprons, warm-up pads, arm/disarm pads, compass calibration pads, power check pads, dangerous/ hazardous cargo pads, and taxiways connecting the primary taxiway to aprons and pads. Type C traffic areas consist of runway interiors between the 152-meter (500-foot) end sections, secondary (ladder) taxiways, hangar floors, washracks, and hangar access aprons. Type C traffic areas are designed using 75 percent of the aircraft gross weight and the same aircraft passes as Type A traffic areas. A typical layout of Army airfield traffic areas for Class III airfields is shown in Figure 2-1.

c. Class IV Airfields. These airfields contain three traffic areas, Types A, B, and C. Type A traffic areas consist of the primary taxiways and the first 305 meters (1,000 feet) of runway ends. Type B traffic areas consist of the parking aprons, warm-up pads, arm/disarm pads, power check pads, compass calibration pads, dangerous/hazardous cargo pads, and taxiways from the primary taxiway to aprons and pads. Type C traffic areas consist of runway interiors between the 305-meter (1,000-foot) end sections, secondary (ladder) taxiways (between runway and primary taxiway), hangar floors, hangar access aprons, and washracks. A typical layout of Army airfield traffic areas for Class IV airfields is shown in Figure 2-1.

d. Class V Heliports. This heliport has only one traffic area, Type B.

e. Class VI Airfields. This airfield has only one traffic area, Type A.

f. Exceptions. At facilities other than assault landing zones where a parallel taxiway is not provided, the runway shall be designed as Type A Traffic Area with double the required traffic.

4. ARMY AIRCRAFT DESIGN LOADS AND PASS LEVELS. Army airfield pavements will be designed according to mission requirements of each airfield, heliport, and helipad for a 20-year design life to include the military and civilian peacetime aircraft traffic plus all anticipated special operations and/or mobilization requirements defined by the Army installation and its MACOM. The total 20-year design aircraft traffic is based on specific aircraft types, their mission operational weights, and their projected pass levels. The airfield mission traffic used for design requires the approval of the MACOM and USAASA. Aircraft hangar floors or apron pavements shall not be designed for jacking loads as long as the foot print of the jack is equal to or greater than the contact area of the combined tires on the aircraft gear being elevated. Army aircraft operational pavements may consist of one or a combination of the following Army airfield-heliport classes:

a. Class I. Heliports and helipads with aircraft maximum operational weights equal to or less than 11,340 kilograms (25,000 pounds). The design of heliports and helipads will be based on the number of equivalent passes of the UH-60 aircraft at a 7,395-kilogram (16,300-pound) operational weight. The projected equivalent passes will be generated for the airfield mission traffic but shall not be less than 50,000 passes for a heliport nor less than 20,000 passes for a helipad.

b. Class II. Heliports that support aircraft with maximum operational weights over 11,340 kilograms (25,000 pounds). The design will be based on the number of equivalent passes of the CH-47 aircraft at a 22,680-kilogram (50,000-pound) operational weight. The projected equivalent passes will be generated for the airfield mission traffic but shall not be less than:

(1) 50,000 passes for visual flight rules (VFR) heliports.

(2) 20,000 passes for VFR helipads.

(3) 100,000 passes for instrument flight rules (IFR) heliports.

(4) 30,000 passes for IFR helipads.

c. Class III. Airfields that primarily support fixed wing aircraft requiring a Class A runway as defined in UFC 3-260-01. The design will be based on the projected number of aircraft operations but not less than 50,000 passes of a C-23 aircraft at an 11,200-kilogram (24,600-pound) operational weight plus 10,000 passes of a CH-47 aircraft at an operational weight of 22,680-kilograms (50,000-pounds).

d. Class IV. Airfields supporting aircraft requiring a Class B runway as defined in EI 02C013/ AFMAN 32-1013/NAVFAC P-971.

(1) The design for an airfield with its longest runway extending less than or equal to 1,525 meters (5,000 feet) will be based on the number of projected equivalent passes of the C-130 aircraft at a 70,310-kilogram (155,000-pound) or the C-17 aircraft at 263,100-kilograms (580,000-pound) operational weight. The projected equivalent passes will be generated for the airfield mission traffic but shall not be less than 75,000 passes for the C-130 or 50,000 passes for the C-17.

(2) The design for an airfield with its longest runway extending over 1,525 meters (5,000 feet) but less than or equal to 2,745 meters (9,000 feet) will be based on the number of projected equivalent

passes of the C-17 aircraft at a 263,100-kilogram (580,000-pound) operational weight. The projected equivalent passes will be generated for the airfield mission traffic but shall not be less than 75,000 passes.

(3) The design for an airfield with its longest runway extending over 2,745 meters (9,000 feet) will be based on the number of projected equivalent passes of the C-17 aircraft at a 263,100-kilogram (580,000-pound) operational weight. The projected equivalent passes will be generated for the airfield mission traffic but shall not be less than 100,000 passes.

e. Class V. Contingency (theater of operations) heliports or helipads supporting Army assault training missions. The design for the heliport or helipad will be based on the number of projected equivalent passes of the CH-47 aircraft at a 22,680-kilogram (50,000-pound) operational weight. The projected equivalent passes will be generated for the airfield mission traffic but shall not be less than 5,000 passes. Army assault heliport or helipad structural sections shall be designed in accordance with the criteria in this document with a bituminous surface or a military landing mat as described in FM5-430-00-2/AFJPAM 32-8013, Vol II.

f. Class VI. Assault landing zones for contingency (theater of operations) airfields or airstrips supporting Army training missions that have semi-prepared or paved surfaces. The design for airfields supporting Army training missions will be based on the number of equivalent passes of the C-130 aircraft at a 70,310-kilogram (155,000-pound) operational weight or the C-17 aircraft at a 263,100-kilogram (580,000-pound) operational weight. The equivalent passes will be not less than 10,000 passes for paved airfields. Army assault airfield or airstrip structural sections shall be designed in accordance with this manual. Army assault airfields with semi-prepared (unsurfaced) surfaces shall be designed in accordance with TM 5-822-12, TM 5-822-14, or Air Force ETL 98-2.

5. ROLLER-COMPACTED CONCRETE PAVEMENT. Roller-compacted concrete pavement (RCCP) is a rigid pavement and can be used as pavement except for runway and high-speed taxiway pavements for fixed-wing aircraft. RCCP can be used for all helipad and heliport pavements. RCCP shall be designed in accordance with ETL 1110-3-475.

6. RESIN MODIFIED PAVEMENT. Resin Modified Pavement (RMP) can be used as an Army pavement except for fixed-wing runways and high-speed taxiways. RMP can be used for helipads and heliport pavements and for both rotary-wing and fixed-wing parking aprons.

7. PAVED SHOULDERS.

a. Location. Paved shoulders should be provided for airfield and heliport construction as designated in UFC 3-260-01.

b. Structural Requirements. As a minimum, paved shoulders shall be designed to support 5,000 coverages of a load of 4,535 kilograms (10,000 pounds) imposed by a single wheel with a tire pressure of 0.69 MPa (100 psi). When shoulder pavements are to be used by support vehicles (snow removal equipment, fire trucks, fuel trucks, etc.), the shoulder should be designed accordingly for whichever governs.

8. SURFACE DRAINAGE. Design of surface drainage shall be in accordance with TM 5-820-1/ AFM 88-5, Chapter 1.

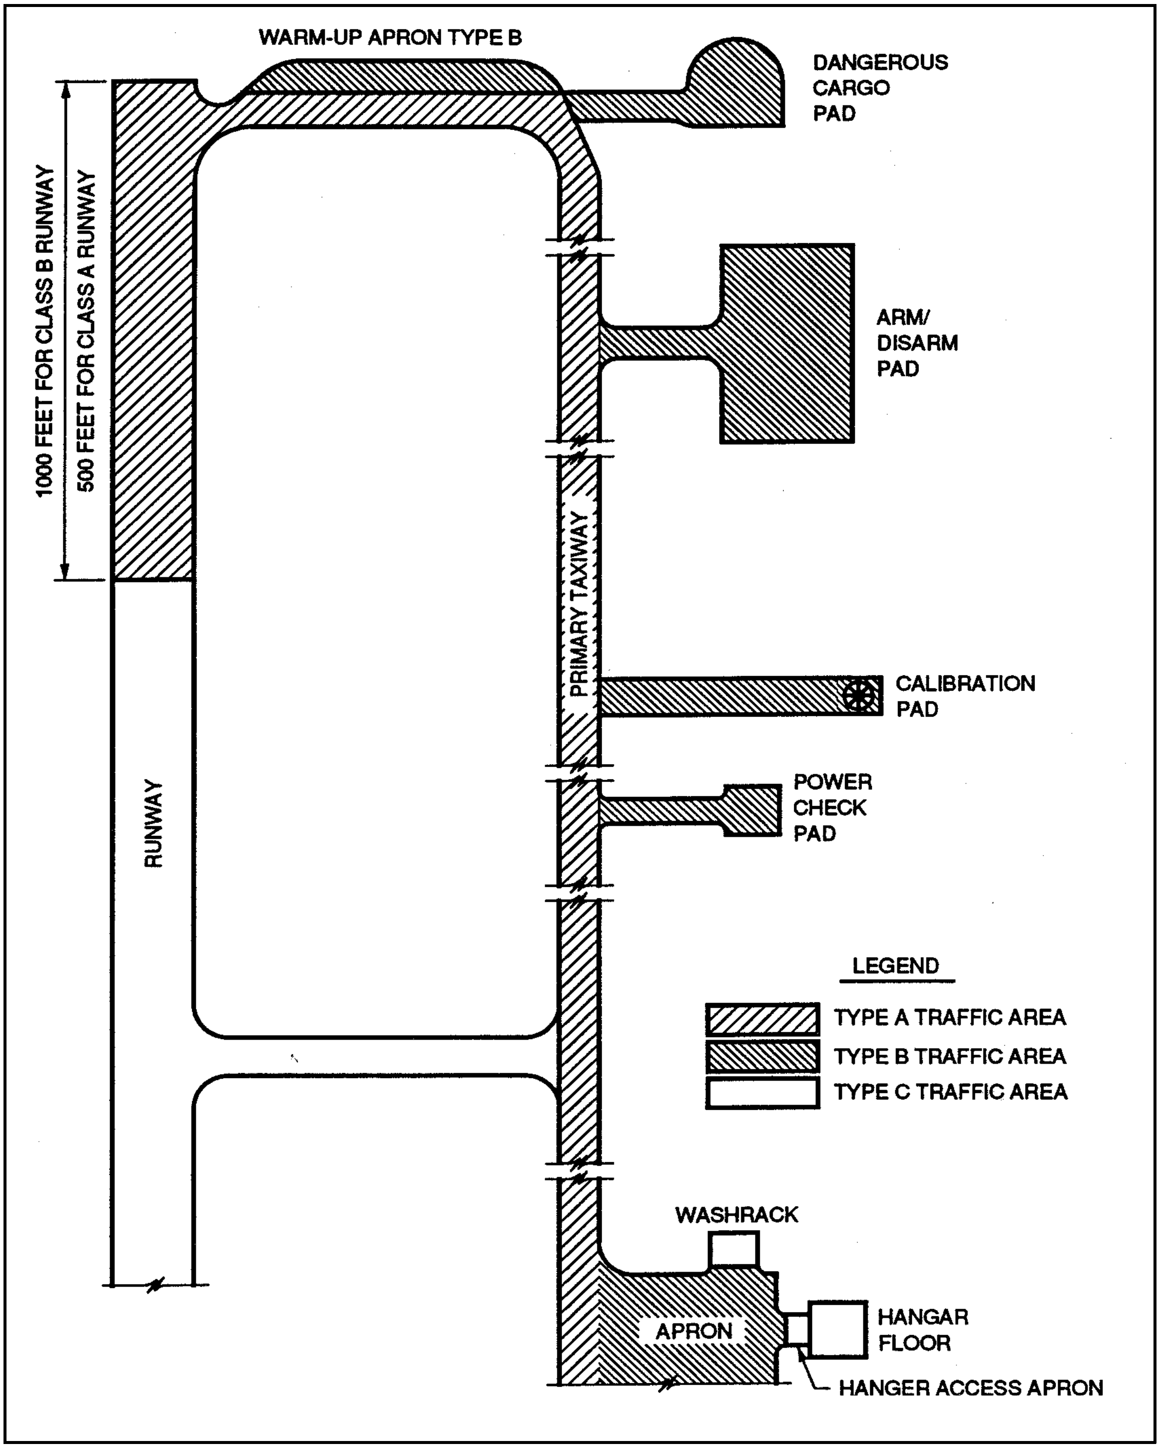

Figure 2-1. Typical layout of traffic areas for Army Class III and IV airfields

CHAPTER 3

AIR FORCE AIRFIELD AND AGGREGATE SURFACED HELICOPTER SLIDE AREAS AND HELIPORT REQUIREMENTS

1. AIR FORCE AIRFIELD TYPES. Airfield mission and operational procedures have resulted in the development of six types of Air Force airfields: light, medium, heavy, modified heavy, auxiliary, and assault landing zone. The decision on which airfield type to design for will be made by the appropriate Major Command (MAJCOM). Designs should generally be based upon medium load criteria with the following exceptions.

a. Air Training Command bases should be designed as light load. Auxiliary airfields at Air Training Command bases will be designed for the load and pass level selected by the Major Command.

b. For bases where B-52's are the critical missions, use heavy load criteria.

c. For bases where the B-1 and/or KC-10's are the critical mission, use modified heavy load criteria.

d. Assault landing zone criteria should be used to design runways for C-130 or C-17 training.

e. MAJCOMs should plan for future missions. For example, if the current mission uses KC-135 tankers but will use KC-10 aircraft in the future, the KC-10 should be the design aircraft.

f. In lieu of the above criteria, MAJCOMs have the option to design for specific aircraft and projected pass levels.

2. TRAFFIC AREAS FOR AIR FORCE AIRFIELDS. On normal operational airfields, the pavements can be grouped into four traffic areas designated as Types A, B, C, and D which are defined below and shown in Figures 3-1, 3-2, or 3-3 for each type airfield. A layout of the assault landing zone is not shown since all areas are Type A traffic areas. Modified heavy-load airfields will have the same traffic areas as medium-load airfields. Auxiliary airfields will have the same traffic areas as light-load airfields.

a. Type A Traffic Areas. Type A traffic areas are those pavement facilities that receive the channelized traffic and full design weight of aircraft. Aircraft with steerable gear, including fighter-type aircraft, operate within a relatively narrow taxilane producing sufficient coverages or stress repetition within the narrow lane to require special design treatment. Type A traffic areas for pavements are dictated by the operational patterns of aircraft. These traffic areas require a greater pavement thickness than those areas where the traffic is more evenly distributed. Pavement features considered to be Type A traffic areas on each airfield type are as follows:

(1) Heavy-load airfield.

(a) Portions of long straight sections of primary taxiways will be Type A traffic areas. Traffic channelization is limited to the center of the taxiway for aircraft with a bicycle-gear configuration. Therefore, the center 7.6-meter (25-foot) (minimum) of long straight sections will be designed as a Type A traffic area. The outside lanes will be designed as Type B traffic areas. An alternative design is to provide uniform thickness for the full width of the taxiway.

(b) Taxiways connecting runway ends and primary taxiways, short lengths of primary taxiway turns, and intersections of primary taxiways will be Type A traffic areas. The effects of traffic channelization on these areas cannot be well defined; therefore, these pavements will be designated as Type A traffic areas requiring a uniform pavement thickness for the full width of the taxiway.

(c) Through taxilanes or portions of through taxiways on aprons (7.6-meter (25-foot) minimum) will be designed as Type A traffic areas.

(d) Portions of the first 305 meters (1,000 feet) of runway ends will be Type A traffic areas. On these pavements, the effects of channelized traffic are generally confined to the center 23-meter (75-foot) width and the approach area from the connecting taxiway. These portions will be designed as Type A traffic areas and will require a uniform thickness. The dimensions of the approach area will correspond to the width of the connecting taxiway plus the taxiway fillets. An alternate design for the first 305 meters (1,000 feet) of runway ends is to provide a uniform thickness for the full width of the pavement. Design of the pavement for channelized traffic must include the lanes where the traffic of the design landing-gear type (bicycle or tricycle) is applied. For the present heavy-load pavement (bicycle-landing gear), the selection of a thickened center section or a uniform thickness for the full width of the facility will be determined on the basis of life cycle costs and projected future mission. In seasonal frost areas, it is often desirable to use a constant transverse section to preclude differential frost heave.

(2) Medium-load and modified heavy-load airfield.

(a) Primary taxiways will be designed as Type A traffic areas. The effects of channelized traffic are well defined on long straight sections. However, the channelization is not as confined as for a heavy-load pavement, and it is not practical to construct primary taxiways of alternating variable thicknesses as indicated by traffic requirements. Therefore, the primary taxiways for medium-load and modified heavy-load airfields will normally be constructed to provide a uniform thickness for the full width of pavement facility. The entire primary taxiway, including straight sections, turns, and intersections, will be designated as Type A traffic areas.

(b) Through taxilanes and portions of through taxiways on aprons (11-meter (35-foot) minimum) will be designed as Type A traffic areas.

(c) Portions of the first 305 meters (1,000 feet) of runway ends will be designed as Type A traffic areas. On these pavements, the effects of channelized traffic are generally confined to the center 23-meter (75-foot) width and the approach area from the connecting taxiway. These portions will be designed as Type A traffic areas and will require a uniform thickness. The dimensions of the approach area will correspond to the width of the connecting taxiway plus the taxiway fillets. An alternate design for the first 305 meters (1,000 feet) of runway ends would be to provide a uniform thickness for the full width of the pavement facility. The selection of a thickened center section or a uniform thickness for full width of the facility will be determined on the basis of life cycle costs unless mission requirements dictate a uniform thickness (an example is formation takeoffs). In frost areas, it is often desirable to use a uniform thickness to preclude differential frost heave.

(3) Light-load and auxiliary airfields. Primary taxiways and the first 305 meters (1,000 feet) of runway ends will be designed as Type A traffic areas. The effects of channelized traffic are reasonably well defined on long straight sections. However, it is not considered practical to construct primary taxiways and runway ends of alternating variable thicknesses for light-load and auxiliary airfields as indicated by traffic requirements. Therefore, the primary taxiways and the first 305 meters (1,000 feet) of runway ends for light-load and auxiliary airfields will normally be constructed to provide a uniform

thickness for the full width of pavement facility. The entire primary taxiway, including straight sections, turns, and intersections, will be designated as Type A traffic areas.

(4) Assault landing zone airfield. The type of aircraft operations conducted on these pavements will require the entire runway, the 91-meter (300-foot) overruns, and the short access taxiways to be designed as Type A traffic areas.

b. Type B Traffic Areas. Type B traffic areas are those in which the traffic is more evenly distributed over the full width of the pavement facility but which receive the full design weight of the aircraft during traffic operations. Inasmuch as there is a better distribution of the traffic on these pavements, the repetition of stress within any specific area is less than on Type A traffic areas; therefore, a reduction in required pavement thickness can be allowed. Pavement facilities considered to be Type B traffic areas on each airfield type are as follows:

(1) Heavy-load airfield. All aprons (except hangar access aprons), pads, and hardstands, and traffic lanes adjacent to the center lane on long straight sections of primary taxiways are designed as Type B traffic areas.

(2) Medium-load and modified heavy-load airfields. All aprons (except hangar access aprons), pads, and hardstands are Type B traffic areas.

(3) Light-load and auxiliary airfields. All aprons (except hangar access aprons), hardstands, and power check pads are Type B traffic areas.

(4) Assault landing zone. No Type B traffic area.

c. Type C Traffic Areas. Type C traffic areas are those in which the volume of traffic is low or the applied weight of the operating aircraft is generally less than the design weight. In the interior portion of runways, there is enough lift on the wings of the aircraft at the speed at which the aircraft passes over the pavements to reduce considerably the stresses applied to the pavements. Thus, the pavement thickness can be reduced in these portions of the runways. Therefore, all runway interiors, except shortfield, will be designated as Type C traffic areas regardless of type of design loadings. For the heavy, modified heavy, and medium-load airfields, the edges of the runway seldom receive a fully loaded aircraft; therefore, for these airfields, the Type C traffic areas are limited to the center 23-meter (75-foot) width of runway interior. However, in seasonal frost areas, it may be necessary to use a uniform thickness for the entire width of the runway to preclude frost heave. Pavement facilities at all airfields considered to be Type C traffic areas are as follows:

(1) Heavy-load airfields.

(a) Secondary (ladder) taxiways.

(b) The center 23-meter (75-foot) width of runway interior between the 305-meter (1,000-foot) runway ends and at runway edge adjacent to intersections with ladder taxiways.

(c) Main gear path area of hangar access aprons and floors and washrack pavements. (The pavement outside the main gear path area of hangar access aprons and floors and washracks are designed as a light-load Type C traffic area.)

(2) Medium-load and modified heavy-load airfields.

(a) Secondary (ladder) taxiways.

(b) The center 23-meter (75-foot) width of runway interior between 305-meter (1,000-foot) runway ends and at runway edges adjacent to intersections with ladder taxiways.

(c) Hangar access aprons and floors and washrack pavements. At Air Mobility Command Installations, hangar access aprons shall be designed as Medium Load Type C Traffic Area for the main gear plus 3 meters (10 feet) on each side. The remainder of the access apron shall be Light Load Type C Traffic Area.

(3) Light-load and auxiliary airfields.

(a) Full width of runway interior between the 305-meter (1,000-foot) runway ends and secondary (ladder) taxiways.

(b) Hangar access aprons and floors.

(c) Washrack pavements.

(4) Assault landing zone. No Type C traffic areas.

d. Type D Traffic Areas. Type D traffic areas are those in which the traffic volume is extremely low and/or the applied weight of operating aircraft is considerably lower than the design weight. The pavement facilities considered to be Type D traffic areas are the edges of runways that are designed for heavy-load, medium-load, and modified heavy-load airfields. Aircraft on heavy-, modified heavy-, or medium-load runways seldom, if ever, operate outside of the center 23-meter (75-foot) width of the runway interior, and the only traffic that will occur on the edges of the runway will be occasional heavy, medium, or modified heavy aircraft loads or frequent light aircraft loads. Therefore, a substantial reduction in required pavement thickness can be made. Pavement facilities considered to be Type D traffic areas are as follows:

(1) Heavy-load airfields. The outside edges of the entire length of runway, except for the approach and exit areas at taxiway intersections, are Type D traffic areas.

(2) Medium-load and modified heavy-load airfields. The outside edges of the entire length of runway except for the approach and exit areas at taxiway intersections are Type D traffic areas.

(3) Light-load and auxiliary airfields. There are no Type D traffic areas on light-load or auxiliary pavements.

(4) Assault landing zone. No Type D traffic areas.

3. AIRCRAFT DESIGN LOADS FOR AIR FORCE PAVEMENTS. The design loads for light, medium, heavy, modified heavy, auxiliary, and assault landing zone airfield pavements have been established by the Air Force and are shown in Table 3-1. The concept is to design each airfield type for a mixture of aircraft traffic at the loads shown. These loads represent the design gross weights for each type traffic area and overruns on the airfield. Aircraft hangar floors or apron pavements shall not be designed for jacking loads as long as the foot print of the jack is equal to or greater than the contact area of the combined tires on the aircraft gear being elevated.

4. DESIGN PASS LEVELS FOR AIR FORCE PAVEMENTS. Aircraft traffic data reports indicating type and frequency of aircraft traffic at selected Air Force bases have been analyzed to establish criteria to be used in the design of airfield pavements. These design pass levels are shown in Table 3-1 for the different traffic areas and aircraft types. Airfield pavements may be designed for alternate pass levels if dictated by the intended use of the facility and subject to the approval of the appropriate Air Force Major Command.

5. RESIN MODIFIED PAVEMENT. Resin Modified Pavement (RMP) can be used as an Air Force pavement except for runways and high-speed taxiways. RMP can be used for helipads and heliport pavements and for both rotary-wing and fixed-wing aprons.

6. PAVED SHOULDERS.

a. Location. Paved shoulders should be provided for airfield and heliport construction as designated in UFC 3-260-01.

b. Structural Requirements. As a minimum, paved shoulders shall be designed to support a load of 4,535 kilograms (10,000 pounds) imposed by a single wheel with a tire pressure of 0.69 MPa (100 psi). When shoulder pavements are to be used by support vehicles (snow removal equipment, fire trucks, fuel trucks, etc.), the shoulders should be signed accordingly for whichever governs.

7. AGGREGATE SURFACED HELICOPTER SLIDE AREAS AND HELIPORTS. Geometric and structural criteria for the design of aggregate surfaced helicopter slide areas and heliports are listed below. These criteria are applicable to all Air Force organizations with pavement design and construction responsibilities.

a. Geometric Criteria. Geometric criteria can be found in UFC 3-260-01.

b. Structural Criteria. Airfield structural design criteria are presented below.

(1) Thickness (Non-Frost Areas). Factors which determine thickness are the California Bearing Ratio (CBR) of the subgrade, helicopter weight, and passes. The minimum required thickness is 150 millimeters (6 inches). Use Figure 3-6 for design of aggregate surface thickness for helicopters. Enter Figure 3-4 with the subgrade CBR (see Chapter 6 for selection of subgrade CBR) to determine the thickness required for a given load and pass level. The thickness determined from the figure may be constructed of surface course material for the total depth over the natural subgrade; or in a layered system consisting of select material, subbase, and surface course over compacted subgrade for the same total depth. Check the layered section to ensure sufficient material protects the underlying layer, based upon the CBR of the underlying layer. The top 150 millimeters (6 inches) must meet the gradation requirements of Table 3-2.

(2) Select Materials and Subbases. Select design CBR values materials and subbases in accordance with Chapter 7, except as modified in Table 3-3.

(3) Thickness (Frost Areas). In areas where frost effects impact pavement design, there are additional considerations concerning thicknesses and required layers in the pavement structure. For frost design, soils are divided into eight groups as shown in Table 3-4. Only the non-frost-susceptible (NFS) group is suitable for base course. NFS, S1, or S2 soils may be used for subbase course, and any

* Nonfrost-susceptible.
** Possible frost-susceptible, but requires laboratory test to determine frost design soil classification.
*** Defined in AFM 89-3, *Materials Testing*.

of the eight groups may be found as subgrade soils. Soils are listed in approximate order of decreasing bearing capability during periods of thaw.

(a) Required Thickness. Where there are frost-susceptible subgrades, determine section thickness according to the reduced subgrade strength method. The reduced 3-5 subgrade strength method uses the frost area soil support indexes (FASSI) in Table 3-5. Use FASSI like CBR values. The term CBR is not applied, because FASSI are weighted average values for an annual cycle and their values cannot be determined by CBR tests. Enter Figure 3-4 with the soil support indexes (vice CBR values) to determine the required section thickness.

Table 3-5
Frost Area Soil Support Indices (FASSI) of Subgrade Soils

Frost Group	FASSI
F1 and S1	9.0
F2 and S2	6.5
F3 and F4	3.5

(b) Pavement Section Layers. When frost is a consideration, recommend the pavement section consist of layers that will ensure the stability of the system, particularly during thaw periods. The layered system may consist of a 150-millimeter- (6-inch-) thick minimum wearing surface of fine crushed stone, a coarse-graded base course, and/or a well-graded subbase of sand or gravely sand. To ensure the stability of the wearing surface, the width of the base course and subbase should exceed the final desired surface width by a minimum of 0.35 meter (1 foot) on each side.

(c) Wearing Surface. The wearing surface contains fines (material passing the #200 sieve) to provide stability in the aggregate surface. The presence of fines improves the layer's compaction characteristics and helps to provide a relatively smooth surface.

(d) Base Course. The coarse-graded base course is important in providing drainage of the granular fill. Base course should be non-frost-susceptible to retain strength during spring thaw periods.

(e) Subbase. A well-graded subbase provides additional bearing capacity over the frost-susceptible subgrade. It also provides a filter layer between the coarsegraded base course and the subgrade to prevent migration of the subgrade into the voids in the coarser material during periods of reduced subgrade strength. Therefore, the material must meet standard filter criteria. The subbase must be either non-frost susceptible or of low frost susceptibility (SI or S2), The filter layer may or may not be necessary depending upon the type of subgrade material. If the subgrade consists principally of gravel or sand, the filter layer may not be necessary, and may be replaced by additional base course if the gradation of the base course meets filter criteria. For finer grained soils, the filter layer will be necessary. If using a geotextile, the sand subbase/filter layer may be omitted, as the fabric will be placed directly on the subgrade and acts as a filter.

(f) Compaction. The subgrade should be compacted to provide uniformity of conditions and a working platform for placement and compaction of subbase. Compaction will not change a subgrade's frost-area soil support index. However, because frost weakens the subgrade, compacted subgrade in frost areas will not be considered part of the layered system of the airfield, which should be comprised of only the wearing, base, and subbase courses.

(g) Base Course and Filter Layer. Relative thicknesses of the base course and filter layer vary, and should be based on the required cover and economic considerations.

(h) Alternate Design. The reduced subgrade strength design provides a soil thickness above a frost-susceptible subgrade which minimizes frost heave. For a more economical design, a frost-susceptible select material or subbase may be used as a part of the total thickness above the frost-susceptible subgrade. However, thickness above the select material or subbase must be determined by using the FASSI of the select or subbase material. Frost-susceptible soils used as select materials or subbases must meet current specifications; the restriction on the allowable percent finer than 0.02 mm is waived.

(4) Surface Course. Materials requirements for construction of aggregate surfaced airfields depend upon whether frost is a factor in the design.

(a) Nonfrost Areas. Material used for airfields should be sufficiently cohesive to resist abrasive action. It should have a liquid limit no greater than 35 and a plasticity index between 4 and 9. It also should be graded for maximum density and minimum volume of voids to enhance optimum moisture retention while resisting excessive water intrusion. Gradation should consist of an optimal combination of coarse and fine aggregates to ensure minimum void ratios and maximum density. This material will exhibit cohesive strength as well as intergranular shear strength. Recommended gradations are shown in Table 3-6. If the fines fraction of the material does not meet plasticity characteristics, the material may be modified by adding chemicals. Chloride products can, in some cases, enhance moisture retention, and lime can be used to reduce excessive plasticity.

(b) Frost Areas. Where frost is a consideration, a layered system should be used. The percentage of fines should be restricted in all the layers to facilitate drainage and reduce the loss of stability and strength during thaw periods. Use gradation numbers 3 and 4 shown in Table 3-6 with caution, since they may be unstable in a freeze-thaw environment.

Table 3-6
Gradation for Aggregate Surface Courses (Percent Passing)

Sieve Designation	No. 1	No. 2	No. 3	No.4
25.0 mm (1”)	100	100	100	100
9.5 mm (3/8”)	50-85	60-100	--	--
No. 4	35-65	50-85	55-100	70-100
No. 10	25.50	40.70	40-100	55-100
No. 40	15.30	24-45	20-50	30-70
No. 200	8-15	8-15	8-15	8-15

Note: The percent by weight finer than 0.02 mm (0.04 in.) shall not exceed 3 percent.

(5) Compaction. Compaction requirements for the subgrade and granular layers are expressed as a percent of maximum CE 55 density as determined by using CRD-C653, *Standard Test Method for Determination of Moisture-Density Relations of Soils*. For granular layers, compact the material to 1 00 percent of maximum CE 55 density. Select materials and sub-qrades in fills must have densities equal to or greater than the values shown in Table 3-7, except that fills will be placed at no less than 95 percent compaction for cohesionless soils (PI - 5; LL 25) or 90 percent compaction for cohesive soils (PI > 5; LL > 25). Subgrades in cuts must have densities equal to or greater than the values shown in Table 3-7. Subgrades occurring in cut sections will be either compacted from the surface to meet the densities shown in Table 3-7 removed and replaced before applying the requirements for fills, or covered with sufficient material so that the uncompacted subgrade will be at a depth where the in-place densities are satisfactory. Depths in Table 3-7 are measured from the surface of the aggregate, and not the surface of the subgrade.

Table 3-7
Compaction Requirements for Helicopter Pads and Slide Areas

	Cohesive Soils					Cohesionless Soils			
Percent	100	95	90	85	80	100	95	90	85
Depth Below Pavement Surface, millimeters	100	150	200	250	300	150	250	325	400
(inches)	(4)	(6)	(8)	(10)	(12)	(6)	(10)	(13)	(16)

c. Drainage. Drainage is a critical factor in aggregate surface airfield design, construction, and maintenance. It should be considered prior to construction; and, when necessary, serve as a basis for site selection.

(1) Provide adequate surface drainage to minimize moisture damage. Quick removal of surface water reduces absorption and ensures more consistent strength and reduced maintenance. Drainage must not result in damage to the aggregate surfaced airfield through erosion of fines or erosion of the entire surface layer. Ensure changes to the drainage regime can be accommodated by the surrounding topography without damage to the environment, or the newly constructed slide area or pad.

(2) The surface geometry of an airfield should be designed so that drainage is provided at all points. Depending upon the surrounding terrain, surface drainage can be achieved by a continual cross slope, or by a series of two or more interconnecting cross slopes.

(3) Provide adequate drainage outside the airfield area to accommodate maximum flow. Use culverts sparingly, and only in areas where adequate cover of granular fill is provided over the culvert. Evaluate drainage for adjacent areas to determine if rerouting is needed to prevent water from other areas flowing across the airfield.

d. Maintenance. The two primary causes of deterioration of aggregate surfaced areas requiring frequent maintenance are the environment and traffic. Rain or water flow will wash fines from the aggregate surface; traffic action causes erosion of surface materials. Maintenance should be performed at least every six months, and more frequently if required. Frequency of maintenance will be high for the first few years of use, but will decrease over time to a constant value. Most of the maintenance will consist of grading to remove ruts and potholes and replacing fines. Occasionally, the surface layer may have to be scarified, additional aggregate added to restore original thickness. and the wearing surface recompacted to the specified density.

e. Dust Control. A dust palliative prevents soil particles from becoming airborne as a result of wind or traffic. Dust palliatives used on traffic areas must withstand abrasion. An important factor limiting use of dust palliatives in traffic areas is the extent of surface rutting or abrasion that will occur under traffic. Some palliatives will tolerate deformations better than others, but ruts in excess of 13 millimeters (1/2 inch) will usually destroy any thin layer or shallow-depth penetration dust palliative treatment. A wide selection of materials for dust control is available, Several materials have been recommended for use and are discussed in AFJMAN 32-1019.

8. SURFACE DRAINAGE. Design of surface drainage shall be in accordance with TM 5-820-1/ AFM 88-5, Chapter 1.

CHAPTER 4

NAVY AND MARINE CORPS AIRFIELD REQUIREMENTS

1. TRAFFIC. Traffic is an important input for pavement thickness design. An airfield pavement shall be designed to support a forecast number of loadings by one or more types of aircraft expected to use the facility over the design period. This requires information related to:

a. Aircraft types (gear configurations).

b. Maximum gross weight of each aircraft type.

c. Lateral wander associated with each aircraft type.

d. Predicted number of operations of each aircraft type over the design life of the pavement.

2.T RAFFIC AREAS. Airfield pavements are categorized by traffic area as a function of either lateral traffic distribution or aircraft weight or both. The three principal traffic areas recognized on Navy and Marine Corps air stations are primary, secondary, and supporting. For purposes of standardization and for preparation of the Tri-Service design criteria, a primary area corresponds to an Air Force B traffic area and a secondary traffic area corresponds to an Air Force C traffic area. These designated traffic areas for a typical airfield layout plan are shown in Figure 4-1.

a. Primary Traffic Areas. Primary traffic areas require high pavement strength due to the combination of high operating weights and channelized traffic. Primary traffic areas include:

(1) First 305 meters (1,000 feet) of runways.

(2) Primary taxiways.

(3) Holding areas.

(4) Aprons.

b. Secondary Traffic Areas. Secondary traffic areas are normally subjected to unchannelized traffic and aircraft operating at lower weights than primary traffic areas. Secondary traffic areas include:

(1) Runway interiors.

(2) Intermediate taxiway turnoffs.

c. Supporting Areas. Supporting areas are not intended for normal aircraft operations. They are designed to withstand occasional passes of aircraft on an emergency basis. Supporting traffic areas include:

(1) Inner 3 meters (10 feet) of runway shoulders.

(2) Stabilized portions of runway overruns.

(3) Blast protective pavement.

3.AIRCRAFT LOADINGS. Factors which must be considered in pavement thickness design are the landing gear configuration, weight distribution, gear loads, number of wheels, wheel spacing, tire width, and tire inflation pressure. These characteristics are different for each aircraft and will result in a different pavement response. All aircraft expected to use the facility over the design period shall be considered in the pavement thickness design.

a. Aircraft Types. A landing gear assembly shall consist of a single wheel for smaller aircraft, or dual and dual tandem wheels for larger aircraft. Figure 4-2 illustrates the various multiwheel landing gear assemblies and lists typical aircraft for each.

b. Design Weight. The maximum static gear loads are used for pavement thickness design. Table 4-1 presents the design gear loads and other characteristics for Navy and Marine Corps aircraft. To use the design curves herein, the design gear load must be converted to the design gross aircraft weight (typically, the maximum gross take-off weight) by assuming that 95 percent of the gross aircraft weight is carried by the main gears. The design gear loads given in Table 4-1 represent the maximum static gear loads expected to be applied to a pavement.

c. Use of Other Gear Loads in Design. Gear loads other than those listed in Table 4-1 may be used for design when required. Since certain areas of an airfield (e.g., runway shoulders, runway overruns) do not normally carry fully loaded aircraft, they do not need to be designed for the maximum gross weight.

d. Hangar Floors. Aircraft in hangars are not normally loaded with cargo, fuel, or armaments. Hangar floors shall be designed for the empty weight of the aircraft. When exact data are not available, 60 percent of the maximum gross weight of the aircraft shall be used. Aircraft hangar floors or apron pavements shall not be designed for jacking loads as long as the foot print of the jack is equal to or greater than the contact area of the combined tires on the aircraft gear being elevated.

e. Standard Design Aircraft. One aircraft in each gear assembly group has been designated the representative aircraft for that group. The tabulation below identifies these five standard aircraft types which are to be used as default values in the design of rigid and flexible pavements only when site-specific aircraft loadings are not available.

Standard Design Aircraft Types

Landing Gear Assembly	Representative Aircraft	Tire Pressure Mpa (psi)	Design Gear Load, kg (lb)
Single	F-14	1.65 (240)	13,608 (30,000)
Dual	P-3	1.31 (190)	30,845 (68,000)
Single Tandem	C-130	0.65 (95)	38,100 (84,000)
Dual Tandem	C-141	1.24 (180)	70,310 (155,000)
Twin Delta Tandem	C-5A	0.79 (115)	86,190 (190,000)

(Continued)

S = Single Tricycle, T = Dual Tricycle, TDT = Twin Delta Tandem, ST = Single Tandem Tricycle, TT = Dual Tandem Tricycle

NOTES:
1. Blank spaces indicate data not readily available.
2. This data represents the best available figures at the time of publication. The user should update this information for later models of the design aircraft.
3. Values given are for rigid and flexible pavements. Pass to Coverage Ratios for flexible pavements for aircraft with Dual Tandem Tricycle Gear are equal to one-half the value shown. All Tandem Wheel Aircraft produce only one maximum stress for each pass of the gear for rigid pavements.
4. A represents the transverse tire spacing on one main gear.
5. B represents the longitudinal tire spacing on one main gear.

4.T RAFFIC VOLUME. The traffic type, volume, and pavement design life are essential inputs to the pavement design procedure. Determine the total number of passes of each aircraft type that the pavement will be expected to support over its design life. The minimum design life for Navy and Marine Corps facilities is 20 years. Only aircraft departures are normally included as passes in pavement thickness design. The exception to this is in touchdown areas on runways where the impact due to aircraft performing touch-and-go operations will cause pavement damage. On pavements that are to be used for touch-and-go operations, add the expected number of touch-and-go operations over the design life to the number of departures to arrive at the design traffic. Obtain data for the specific Navy and Marine Corps airfield facility under design to forecast aircraft traffic operations over the design life of the pavement. When site-specific traffic projections are not available, the traffic pass levels listed below are the minimum pass levels to be used in design.

Aircraft	**Total Passes Over 20 Year Design Life**[1]
F-14	300,000
P-3	100,000
C-130	50,000
C-141	25,000
C-5A	25,000

[1] Departures at Maximum Gross Weight.

5.RO LLER-COMPACTED CONCRETE PAVEMENT. Roller-compacted concrete pavement (RCCP) is a rigid pavement and can be used as pavement except for runway and high-speed taxiway pavements for fixed-wing aircraft. RCCP can be used for all helipad and heliport pavements.

6.RESIN MODIFIED PAVEMENT. Resin Modified Pavement (RMP) can be used as an Navy pavement except for fixed-wing runways and high-speed taxiways. RMP can be used for helipads and heliport pavements and for both rotary-wing and fixed-wing parking aprons.

7.PAVED SHOULDERS.

a. Location. Paved shoulders should be provided for airfield and heliport construction as designated in EI 02C013/AFJMAN 32-1013/NAVFAC P-971.

b. Structural Requirements. As a minimum, paved shoulders shall be designed to support a load of 4,535 kilograms (10,000 pounds) imposed by a single wheel with a tire pressure of 0.69 MPa (100 psi).

8.PAVEMENT DESIGN POLICY. The Navy recognizes PCASE rigid and flexible pavement design programs and consensus industry standard programs in addition to the traditional Navy rigid pavement design program. Designers are encouraged to consider life cycle costs when designing new pavements. When the life of the pavement can be extended by more than 10 times, it is acceptable to increase the pavement thickness by 1 inch or less as determined by the Navy's traditional rigid pavement center panel loading procedure. Use of the Army/Air Force edge loading condition is another way to provide for improved pavement life cycle costs. Designers shall complete a sensitivity analysis of the above mentioned programs and review with the senior airfield designer in their geographic area of responsibility.

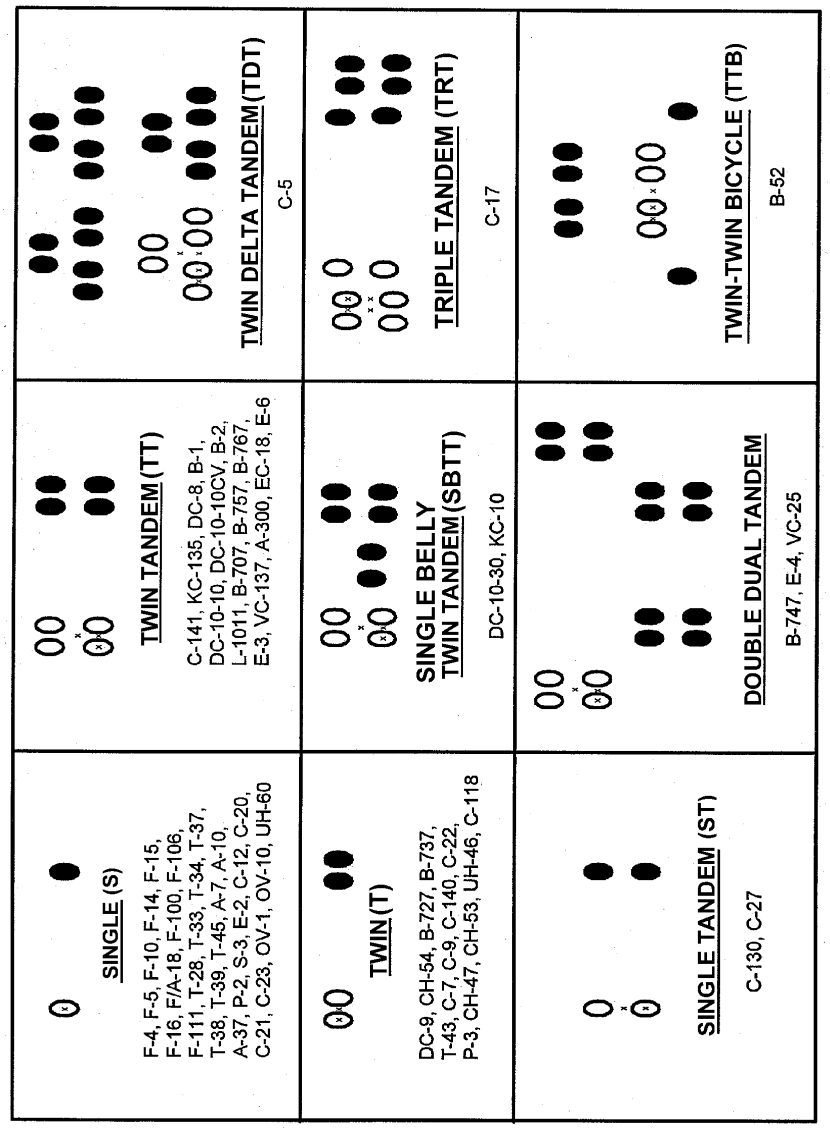

Figure 4-2. Landing gear assemblies

CHAPTER 5

SITE INVESTIGATIONS

1. GENERAL. The design of pavements must be based on a complete and thorough investigation of climatic conditions, topographic conditions, subgrade conditions, borrow areas, and sources of base course, subbase course paving, and other materials. These preliminary investigations will necessitate use of standard tests and all other available information such as aerial photographs, pavement evaluations, condition surveys, construction records, soil maps, geologic maps, topographic maps, and meteorological data. Table 5-1 lists sampling and testing standards used in soil investigations. Although previous investigations should be used to establish preliminary soil characteristics, additional investigations must be performed for final design.

2. SUBGRADE INVESTIGATIONS.

a. Field Reconnaissance. Conduct field reconnaissance with the available topographical, geographical, and soil maps; aerial photographs; meteorological data; previous investigations; and condition surveys and pavement evaluation reports. This step should precede an exploratory boring program.

b. Spacing of Preliminary Borings. The subgrade conditions in the area to be used for airfield pavement construction should be determined by exploratory borings. The recommended maximum spacing of borings should be as shown in the following tabulation, and should be supplemented with additional borings whenever variations in soil conditions or unusual features are encountered.

Item	**Spacing of Borings**
Runway and taxiways ≤ 61 meters (200 ft) wide	One boring every 61 to 152 meters (200 to 500 feet) longitudinally on alternating side of pavement centerline
Runways >61 meters (200 feet) wide	Two borings every 61 to 152 meters (200 to 500 feet longitudinally (one boring on each side of centerline)
Parking aprons and pads	One boring per 2,325-square-meter (25,000-square-foot) area

c. Depth of Borings. In cut sections, borings should extend to a minimum depth of 3 meters (10 feet) below the finished grade or to rock. In shallow fill sections, borings should extend to a minimum depth of 3 meters (10 feet) below the surface of the natural subgrade or to rock. Shallow fills are those where the effect of the weight of the fill on the natural subgrade is small compared to the weight of the design aircraft (generally 1.8 meters (6 feet) or less). In high-fill sections, borings should extend to a minimum depth of 15.2 meters (50 feet) below the surface of the natural subgrade or to rock. Results of borings will be used to develop boring logs as illustrated in Figure 5-1.

d. Samples. Soil samples should be obtained from the borings for classification purposes. After these samples are classified, soil profiles should be developed and representative soils selected for testing. A typical soil profile is shown in Figure 5-2. Test pits or large-diameter borings may be required to obtain the samples needed for CBR testing, or to permit in-place tests of the various soil layers. The types and number of samples required will depend on the characteristics of the subgrade soils. Subsoil

Table 5-1
Soil Sampling and Testing Standards

Category	Description	ASTM	CRD

	CBR by small aperture		
	Modulus of soil reaction		C-655

Note: (1) Testing for Air Force and Army Pavements will be by ASTM or CRD.
(2) Description and application of the DCP is provided in FM 5-430-00-2/AFJPAM 32-8013, Vol II, Appendix J.

investigations in the areas of proposed pavement should include measurements of in-place water content, density, and strength to ascertain the presence of weak areas and soft layers in the subsoil.

e. Borrow Areas. Where material is to be borrowed, borings should be made in these areas to a depth of 0.6 to 1.2 meters (2 to 4 feet) below the anticipated depth of borrow. One boring should be made for each 930 square meters (10,000 square feet) with a minimum of three borings per borrow area. Samples from the borings should be classified and tested for water content, density, and strength.

f. Environmental Hazards. When conducting subsurface investigations, hazardous or toxic waste material may be located, and appropriate environmental actions will have to be taken. This may be true around fueling areas particularly if replacing an existing fueling apron where fuel has leaked through the pavement and contaminated the soil. There may also be buried materials that have to be dealt with in some areas.

3. SELECT MATERIAL AND SUBBASE FOR FLEXIBLE PAVEMENTS. Areas within the airfield site or within a reasonable haul distance from the site should be explored for possible sources of select material and subbase. Exploration procedures similar to those described for subgrades should be used. Test pits or large auger borings are required to obtain representative samples of gravelly materials.

4. BASE COURSES, DRAINAGE LAYERS, SEPARATION LAYERS, CONCRETE AND BITUMINOUS CONCRETE. Since these pavement layers are generally constructed using crushed and processed materials, a survey should be made of existing sources plus other possible sources in the general area. Significant savings may be made by developing possible quarry sites near the airfield location. This is particularly important in remote areas where no commercial producers are operating and in areas where commercial production is limited in quantity.

5. OTHER CONSTRUCTION MATERIALS. The availability and quality of bituminous materials and portland cement should be determined. The availability and type of lime and fly ash will also aid in the evaluation and applicability of stabilized layers. This information will be helpful in developing designs and alerting designers to local conditions and shortages.

6. SOIL CLASSIFICATION. All soils will be classified in accordance with the unified soil classification system (USCS) as given in American Society for Testing and Materials (ASTM) D 2487. Sufficient investigations will be performed at a particular site so that all soils to be used or removed during construction can be described in accordance with the USCS plus any additional description considered necessary. When classifying soils, be alert to the presence of problem soils such as:

a. Clays that Lose Strength When Remolded. The types of clays that show a decrease in strength when remolded are generally in the CH and OH groups. They are clays that have been consolidated to a very high degree, either under an overburden load or by alternate cycles of wetting and drying, or that have by other means developed a definite structure. They have a high strength in the undisturbed state. Scarifying, reworking, and rolling these soils in cut areas may produce a lower bearing value than that of the undisturbed soils.

b. Soils that Become “Quick” When Molded. Some soils deposits such as silts and very fine sands, (predominantly in classifications ML, SM, and SC) when compacted in the presence of a high water table, will pump water to the surface and become “quick” or “spongy” with a loss of practically all bearing value. The condition can also develop in most silts and poorly drained very fine sands if these materials are compacted at a moisture content higher than optimum. This is because compaction reduces the air voids so that the available water fills practically all the void space.

c. Soils With Expansive Characteristics. Expansive soils are generally those with a liquid limit more than 40 and a plasticity index more than 15. Soils with expansive characteristics give the most trouble when significant changes occur in moisture content of the subgrade during different seasons of the year. TM 5-818-7 may be helpful in identifying expansive soils.

7. SOIL COMPACTION TESTS. Soil compaction tests will be used to determine the compaction characteristics of soils. The degree of compaction required is expressed as a percentage of the maximum density obtained by the test procedure used. Table 5-1 shows test methods to be used for determining density. The laboratory compaction control tests should not be used on soil that contains particles easily broken under the blow of the hammer. Also, the unit weight of certain types of sands and gravels obtained by this method is sometimes lower than the unit weight that can be obtained by field methods. Density tests in these cases should be made under some variations of the test methods, such as vibration or tamping (alone or in combination) to obtain higher laboratory density. In some cases, it may be necessary to construct field test sections to establish compaction characteristics.

8. SOIL STRENGTH. Soil strength is measured by the CBR for use in designing flexible pavements and by the modulus of soil reaction (k) for the design of rigid pavements. Strength tests must be made on material that represents the field condition that will be most critical from a design standpoint. Details of the CBR test procedure are given in CRD-C 654 and details of the modulus of soil reaction test are given in CRD-C 655. Figure 5-3 shows approximate relationships between soil classifications and soil strength values. The relationships will not be used for design of pavements. They are given for checking and estimating, not as a substitute for testing. Guidance in determining soil strength values are presented in Chapters 6 through 8.

9. IN-PLACE SOIL STRENGTH TESTS. Test pits for in-place soil strength tests and associated moisture-density tests should be located at approximately 305-meter (1,000-foot) intervals for runways and taxiways. For parking aprons and pads, one test pit should be located for each 16,720 square meters (20,000 square yards). The number and spacing of test pits may be modified whenever variations in soil conditions or unusual features are encountered.

CHAPTER 6

SUBGRADE

1. SUITABILITY OF SUBGRADE. The information obtained from the explorations and tests previously described should be adequate to enable full consideration of all factors affecting the suitability of the subgrade and subsoil. The primary factors are as follows:

a. The general characteristics of the subgrade soils.

b. Depth to bedrock.

c. Depth to water table (including perched water table).

d. The compaction that can be attained in the subgrade and the adequacy of the existing density in the layers below the zone of compaction requirements.

e. The strength that the compacted subgrade, uncompacted subgrade, and subsoil will have under local environmental conditions.

f. The presence of weak or soft layers in the subsoil.

g. Susceptibility to detrimental frost action.

h. Settlement potential.

I. Expansion potential.

j. Drainage characteristics.

2. GRADE LINE. The soil type together with information on the drainage requirements, balancing cut and fill, flooding potential, depth to water table, depth to bedrock, and the compaction and strength characteristics should be considered in locating the grade line of the top of the subgrade. Generally, this grade line should be established to obtain the best possible subgrade material consistent with the proper utilization of available materials; however, economics of plans for construction must be given prime consideration.

3. SUBGRADE CBR. The strength of the subgrade may be expressed in terms of the CBR for flexible pavement design. The CBR test is described in CRD-C 654. It includes procedures for making tests on samples compacted to the design density in test molds and is soaked 4 days for making in-place CBR tests and for making tests on undisturbed samples. These tests are used to estimate the CBR that will develop in the pavement structure. However, a subgrade design CBR value above 20 is not permitted unless the subgrade meets the requirements for subbases. The CBR selected for the subgrade will be based on the predominant moisture conditions occurring during the life of the pavement. This moisture situation can be obtained from pavement evaluation reports and from soil tests under existing pavements. Where long duration soil moisture conditions cannot be determined with confidence, the soaked laboratory CBR will be selected for the subgrade soil.

a. Laboratory Tests. Tests results should include a full family of curves (Figure 6-1) as described in CRD-C 654. These curves show the three-way relationship of water content at the time of compaction, compacted density, and CBR after soaking. These curves should be studied in view of the actual water contents and densities that can be expected considering the natural scatter when specific control values are specified. The scatter that can be expected with normal control procedures will vary with the soil type. A spread of plus or minus 2 percent can be anticipated for soils with low optimum moisture contents (in the range of 10 percent), whereas a spread of plus or minus 4 percent can be anticipated for soils with high optimum moisture contents (in the range of 25 percent). Poor construction control may result in even greater scatter. A comparable scatter in the density can also be expected. After the range of moisture contents and densities that can be expected during actual construction is estimated, the range of CBR values that will result from these variations in moisture and density should be determined. The design CBR value for the specific soil tested should be selected near the lower part of the range. The following steps along with Figure 6-1 illustrate the selection of a design CBR value.

(1) Step A. Determine moisture/density relationship (CRD-C 653) at 12, 26, and 55 blows/layer. Plot density to which soil can be compacted in the field. For the clay of this example, use 95 percent of maximum density. Plot the desired moisture content range. For the clay of this example, use ±1-1/2 percent of optimum moisture content for approximately 13 and 16 percent. Shaded area represents compactive effort greater than 95 percent and within ±1-1/2 percent of optimum moisture content.

(2) Step B. Plot laboratory CBR (CRD-C 654) for 12, 26, and 55 blows/layer.

(3) Step C. Plot CBR versus dry density at constant moisture content. Plot attainable compaction limits of 1,770 and 1,840 kg/m^3 (110.6 and 115 lb/ft^3) for this example. The hatched area represents attainable CBR limits for desired compaction 1,770 and 1,840 kg/m^3 (110.6 to 115 lb/ft^3) and moisture content (13 to 16 percent). CBR varies from 11 (95 percent compaction and 13 percent moisture content) to 26 (15 percent moisture content and maximum compaction). For design purposes, a CBR at the low end of range is used. In the example, a CBR of 12 with a moisture content specified between 13 and 16 percent is selected.

b. In-place Tests and Tests on Undisturbed Samples. Where an existing pavement at the site has a subgrade constructed to the same standards as the job being designed, in-place tests or tests on undisturbed samples may be used in selecting the design CBR value. Also, where no compaction is anticipated, as in the layers below the zone of compaction, tests should be conducted on the natural material. The in-place CBR may be used where little increase in moisture is anticipated, such as coarse grained cohesionless soils, soils which are at least 80 percent saturated in the natural state, and soils under existing similar pavements which have reached the maximum water content expected, and thus no soaking is required. When in-place tests or tests on undisturbed soils are used, a statistical approach is recommended for selecting the design CBR. An illustration of selecting the design CBR is as follows: Given 20 CBR test values from a runway site.

(1) CBR = 4, 4, 4, 4, 5, 5, 5, 5, 5, 6, 6, 6, 6, 6, 7, 7, 8, 8, 10, and 11. This is a total of 20 separate tests.

(2) Percent of CBR values equal to or greater than each different value:

CBR	Number Equal to or Greater than Each Different Value	Percent Equal to or Greater than Each Different Value
4		
4		
4		
4	20	(20/20)100 = 100
5		
5		
5		
5		
5	16	(16/20)100 = 80
6		
6		
6		
6		
6	11	(11/20)100 = 55
7		
7	6	(6/20)100 = 30
8		
8	4	(4/20)100 = 20
10	2	(2/20)100 = 10
11	1	(1/20)100 = 5

(3) Plot CBR versus percent equal to or greater as shown in Figure 6-2.

(4) Enter Figure 6-2 at 85 percent. Continue to plotted curve then down to design CBR value of 4.7. If a sample from a test location has a value so low (indicating a weak area) that it is not representative of the other tests in the area, obtain additional samples to determine the extent of the area and whether special consideration is required. Where soil conditions vary substantially, a separate set of CBR determinations will be required for each distinct soil type.

4. SUBGRADE MODULUS OF SOIL REACTION. The strength of the subgrade is expressed in terms of the modulus of soil reaction (k) for rigid pavement design. The k value will be determined by the field plate bearing test as described in CRD-C 655.

a. Strength Test. The field plate bearing test will be performed on representative areas of the subgrade, taking into consideration such things as changes in material classification, fill or cut areas, and varying moisture (drainage) conditions which would affect the support value of the subgrade. While it is not practical to perform a sufficient number of field plate bearing tests to make a statistical analysis of the k value, a sufficient number must be performed to give confidence that the selected value will be representative of the in-place conditions. This means that at least two tests for each significantly different subgrade condition should be conducted. Considering the limited number of measured k values that can be obtained, maximum use of other pertinent soil data must be made to aid in the selection of the design k value. The pavement thickness is not affected appreciably by small changes in k values.

Therefore, the assignment of k values in increments of 2.71 MN/m^3 (10 pci) for values up to and including 68 MN/m^3 (250 pci) and in increments of 6.8 MN/m^3 (25 pci) for values exceeding 68 MN/m^3 (250 pci) should be sufficient. A maximum k value of 135 MN/m^3 (500 pci) will be used. Typical values of k for different soil types and moisture contents are shown in Table 6-1.

Table 6-1
Typical Values of Modulus of Soil Reaction

Soils	Typical Range (lb/in.^{2}/in.)	Suggested Default Pavement Design Values if No Test Data is Available (lb/in.^{2}/in.)
Organic Soils (OL, OH, Pt)	25 - 100	25
Silts and Clays of High Plasticity (CH, MH)	50 - 150	50
Silts and Clays of Low Plasticity (CL, ML)	50 - 200	100
Silty and Clayey Sands (SM, SC)	50 - 250	150
Well- and Poorly-Graded Sands (SW, SP)	150 - 400	200
Silty and Clayey Gravels (GC, GM)	200 - 500	250
Well- and Poorly-Graded Gravels (GW, GP)	300 - 500	350

Pavement design should be based on test data or at least historical data of past designs and evaluations at the same facility if at all possible. These default values are suggested for use for preliminary calculations or for small projects or projects where better data simply cannot be obtained. Inadequate testing or evaluation budgets are not an excuse to use these values for final design.

b. Special Conditions. Test Method CRD-C 655 requires a correction of the field plate bearing test results to account for saturation of the soil after the pavement has been constructed. Most fine-grained soils exhibit a marked reduction in the modulus of soil reaction with an increase in moisture content, and a saturation correction is applicable. However, in arid regions or regions where the water table is 3.0 meters (10 feet) or more below ground level throughout the year, the degree of saturation that may result after the pavement has been constructed may be less than that on which the saturation correction is based. If examination of existing pavements (highway or airfield) in the near vicinity indicates that the degree of saturation of the subgrade is less than 95 percent and if there is no indication of excessive loss of subgrade support at joints due to erosion or pumping, the correction for saturation may be deleted.

5. SUBGRADE COMPACTION FOR FLEXIBLE PAVEMENTS - NORMAL CASES. In general, compaction increases the strength of subgrade soils and the normal procedure is to specify compaction in accordance with the following requirements.

a. Subgrades with CBR values above 20.

(1) Army and Air Force. One hundred percent density from ASTM D 1557 except where it is known that a higher density can be obtained practically. Then, the higher density will be required.

(2) Navy and Marine Corps. Compact to 95 percent of ASTM D 1557 maximum density.

b. Subgrades with CBR values of 20 or less.

(1) Fills. Subgrades in fills shall have densities equal to or greater than the values determined from Tables 6-2 through 6-7. Cohesionless fill will not be placed at less than 95 percent nor cohesive fill at less than 90 percent of maximum density from ASTM D 1557. The top 6 inches of subgrade will be compacted to 95 percent of maximum density from ASTM D 1557.

(2) Cuts. Subgrades in cuts shall have natural densities equal to or greater than the values determined from Tables 6-1 through 6-6. When they do not, the subgrade shall be (a) compacted from the surface to meet the densities required, (b) removed and replaced (then the requirements given above for fills apply), or (c) covered with sufficient select material, subbase, and base so that the uncompacted subgrade will be at a depth where the in-place densities are satisfactory. The top 152 millimeters (6 inches) of subgrade will be compacted to 95 percent of maximum density from ASTM D 1557.

c. Natural Densities. The natural densities occurring in the subgrade should be compared with the compaction requirements to determine if densification at the deeper depths under design traffic is a problem. If such densification is likely to occur, means must be provided for compacting these layers, or the flexible pavement structure must be established so that these layers are deep enough that they will not be affected by aircraft traffic.

d. Compaction Levels and Moisture Content. Compaction of soils and aggregates accomplishes two specific purposes: (1) it achieves sufficient density in each layer of material such that future traffic will not cause additional densification and consequent rutting and (2) it achieves the designer's desired engineering properties, normally strength used for the pavement design. The requirements for density in Tables 6-2 through 6.6 coupled with proof rolling (paragraph 9 of Chapter 8) accomplish the first objective. The interaction between specified compaction levels and moisture contents and design strength is described in paragraph 3 of this chapter and Figure 6-1. Controlling field compaction of soils and aggregates using a specified percent of a laboratory compaction value and a specific range of allowable compaction moisture contents based on the laboratory optimum has proven simple and effective in practice for over a half century. Compaction curves of actual rollers in the field conform to the general shape and characteristics of the laboratory compaction curves but will deviate slightly from the actual laboratory curve. This deviation is not generally significant. Failure to control compaction moisture is probably one of the most common causes of failure to achieve specified density in the field. The contractor must thoroughly mix and disperse the moisture in the soils and aggregates and must allow for evaporation which can be significant on clear or windy days in many soils. Some soils such as silts have very steep compaction curves requiring fairly close control of the moisture to achieve compaction. Truly cohesionless soils compact best saturated but a relatively small increase in fines in such materials can make them spongy and uncompactable at saturation. Experience and field evaluation of each soil's behavior under compaction is usually needed to meet the stringent compaction standards used in military airfield construction. It is important to meet both the minimum specified density and to accomplish the compaction within the specified ranges of moisture content.

6. SUBGRADE COMPACTION FOR RIGID PAVEMENTS - NORMAL CASES. Compaction improves soil strength and ensures that densification with resulting voids under the concrete slab does not occur. Subgrade soils that gain strength when remolded and compacted will be prepared in accordance with the following criteria.

Table 6-7
Compaction Requirements for Shoulders

Percent Compaction	[1]Depth of Compaction in inches for Cohesive Subgrades and Select Materials (LL $\leq$ 25; PI $\leq$ 5)	[1]Depth of Compaction in inches for Cohesionless Subgrades and Select Materials (LL > 25; PI > 25)
85	17	29
90	14	23
95	10	16
100	6	10

[1] Depth is measured from pavement surface.
Conversion Factor: Millimeters = 25.4 × inches.

a. Compacting Fill Sections. Fills composed of soil having a plasticity index (PI) greater than 5 or a liquid limit (LL) greater than 25 will be compacted to not less than 90 percent of ASTM D 1557 maximum density. Fills composed of soil having a PI equal to or less than 5 and an LL equal to or less than 25 will be compacted as follows: the top 152 millimeters (6 inches) will be 100 percent of ASTM D 1557 maximum density; the remaining depth of fill will be 95 percent of ASTM D 1557 maximum density. Large fills on natural soil should be analyzed for bearing capacity and settlement using conventional soil mechanics.

b. Compacting Cut Sections. The top 152 millimeters (6 inches) of subgrades composed of soil having a PI greater than 5 or an LL greater than 25 will be compacted to not less than 90 percent of ASTM D 1557 maximum density. If the natural subgrade exhibits densities equal to or greater than 90 percent of other ASTM D 1557 maximum density, no compaction is necessary other than that required to provide a smooth surface. Soils having a PI equal to or less than 5 and an LL equal to or less than 25 will be compacted as follows: the top 152 millimeters (6 inches) will be 100 percent of ASTM D 1557 maximum density; the 455 millimeters (18 inches) below the top 152 millimeters (6 inches) will be 95 percent of ASTM D 1557 maximum density. Again, if the natural subgrade exhibits densities equal to or in excess of the specified densities, no compaction will be necessary other than that required to provide a smooth surface; in most cases, these densities can be obtained by surface rolling only.

c. Permissible Variations in Field Density. The above criteria should be considered as minimal values. Also, it is emphasized that it is often difficult to correlate field densities with those obtained by practical compaction procedures in the field. Higher densities should result in higher foundation strengths and thus thinner pavements which may offset the added cost of compaction. Experience has shown that the highest densities for all but the special cases (that is, soils that lose strength when remolded, become “quick” when remolded, or have expansive characteristics) result in lower permanent deformations, less susceptibility to pumping, and improved overall performance.

7. TREATMENT OF PROBLEM SOILS. Although compaction increases the strength of most soils, some soils decrease in stability when scarified, worked, and rolled. There are also some soils that shrink excessively during dry periods and expand excessively when allowed to absorb moisture. When these soils are encountered, special treatment is required. General descriptions of the soils in which these conditions may occur and suggested methods of treatment are outlined as follows:

a. Clays that Lose Strength When Remolded. These types of clays have a high strength in the undisturbed state. Scarifying, reworking, and rolling these soils in cut areas may produce a lower bearing value than that of the undisturbed soils. When such clay soils are encountered, bearing values should be obtained for both the undisturbed soil and the soil remolded and compacted to the design density at the design moisture content and adjusted to the future moisture content conditions. If the undisturbed value is the higher, no compaction should be attempted, and construction operations should be conducted to produce the least possible disturbance of the soil. Since compaction cannot be effected in these cases, the total thickness design above the subgrade may be governed by the required depth of compaction rather than the CBR requirements.

b. Soils that Become “Quick” When Molded. It is difficult to obtain the desired densities in these silts and very fine sands at moisture contents greater than optimum. Also, during compaction of the base, the water from a wet, spongy silt subgrade will often enter the subbase and base with detrimental effects. The bearing value of these silts and very fine sand is reasonably good if they can be compacted at the proper moisture content. Drying is not difficult if the source of water can be removed, since the soils are usually friable and can be scarified readily. If the soils can be dried, normal compaction requirements should be applied. However, removing the source of water is often very difficult and in some cases impossible in the allotted construction period. In cases of high water table, drying is usually not satisfactory until the water table is lowered, as recompacting operations will again cause water to be pumped to the surface. Local areas of this nature are usually treated satisfactorily by replacing the soil with subbase and base materials or with a dry soil that is not critical to water. There are cases where drainage is not feasible and a high water table cannot be lowered, or cases where such soils become saturated from sources other than high water table and cannot be dried out (as in necessary construction during wet seasons). In such cases, the subgrade should not be disturbed, and additional thickness of base and pavement should be used to ensure that the subgrade will not be overstressed or compacted during subsequent traffic by aircraft.

c. Soils with Expansive Characteristics. Soils with expansive characteristics, if highly compacted, will swell and produce uplift pressures of considerable intensity if the moisture content of the soil increases after compaction. This action may result in intolerable differential heaving of flexible pavements. Where the amount of swell is less than about 3 percent (as determined from soaked CBR test), special consideration will not normally be needed. However, where an airfield subgrade includes interspersed patches of soil with different swell characteristics, even amounts of swell less than 3 percent may require special consideration.

(1) Proper moisture content and density. A common method of treating a subgrade with expansive characteristics is to compact it at a moisture content and to a unit weight that will minimize expansion. The proper moisture content and unit weight for compaction control of a soil with marked expansion characteristics are seldom the optimum moisture content and unit weight determined by the compaction test. These factors may be determined from a study of the relations between moisture content, unit weight, percentage of swell, and CBR for a given soil. A combination of moisture, density,

CBR, and swell that will give the greatest CBR and density consistent with a tolerable amount of swell must be selected. The CBR and density values so selected are those that must be considered in the design of overlying layer thickness. Field control of the moisture content must be carefully exercised because if the soil is too dry when compacted, the expansion will increase; and if it is too wet, low unit weight will be obtained and the soil will shrink during a dry period and then expand during a wet period. This method requires detailed testing and extensive field control of compaction.

(2) Overburden load. In order to limit swell of expansive soils, it may be desirable to provide overburden if expansion cannot be limited by other procedures to acceptable amounts. Special swell tests normally will be needed to determine the amount of weight (overburden) necessary to restrict the swell to tolerable magnitudes. These tests can be variations of the standard soaked CBR test described in CRD-C 656, or they can be specially designed tests using a consolidometer apparatus.

(3) Special solutions. Special solutions to the problem of swelling soils are sometimes possible and should not be overlooked where pertinent. For instance, where climate is suitable, it may be possible to place a permeable layer (aquifer) over a swelling soil to maintain the swelling soil in a saturated condition. Moisture buildup in this layer maintains the soil in a stable, swelled condition. Designs must, of course, be based on the swelled CBR and density values of such a material when so treated. Other possible solutions are treatment with lime (TM 5-822-14/AFJMAN 32-1019), replacement of the swelling soil, or working the soil to make it more uniform.

d. Design Considerations for Special Cases. Whenever subgrades are given special treatments that cause their resulting strength or their resulting density to be less than when normally treated, these lesser values must be considered in design of the overlying layers. When a low CBR results, sufficient thickness of overlying structure must be provided to protect a subgrade of such low strength. When a low density results, the thickness of overlying material must be such that the density versus depth requirements of the specifications are met.

8. STABILIZED SUBGRADES. Subgrades can be stabilized by the addition of lime, cement, or a combination of these materials with flyash. Design of pavements using stabilized soils is discussed in Chapter 9 of this document and in TM 5-822-14/AFJMAN 32-1019. Lime should not be used with soils containing sulfates.

9. SUBGRADES IN FROST AREAS. In areas where frost susceptible subgrade soils will be subjected to cycles of freeze-thaw, pavements must be designed in accordance with the requirements of Chapter 20.

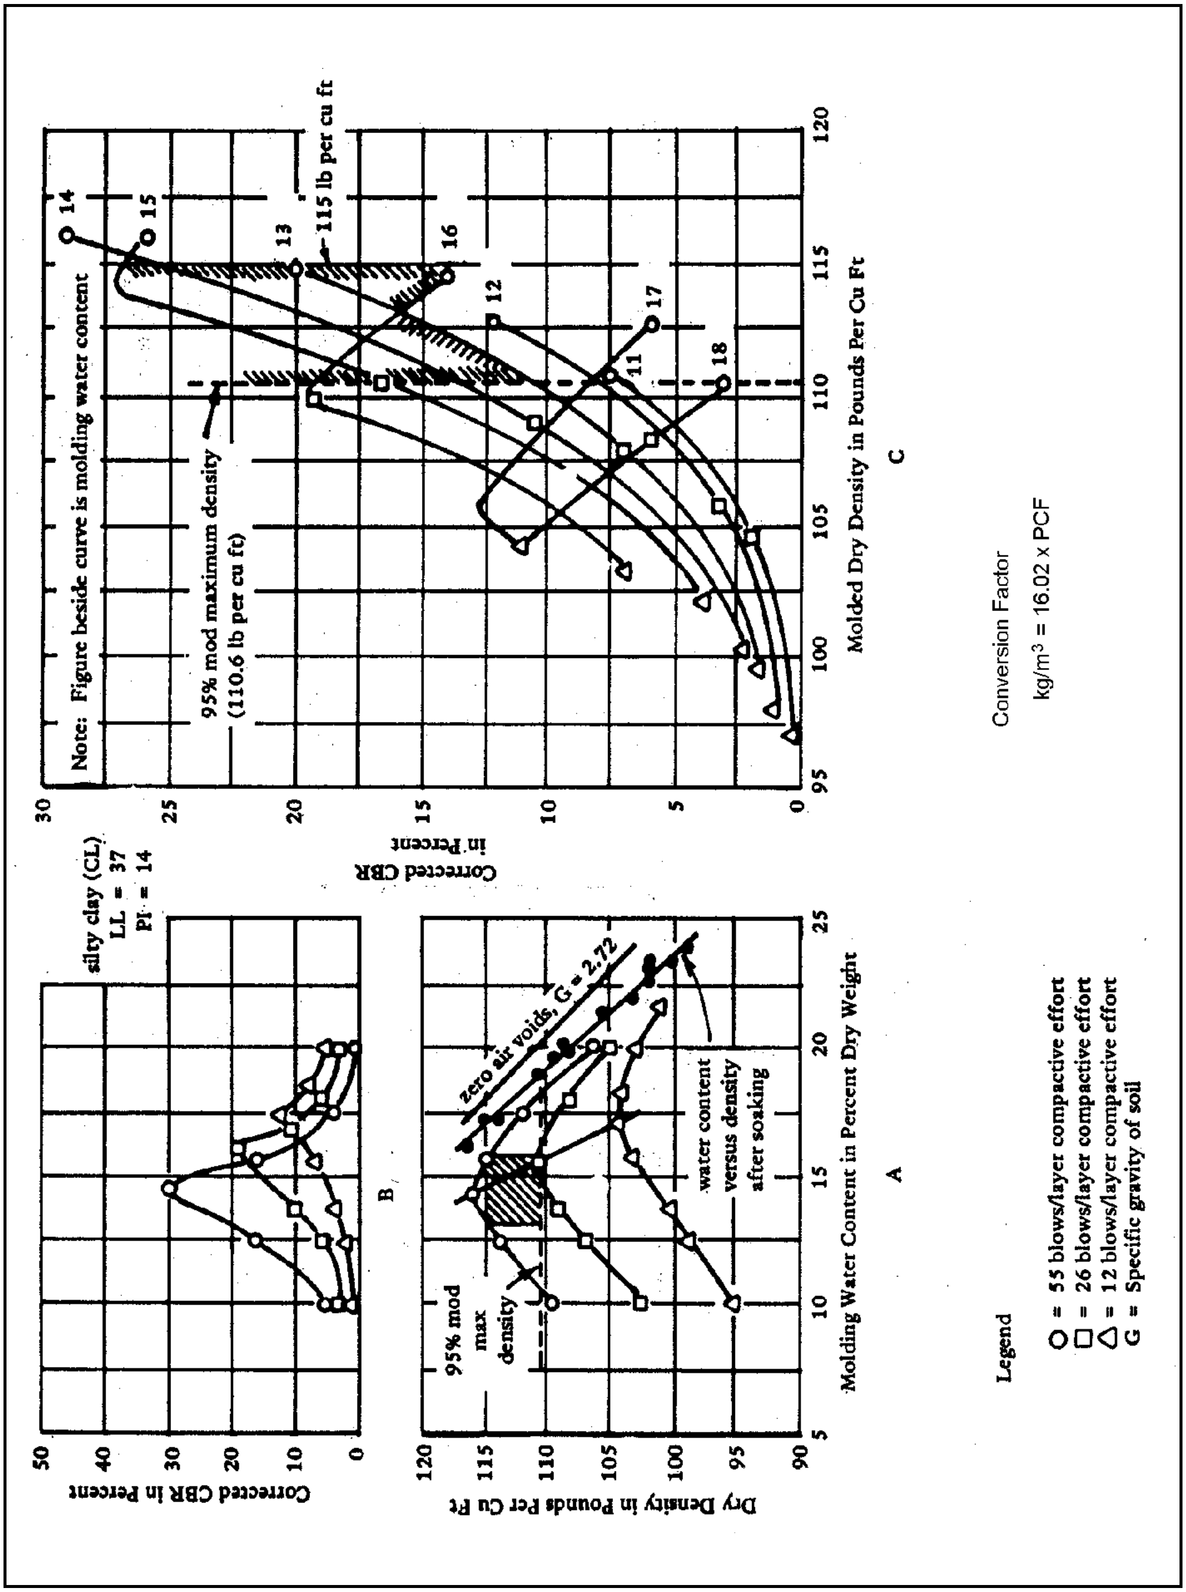

Figure 6-1. Procedure for determining laboratory CBR of subgrade soils

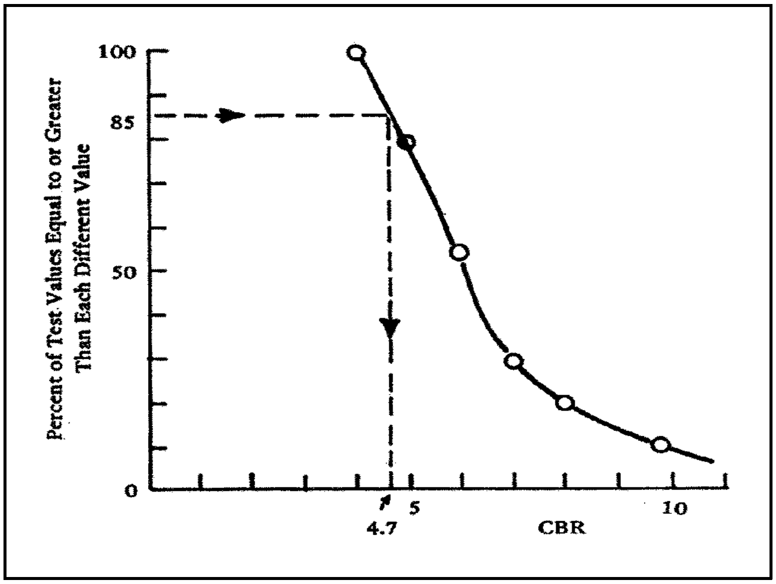

Figure 6-2. Selection of design subgrade CBR using in-place tests

CHAPTER 7

SELECT MATERIALS AND SUBBASE COURSES FOR FLEXIBLE PAVEMENTS

1.GEN ERAL. It is common practice in flexible pavement design to use locally available or other readily available materials between the subgrade and base course for economy. The Navy and Marine Corps designate these layers as subbases and require a minimum CBR of 30. The Army and Air Force refer to these layers as subbases when the design CBR is above 20 and as select materials subbase when the CBR is 20 or less. Minimum thicknesses of pavement and base have been established to eliminate the need for subbases with design CBR values above 50. Guide specifications have been prepared for select materials and subbases. Where the design CBR value of the subgrade without processing is in the range of 20 to 50, select materials and subbases may not be needed. However, the subgrade cannot be assigned design CBR values above 20 unless it meets the gradation and plasticity requirements for subbases. In some cases, where subgrade materials meet plasticity requirements but are deficient in grading requirements, it may be possible to treat an existing subgrade by blending in stone, limerock, sand, etc., to produce an acceptable subbase. However, “blending in” cohesionless materials to lower the plasticity index will not be allowed.

2.MAT ERIALS. The investigations described in Chapter 5 will be used to determine the location and characteristics of suitable soils for select material and subbase construction. Limerock, coral, shell, blast furnace slags (steel slag is not suitable), cinders, caliche, recycled concrete and asphalt, and other such materials in addition to gravels and rock should be considered when they are economical and when they meet the requirements of paragraph 4 entitled SELECTION OF DESIGN CBR. Do not use material which has a swell of 3 percent or greater, as determined from the CBR mold, for subbase. These materials will meet the LA Abrasion requirements of not more than 50 percent..

a. Select Materials. Select materials will normally be locally available coarse-grained soils. Recommended gradation and plasticity requirements for select materials are listed in paragraph 4 entitled SELECTION OF DESIGN CBR.

b. Subbase Materials. Subbase materials may consist of naturally occurring coarse-grained soils or blended and processed soils. Gradation and plasticity requirements for subbases are listed in paragraph 4 entitled SELECTION OF DESIGN CBR. The existing subgrade may meet the requirements for a subbase course or it may be possible to treat the existing subgrade to produce a subbase. Also, admixing native or processed materials will be done only when the unmixed subgrade meets the liquid limit and plasticity index requirements for subbases because it has been found that “cutting” plasticity in this way is not satisfactory. However, it may be permissible to decrease the plasticity of some materials by using lime or portland cement in sufficient amounts to meet the plasticity requirements of subbases. In order to be considered stabilized for thickness design purposes, the soil must meet the minimum strength requirements as shown in Table 7-1.

3.CO MPACTION REQUIREMENTS. Subbases will be compacted to 100 percent of maximum density as determined by ASTM D 1557. Select materials will be compacted to the densities shown in Tables 6-2 to 6-7, except that cohesionless select materials will be placed at no less than 95 percent and cohesive select materials at no less than 90 percent of ASTM D 1557 maximum density.

4.SELECT ION OF DESIGN CBR. The select material or subbase will generally be uniform, and the problem of selecting a limiting condition, as described for the subgrade, does not ordinarily exist. Tests

Table 7-1
Minimum Unconfined Compressive Strength for Cement, Lime, Lime-Cement, and Lime-Cement-Fly Ash Stabilized Soils

	Minimum Unconfined Compressive Strength, psi[1]	
Stabilized Soil Layer	Flexible Pavement	Rigid Pavement
Base course	750	500
Subbase course, select material or subgrade	250	200

[1] Unconfined compressive strength determined at 7 days for cement stabilization and 28 days for lime, lime fly ash, or lime-cement-fly ash stabilization.

are usually made on soaked remolded samples; however, where existing similar construction is available, CBR tests should be made in-place on material when it has attained its maximum expected water content or on undisturbed soaked samples. The procedures for selecting test values described for subgrades apply to select materials and subbases. Experience has shown that CBR tests on gravelly materials in the laboratory have tended to give CBR values higher than those obtained in tests in the field. The difference is attributed to the processing necessary to test the sample in the 152-millimeter (6-inch) mold, and to the confining effect of the mold. Therefore, the CBR test is supplemented by gradation and Atterberg limits requirements for subbases, as shown in Table 7-2. Suggested limits for select materials are also indicated. In addition to these requirements, the laboratory CBR must be equal to or higher than the CBR assigned to the material for design purposes.

Table 7-2
Gradation and Atterberg Limit Requirements for Subbases and Select Materials

			Maximum Permissible Value[1]			
	Maximum[1]		Gradation Requirements Percent Passing			
Material	Design CBR	Size, mm (in.)	2.0 mm (No. 10)	.075 mm (No. 200)	LL	PI
Subbase	50	75 (3)	50	15	25	5
Subbase	40	75 (3)	80	15	25	5
Subbase	30	75 (3)	100	15	25	5
Select material	20	75 (3)[2]	--	25[2]	35[2]	12[2]

Note: LL signifies liquid limit; PI signifies plasticity index.
[1] EI 02C202/AFJMAN 32-1016 contains maximum values for open graded and rapid draining materials.
[2] Suggested limits.

a. Navy Minimum Subbase CBR. On Navy airfield pavements, material with a minimum CBR of 30 should be used in the upper 152 millimeters (6 inches) of the subbase.

b. Exceptions to Gradation Requirements. Cases may occur in which certain natural materials that do not meet the gradation requirements may develop satisfactory CBR values in the field. Exceptions to the gradation requirements are permissible when supported by adequate in-place CBR tests on construction that has been in service for several years.

c. Example. As an example of the selection of a design CBR for subbases or select materials, consider the following material.

Soaked laboratory CBR = 40
Maximum size, millimeters (inches) = 50 (2.0)
Percent passing 2.0 millimeters (No. 10) = 85
Percent passing 0.075 millimeters (No. 200) = 14
Liquid limit = 12
Plasticity index = 3

The design CBR for this material would be 30 rather than the measured value of 40 because 80 percent passing the 2.0 millimeters (No. 10) sieve is the maximum permitted for higher CBR values and this material has 85 percent passing.

5. SEPARATION LAYERS. The gradation requirements shown in paragraph 4 are the maximum allowable limits. The designers can and should include additional gradation requirements to ensure that this material will meet the requirements for a separation layer as described in EI02C202/AFJMAN 32-1016. These additional gradations are dependent on the base course or drainage layer gradations and the gradations of the existing subgrade material; therefore, the designer should tailor these changes for each project.

6. STABILIZED SELECT MATERIALS AND SUBBASES. The design of pavements using stabilized soils is discussed in Chapter 9 of this document and in TM 5-822-14/AFJMAN 32-1019.

7. DESIGN FOR SEASONAL FROST CONDITIONS. In areas where the pavement will be subject to cycles of freezing and thawing, Army and Air Force pavements will be designed in accordance with the requirements in Chapter 9.

8. DRAINAGE LAYERS. The requirements for drainage layers used for subbase are presented in EI 02C202/AFJMAN 32-1016 and NAVFAC DM 21.06. For pavements in nonfrost areas and having a subgrade with a permeability greater than 20 feet/day, one can assume that the vertical drainage will be sufficient such that no drainage layer is required. Also, flexible pavements in nonfrost areas with a total thickness of 8 inches or less are not required to have a drainage layer. For pavements requiring drainage layers, the design of the drainage layer shall be based on the premise that the capacity of the drainage layer should be greater than the volume of water entering the pavement and that the drainage layer, if saturated, should reach a degree of drainage of 0.85 within 1 day after the inflow of water stops. The degree of drainage for the drainage layer is defined as the volume of water that has drained from the layer over a specified time period divided by the total volume of water in the layer that can be drained by gravity.

CHAPTER 8

AGGREGATE BASE COURSES

1. USE OF AGGREGATE BASE COURSES. Aggregate base courses may be required for one or more of the following reasons: distribution of load, provide drainage, protect from frost, provide uniform bearing surface for the pavement surfacing, replace unsuitable soils, provide working platform, increase strength of pavement system or prevent pumping.

2. MATERIALS FOR AGGREGATE BASE COURSES IN FLEXIBLE PAVEMENTS. Aggregate base-course materials for flexible pavement must be of high quality and conform to agency guide specifications. Since natural cementation of the materials listed in subparagraphs c, d, e, f, and g occurs progressively in place, there is a potential that the strength of these materials will increase with time, resulting in higher CBR values than laboratory tests indicate. Special requirements for aggregate base courses in frost areas are discussed in Chapter 20. Aggregate base courses used as drainage layers must meet the requirements of EI 02C202/AFJMAN 32-1016. Those materials generally used as aggregate base-course materials are listed below:

a. Graded Crushed Aggregate Base Course--100 CBR. Stone is quarried from formations of granite, traprock, and limestone. Gravel is quarried from deposits of river or glacial origin. The stone and gravel are crushed and screened to produce a dense-graded crushed aggregate material meeting requirements of guide specifications. The percentage of loss shall not exceed 40 when tested in accordance with ASTM C-131. The material shall also meet the requirements listed in CEGS 02722 for flat and elongated particles, liquid limit and plasticity index, and magnesium sulfate soundness when tested in accordance with ASTM C 88. Gradation requirements for graded crushed aggregates are as follows:

Table 8-1
Gradation Requirements for Graded Crushed Aggregates, Base Courses, and Aggregate Base Courses

	Percentage by Weight Passing Square-Mesh Sieve		
Sieve Designation	No. 1	No. 2	No. 3
50-mm (2-in.)	100	--	--
37.5-mm (1-1/2-in.)	70-100	100	--
25-mm (1-in.)	45-80	60-100	100
12.5-mm (1/2-in.)	30-60	30-65	40-70
4.75-mm (No. 4)	20-50	20-50	20-50
2.0-mm (No. 10)	15-40	15-40	15-40
0.425-mm (No. 40)	5-25	5-25	5-25
0.075-mm (No. 200)	0-8	0-8	0-8

b. Aggregate Base Course--80 CBR. This material is a blend of crushed and natural materials processed to provide a dense graded mix (often referred to as mechanically stabilized base course).

The percentage of loss shall not exceed 50 when tested in accordance with ASTM C-131. The material shall also meet the requirements listed in CEGS 02722 for flat and elongated particles, liquid limit and plasticity index, and magnesium sulfate soundness when tested in accordance with ASTM C 88. The gradation requirements are the same as for the 100 CBR material, but fractured faces relaxed to 50 percent.

c. Blast Furnace Slag. Slag is a by-product of steel manufacturing. It is air cooled, crushed, and graded to produce a dense mix. Fines from other sources may be used for blending. Requirements for a graded crushed aggregate apply. Only blast furnace slag will be used. Minimum required unit weight of slag is 1,200 kg/m^3 (75 lb/ft^3).

d. Shell Sand. Shell sand consists of oyster and clam shells that have been crushed, screened, and blended with sand filler. Ratio of the blend shall be not less than 67 percent shell to 33 percent sand. Refer to local specifications where available.

e. Coral. Coral consists of hard cemented deposits of skeletal origin. Coralline limestone quarried from inland deposits and designated quarry coral is the most structurally sound of the various coral materials available. Other types useful for base materials are reef coral and bank run coral. Quarry coral is crushed and graded to a dense mix. The following gradation is recommended:

Sieve Designation	**Percent Passing**
50-mm (2-in.)	100
37.5-mm (1-1/2-in.)	70-100
19-mm (3/4-in.)	40-90
4.75-mm (No. 4)	25-60
0.425-mm (No. 40)	5-20
0.075-mm (No. 200)	0-10

The percentage of wear (ASTM C-131) is not to exceed 50.

f. Limerock. Limerock is a fossiliferous limestone of the oolitic type generally located in Florida.

g. Shell Rock. Shell rock or marine limestone are deposits of hard cemented shells located in North Carolina and South Carolina. Refer to local guide specifications where available. Percentage of loss should not exceed 50 when tested in accordance with ASTM C-131..

h. Stabilized Materials. Stabilized materials consist of granular materials that have been improved by the addition of cement, lime, bitumen, or a combination of those additives with flyash. See Chapter 9 for a discussion of stabilization.

i. Crushed Recycled Concrete. Crushed recycled concrete shall consist of previously hardened portland cement concrete or other concrete containing pozzolanic binder material. The recycled material shall be free of all reinforcing steel, bituminous concrete surfacing, and any other foreign material and shall be crushed and processed to meet the required gradations for coarse aggregate. Crushed recycled concrete shall meet all other applicable requirements specified below. Recycled concrete to be exposed to sulfates in the ground or water must be checked for sulfate resistance. Contact MAJCOM for guidance.

3. AGGREGATE BASE COURSES FOR ARMY AND AIR FORCE RIGID PAVEMENT.

a. General. Drainage layers generally serve as aggregate base courses under rigid pavements and must meet the requirements of EI 02C202/AFJMAN 32-1016. A minimum aggregate base-course thickness of 102 millimeters (4 inches) will be required over subgrades that are classified as CH, CL, MH, ML, and OL (ASTM D 2487) for protection against pumping except in arid climates where experience has shown that there is no need for the aggregate base course to prevent pumping. In certain cases of adverse moisture conditions (high water table or poor drainage), SM and SC soils may also require aggregate base courses to prevent pumping. Engineering judgment must be exercised in the design of aggregate base-course drainage to ensure that water is not trapped directly beneath the pavement, which invites the pumping condition that the base course is intended to prevent. In addition, aggregate base courses in inlay sections should be constructed to drain toward the outside edge. Daylighting of the aggregate base course may also be required. Care must also be exercised when selecting aggregate base-course materials to be used with slipform construction of the pavement. Generally, slipform pavers will operate satisfactorily on materials meeting aggregate base-course requirements. However, cohesionless sands, rounded aggregates, etc., may not provide sufficient stability for slipform operation and should be avoided if slipform paving is to be a construction option. The designer should consider extending the aggregate base course 1.5 to 3.0 meters (5 to 10 feet) outside the edge of the pavement to provide a working platform for construction equipment.

b. Material Requirements. A complete investigation will be made to determine the source, quantity, and characteristics of available materials. The aggregate base course may consist of natural materials or processed materials, as discussed for flexible pavements. In general, the unbound aggregate base material will be a well-graded, high-stability material. All aggregate base courses to be placed beneath airfield rigid pavements will conform to the following requirements in addition to those requirements in base course guide specifications (sieve designations are in accordance with American Society for Testing and Materials (ASTM E 11):

- Well-graded, coarse to fine.
- Not more than 85 percent passing the 2.0-millimeter (No. 10) sieve.
- Not more than 15 percent passing the 0.075-millimeter (No. 200) sieve.
- PI not more than 8 percent.

However, when it is necessary for the base course to provide drainage, the requirements set forth in EI 02C202/AFJMAN 32-1016 will be followed.

4. AGGREGATE BASE COURSES FOR NAVY AND MARINE CORPS RIGID PAVEMENTS.

a. General. The main structural support element in a rigid pavement is the portland cement concrete slab. The most important function of the aggregate base-course material in a rigid pavement is to provide uniform long-term support to the slab with adequate drainage to prevent pumping and loss of support. The aggregate base course must be constructed of quality material and properly designed to ensure a good foundation. If pumping and loss of support occur, the performance of the concrete slab will be reduced.

b. Material Requirements. Suitable materials for aggregate base courses include natural, processed, manufactured, and stabilized materials which meet ASTM D 2940. These are the most common types of base course materials. Select local materials if possible, and consider local experience and practices when selecting a base material.

c. Gradation. To provide adequate drainage, the base course must contain little or no fines (material that passes the 0.075-millimeter (No. 200) sieve). Gradation requirements assure adequate stability and drainage by the base course under repeated loads. Crushed aggregates have greater stability than round-grained materials.

d. Wear Resistance. Aggregates suitable for base-course material must have the ability to withstand abrasion and/or crushing. Do not use soft aggregates for base course material because they may break down into fines which will inhibit drainage. Use the Los Angeles abrasion test (ASTM C 131) for determining aggregate abrasion resistance. Aggregates suitable for base course shall have a percentage loss in the Los Angeles abrasion test less than or equal to 40 percent.

e. Lean Concrete Bases. Lean concrete mixtures may be used as base material to provide increased support and reduce pumping. They may also be more economical than stabilized bases. Lean concrete refers to a mixture composed of low-cost, locally available aggregates that may not meet specifications for normal concrete mixtures and an amount of portland cement that is usually less than for normal concrete mixtures. Local aggregates, substandard aggregates, and recycled materials may all be used in lean concrete mixtures for base materials. When properly designed, these materials can provide a strong and erosion-resistant base.

(1) Material specifications and gradation requirements for aggregates used in lean concrete mixtures are not as restrictive as those for aggregates used in normal concrete. Aggregate gradations should conform to one of the gradations given in Table 8-2. The aggregate materials should be free from any elongated or soft pieces and dirt. Mix design for lean concrete bases is discussed in Chapter 11.

Table 8-2
Gradations for Lean Concrete Base Materials

Sieve Size (square opening) mm (in.)	Percentage by Weight Passing Sieve		
	A	B	C
50 (2)	100	--	--
37.5 (1.5)	--	100	--
25 (1.0)	55-85	70-95	100
19 (0.75)	50-80	55-85	70-100
4.75 (No. 4)	30-60	30-60	35-65
0.425 (No. 40)	10-30	10-30	15-30
0.075 (No. 200)	0-15	0-15	0-15

(2) Any bond between the lean concrete base and the concrete slab to be placed on top must be prevented to retard reflective cracking. A bond breaking material such as a wax-based curing compound should be placed on top of all lean concrete base courses.

f. Recycled Concrete Bases. Recycled portland cement concrete can serve as an aggregate for use in a granular base course or in recycled concrete base. The concrete must be properly crushed and sized to meet gradation requirements.

g. Geotextile Fabrics. Geotextile fabrics may be considered for reinforcement of the subgrade to provide a working platform for base course construction and to separate the subgrade and base course to maintain the original base course gradation. See NAVFAC DM 7.01 and NAVFAC DM 21.06 for design criteria on geotextile fabrics. The use of geotextile fabric is encouraged to prevent loss of fines from the surrounding soil through subsurface utility lines.

5. STRENGTH OF AGGREGATE BASE COURSES FOR RIGID PAVEMENTS. The modulus of soil reaction k of the unbound base courses will be determined by field plate bearing tests performed on the surface of the compacted base course or by tests on the subgrade and from Figure 8-1. If both methods are used, the lower value obtained by the two methods will be used for the pavement design. A sufficient number of field plate bearing tests must be performed on the top of a finished base course to determine a realistic design K value. Consideration should be given to the variations in base-course thickness, types of materials, and the variation in subgrade strengths. Figure 8-1 yields an effective k value at the surface of the base course as a function of the subgrade k value and base-course thickness. These relationships have been generated by field testing. If the design k value is selected from Figure 8-1, it should be verified in the field. The maximum value for the modulus of soil reaction to be used in design is 135 KPa/mm (500 pci).

6. STRENGTH OF AGGREGATE BASE COURSES FOR FLEXIBLE PAVEMENTS. Because of the effects of processing samples for the laboratory CBR tests and because of the effects of the test mold, the laboratory CBR test will not be used in determining CBR values of base courses. Instead, selected CBR ratings will be assigned as shown in the following tabulation. These ratings have been based on service behavior records and, where pertinent, on in-place tests made on materials that have been subjected to traffic. It is imperative that the materials conform to the quality requirements given in the guide specifications so that they will develop the needed strengths.

Aggregate Base Course	**Design CBR**
Graded Crushed Aggregate	100[1]
Aggregate[2]	80
Limerock	80
Shell Sand	80
Coral	80
Shell Rock	80

Note: See Chapter 6 for open-graded and rapid-draining material requirements
[1] Limited to 80 CBR for Navy and Marine Corps.
[2] Formerly mechanically stabilized aggregate.

7. MINIMUM THICKNESS REQUIREMENTS FOR FLEXIBLE PAVEMENTS. The minimum allowable thicknesses for aggregate base courses in flexible pavements are listed in Table 8-3 for Army airfields, Table 8-4 for Navy and Marine Corps airfields, and Table 8-5 for Air Force airfields. These thicknesses have been established so that the required subbase CBR will always be 50 or less.

Table 8-3
Minimum Surface and Aggregate Base-Course Thickness Requirements for Army Flexible Pavement Airfields, Inches

		100 CBR Base			80 CBR Base[1]		
Airfield Heliport Class	Traffic Area	Surface	Base	Total	Surface	Base	Total

	C	3	6	9	3	6	9
	Shoulders	2	6	8	2	6	8

Note: When the underlying subbase has a design CBR of 80, the minimum base-course thickness will be 6 inches.
[1] Restricted to Florida limerock for heavy load pavements and modified heavy load pavements except that graded crushed aggregate (80 CBR) or cement modified or bituminous modified aggregate will be permitted in type D traffic areas.
[2] Florida limerock or graded crushed aggregate (80 CBR) cement modified or bituminous modified aggregates permitted in type B, C, and D traffic areas for medium load pavements.
[3] Florida limerock or graded crushed aggregate (80 CBR), cement modified or bituminous modified permitted for light load, shortfield, and auxiliary pavements.
Conversion Factor: Millimeters = 25.4 × inches.

8. MINIMUM THICKNESS REQUIREMENTS FOR RIGID PAVEMENTS.

a. Army and Air Force. The minimum thickness of aggregate base course under rigid pavements will be 100 millimeters (4.0 inches) over CH, CL, MH, ML, and OH subgrades or that required to meet minimum thicknesses for drainage layers as shown in EI 02C202/AFJMAN 32-1016.

b. Navy and Marine Corps. The minimum thickness requirements for aggregate base courses are listed in Table 8-6. The minimum thickness for granular materials is set for construction purposes. The additional base thickness required over clays and silts is to aid in preventing pumping. Consider experience with local aggregates and materials when selecting the base course thickness.

Table 8-6
Aggregate Base-Course Minimum Thickness Requirements for Navy and Marine Corps Rigid Pavements

Base Material	Minimum Thickness
Granular Material	152 mm (6 in.)
Cement Stabilized	152 mm (6 in.)
Asphalt Stabilized	152 mm (6 in.)
Asphalt Concrete	102 mm (4 in.)
Lean Concrete Mixture	102 mm (4 in.)

Note: For subgrades classified as CH, CL, MH, ML, or OL, the minimum granular base-course thickness shall be 203 mm (8 in.).

9. COMPACTION AND PROOF ROLLING REQUIREMENTS FOR FLEXIBLE PAVEMENTS. The aggregate base course will be compacted to 100 percent of ASTM D 1557 maximum density. In addition to compacting the base course to the required density, proof rolling shall be performed on the surface of completed aggregate base courses as designated below. Open-graded and rapid-draining layers will not be proof rolled. The layer immediately under lying the open-graded or rapid-draining layer shall be proof rolled instead. The proof roller will consist of a heavy rubber-tired roller having four tires, each loaded to 13,608 kilograms (30,000 pounds) and inflated to 720 kPa (125 psi). Repetitions of the proof roller are expressed as coverages where a coverage is the application of one tire print over each point on the surface of the designated area. TM 5-820-2/AFJMAN 32-1016 presents special proof rolling and compaction requirements for drainage layers.

a. Air Force Bases. Proof roll top of subbase and each layer of base course of type A traffic areas and the center 23 meters (75 feet) of heavy, modified heavy, and medium load runways with 30 coverages.

b. Navy and Marine Corps Airfields. Proof roll top of completed aggregate base course on center 12 meters (40 feet) of taxiways and on center 30.5 meters (100 feet) of runways with eight coverages. To all other paved areas exclusive of runway overrun and blast protection areas, apply four coverages.

c. Army Airfields. On Class IV airfields with runways greater than 1,525 meters (5,000 feet), proof roll top of subbase and each layer of crushed aggregate base course in type A traffic areas and center 23 meters (75 feet) of runways with 30 coverages.

10. COMPACTION REQUIREMENTS FOR ARMY AND AIR FORCE RIGID PAVEMENT AGGREGATE BASE COURSES. High densities are essential to keep future consolidation to a minimum, but thin aggregate base courses placed on yielding subgrades are difficult to compact to high densities. Therefore, the design density in the aggregate base-course materials should be the maximum that can be obtained by practical compaction procedures in the field but not less than:

a. 95 percent of ASTM D 1557 maximum density for aggregate base courses less than 254 millimeters (10 inches) thick.

b. 100 percent of ASTM D 1557 maximum density in the top 152 millimeters (6 inches) and 95 percent of ASTM D 1557 maximum density for the remaining thickness for aggregate base courses 254 millimeters (10 inches) or more in thickness.

11. COMPACTION REQUIREMENTS FOR NAVY AND MARINE CORPS RIGID PAVEMENT AGGREGATE BASE COURSES. Compact granular and cement-treated base courses to 100 percent of maximum density according to ASTM D 1557 and D 558, respectively. Compact asphaltic concrete base courses to 97 percent of the maximum density as determined from the Marshall mix design method.

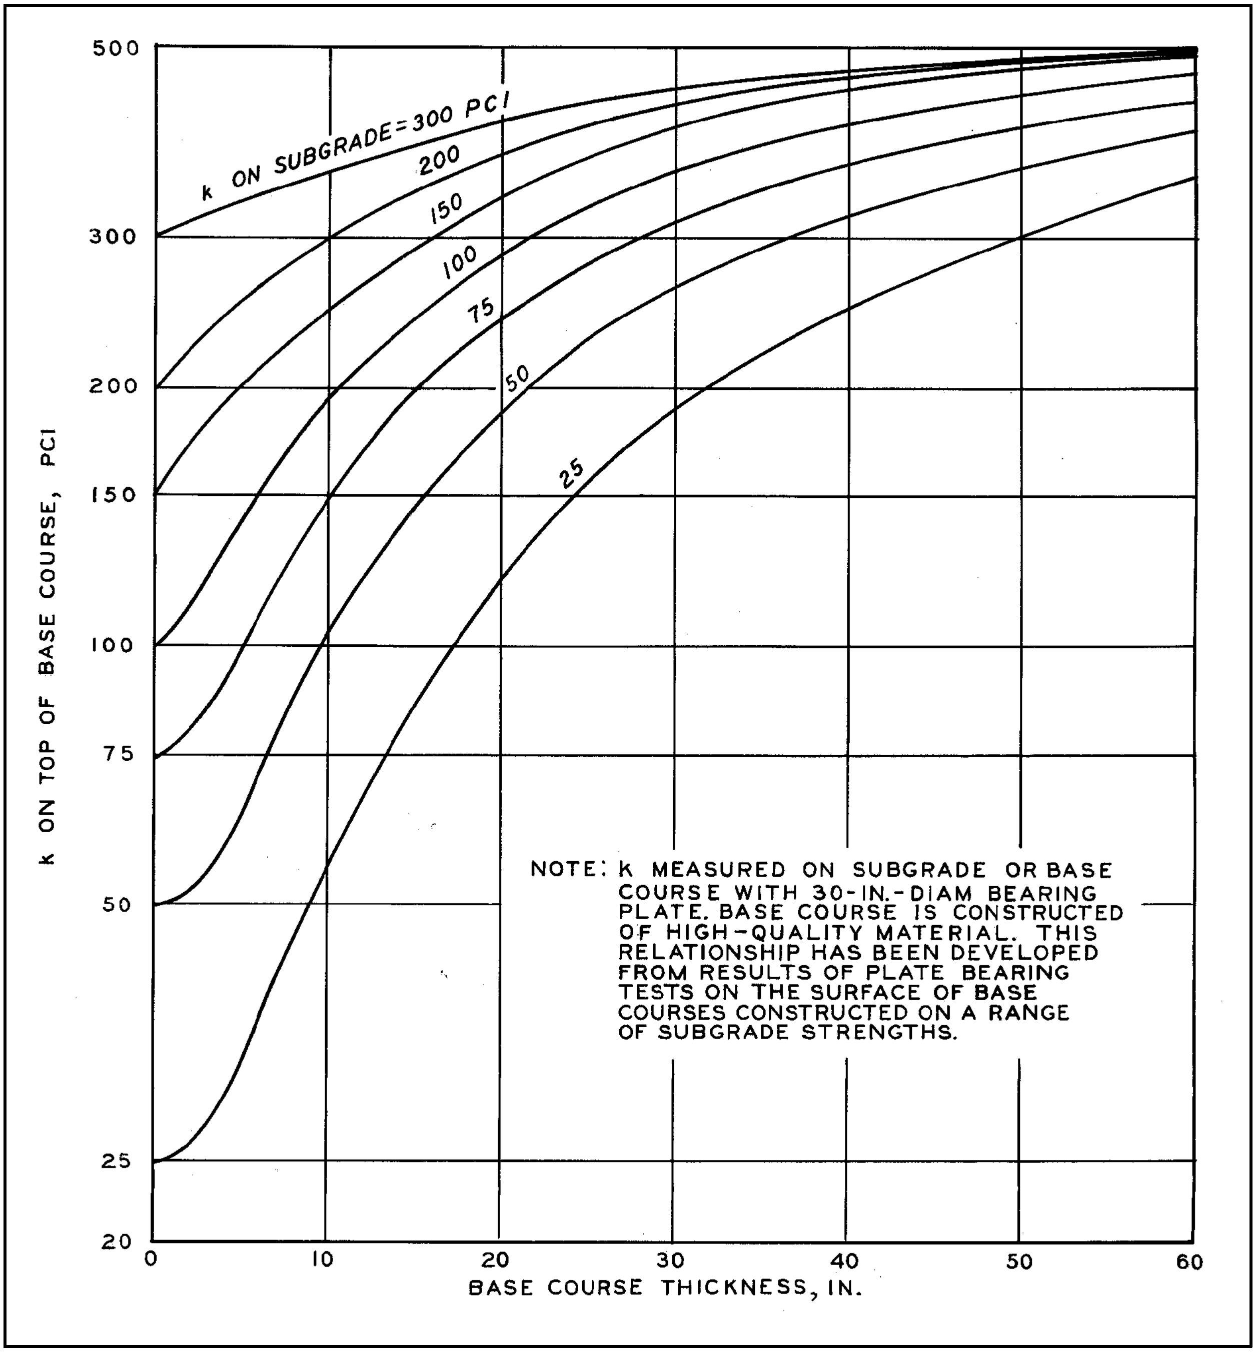

Figure 8-1. Effect of base-course thickness on modulus of soil reaction for nonfrost conditions

CHAPTER 9

PAVEMENT MATERIALS

1. GENERAL. This chapter provides the designer an overview of pavement materials that might be used in military airfield pavements. This overview will include soil and aggregate stabilization, asphaltic concrete, portland cement concrete, and recycled materials. More comprehensive and detailed descriptions, policy, and guidance on uses and limitations, testing requirements, suitable materials, mixture proportioning, and construction can be found in TM 5-822-14/AFJMAN 32-1019 for stabilization, TI 822-08/AFMAN 32-1131 V8(1)/DM 21.11 for asphalt concrete, and TM 5-822-7/AFM 88-6, Chapter 8, for portland cement concrete. In addition, each service also maintains recommended guide specifications for these materials that the engineer can edit for specific jobs. Materials technology evolves constantly, and new guidance on pavements materials is available from HQUSACE (CEMP-ET), appropriate Air Force MAJCOM pavements engineer, or Naval Facilities Engineering Service Center as changes develop. This chapter is a short overview to aid the designer during the design process, and the more comprehensive guidance documents noted above should be consulted concerning each service's specific limitations and requirements for these materials and for preparing individual project specifications.

2. STABILIZATION. . Existing soils or aggregates may not be suitable for use in airfield construction (e.g., poor grading, low strength, or excessive plasticity) or may have other undesirable characteristics (e.g., tendency to shrink or swell with moisture content changes). By stabilizing such materials with appropriate additives, their engineering and construction properties can be improved. Lime, portland cement, and asphalt are the most common stabilizers, but pozzolans (notably fly ash), ground granulated blast furnace slag, and a wide variety of proprietary materials are also available. TM 5-822-14/AFJMAN 32-1019 provides official guidance on use of lime, portland cement, lime-fly ash, and bituminous materials for stabilization. HQUSACE (CEMP-ET), appropriate Air Force MAJCOM pavements engineer, or Naval Facilities Engineering Service Center should be consulted for assistance on use of other stabilizers and conditions not covered in the existing guidance.

a. Purpose. Stabilization is most commonly associated with achieving strength to reduce pavement thickness requirements. However, other equally important and perhaps even more important uses of stabilization include improvement in soil workability, prevention of pumping in rigid pavements, mitigation of adverse volume changes in expansive soils, providing a construction platform to ease and speed construction operations, reduction of effects of adverse weather during construction, and allowing use of an economical local material that fails conventional specifications in lieu of importing more expensive materials from elsewhere.

b. Requirements. Subsequent chapters in this manual provide detailed guidance on how to incorporate stabilized materials in each of the different thickness design methods for flexible and rigid pavements. To qualify for a reduced thickness in these design methods, the stabilized material must achieve a compressive strength of not less than 5.17 MPa (750 psi) for base courses in flexible pavements, 3.45 MPa (500) psi for base courses in rigid pavements, and 1.72 MPa (250) psi for flexible pavement subbases for the Army and Air Force or 1.03 MPa (150 psi) for subbases for the Navy. These strengths are determined after 7 days of curing at 22.8 °C (73 °F) for portland cement and after 28 days of curing at 22.8 °C (73 °F) for lime, slag, and combinations with pozzolanic materials (e.g., lime-fly ash mixtures). In addition to strength, there are specific requirements for durability and material properties that must also be met. Even if a material fails to qualify for the reduced pavement thickness requirements, stabilization may prove desirable for some of the other reasons noted above. If stabilization results in granular layers sandwiched between relatively impervious layers (e.g., granular base course between an asphalt concrete surface and a stabilized subbase), then this pervious intermediate layer should be positively drained. Because of the potential for poor performance of such geometries, such designs must be approved before use by HQUSACE (CEMP-ET), appropriate Air Force MAJCOM pavements engineer, or Naval Facilities Engineering Service Center.

c. Terminology. The term "*stabilization*" as used in this chapter will encompass the addition of any materials to a soil or aggregate to improve its strength or physical characteristics for use as pavement subgrade, fill, subbase, or base course. As employed here, the term will include combinations with common additives such as lime and portland cement or lime-portland cement-fly ash as well as those materials often referred to as *soil-cement, lean concrete base*, *econocrete*, etc. TM 5-822-14/AFJMAN 32-1019 differentiates between soil stabilization and soil modification where the later only results in an improvement in some property but does not by design cause a significant increase in strength. This level of differentiation is not needed for the generalized discussion of the topic in this chapter, so *stabilization* is used here as an all-inclusive term.

d. Seasonal Frost Areas. Use of stabilized materials in areas subject to seasonal frost must address two extra concerns. First, the stabilized material must be durable for its intended purpose under the freezing and thawing exposure to which it will be exposed. Secondly, many stabilizers (e.g., portland cement or lime) must cure to gain strength, and the necessary chemical reactions to gain strength are greatly retarded and may cease altogether at low temperatures. Consequently, some stabilized materials placed late in the fall may not be able to gain adequate strength prior to the onset of freezing weather. Consequently, local climatic conditions will determine a cutoff date well in advance of anticipated freezing conditions after which date it is not prudent to place stabilized materials. Additional assistance on problems with stabilized materials under seasonal frost exposure is available from the Army Cold Regions Research and Engineering Laboratory, 72 Lyme Road, Hanover, NH 03755.

e. Combinations of Stabilizers. Under some circumstances, it may be desirable to use combinations of stabilizers to take advantage of each stabilizer's characteristics (e.g., use of a combination of lime and then portland cement relying on the lime to improve a plastic clay's workability and the portland cement for more rapid strength gain than available from the slower pozzolanic reactions of lime alone).

f. Mixing. The stabilizer and soil or aggregate to be stabilized may be mixed in situ or mixed at a central plant and then transported to the construction site and placed according to the project specifications. Proper mixing is crucial to stabilizers achieving their desired purpose. Central plants provide the best and most consistent product. In situ mixing may vary from repeated working with a grader to highly sophisticated mixers specifically designed for the task. It is harder to achieve good distribution and mixing of the stabilizer with in situ mixing techniques than with plant mixing. Consequently, stabilizer contents are sometimes increased ½ to 1 percent over the laboratory determined design stabilizer content to account for uncertainties of in situ mixing.

g. Compaction. Stabilized materials must be adequately compacted to achieve their desired purpose. Stabilization is not a substitute for compaction, and poorly compacted stabilized layers are prone to premature failure. Essentially, the compaction equipment and procedures and the quality-control techniques used with conventional earthwork are adequate for stabilized materials. Compaction equipment of sufficient size is needed, and lift thicknesses should be restricted to a maximum of 150 millimeters (6 inches) unless the contractor can demonstrate in the field that project specified density levels are achieved throughout the lift for thicker placements. To check the latter, the density must be measured in the bottom of the lift and not just at the surface or as an average through the entire lift. Generally, stabilized layers used in subbase and base courses of military airfields should be compacted to 100 percent of the laboratory modified compaction-energy density. TM 5-822-14/AFJMAN 32-1019 provides more comprehensive guidance on requirements for laboratory compaction and testing procedures to be used with different stabilized materials. Addition of the stabilizer changes the laboratory compaction characteristics of the soil or aggregates, and the trends are not always predictable. For example, increasing the percent of portland cement used to stabilize a soil may either shift the laboratory compaction curve up and to the left (i.e., increase maximum density and decrease optimum moisture content) or down and to the right (i.e., decrease maximum density and increase optimum moisture content). On the other hand, increasing lime contents decrease the laboratory maximum density and increase the optimum moisture content for compaction. If field stabilizer contents are increased for in situ mixing as noted in the previous paragraph, this may affect the laboratory maximum density value that the contractor is required to meet in the field, and assessment of the contractor’s field compaction must take this into account. For instance, if the lime content is increased in the field over that used in the laboratory, the contractor may encounter problems achieving the specified density because the actual laboratory target density was decreased by the additional lime. When these complex soil-stabilizer interactions are combined with field variation from distribution and mixing of the stabilizer, fairly assessing the contractor’s compaction efforts may become difficult. In circumstances where stabilizer contents are being increased in the field, supplemental one-point compaction tests of the in situ stabilized materials may prove helpful for assessing compaction compliance. HQUSACE (CEMP-ET), appropriate Air Force MAJCOM pavements engineer, or the Naval Facilities Engineering Service Center may be consulted for assistance with difficult cases.

h. Curing. In the subsequent sections, curing requirements are identified for many stabilizers. It is crucial that this curing take place adequately for the stabilizer to achieve the desired results. Generally, this means that temperatures must be high enough for the desired chemical reactions to occur, and moisture must be maintained within the material and evaporation stopped or at least severely retarded. Inadequate curing can negate the benefits of stabilization.

i. Testing. Tight financial restraints on military construction today often discourage adequate testing. However, when working with stabilized materials, it is important to verify in the laboratory that the proposed stabilization scheme will achieve the desired results. For instance, it is not sufficient to simply select a suggested lime content for stabilizing a clay because the soils/clay mineralogy or the presence of organic or some iron compounds in the soil may totally change or inhibit the chemical reactions that occur. It is always prudent to perform sufficient laboratory work to verify that the percentages of stabilizer, stabilizer type, and actual soil or aggregate will achieve the desired results when they are mixed, compacted, and cured.

j. Lime Stabilization. Hydrated lime ($Ca(OH)_2$), quick lime (CaO), or the dolomitic variants of these limes are suitable for lime stabilization of soils. Requirements for the limes for soil stabilization are contained in ASTM C 977. Calcium carbonate ($CaCO_3$) is often sold under names such as agricultural lime and is not suitable for soil stabilization.

(1) Mechanisms. Several things happen when lime is added to a soil. As the lime hydrates, it dries the soil. Anhydrous quicklime is particularly effective for this. Some fine clay-sized soil particles agglomerate when lime is added to the soil which results in a decrease in the measured number of clay-sized soil particles. Essentially, a clayey soil fabric becomes siltier, and the soil is easier to work, dry, etc. Also, cation exchange occurs, and the calcium from the lime replaces sodium and potassium in clay minerals. This results in a reduction in plasticity of the soil. The above reactions (drying, particle agglomeration, and cation exchange) occur rapidly after the lime is added to the soil. With time, some, but not all, clays may undergo a further pozzolanic reaction with the lime and develop additional strength

from the resulting calcium silicate and calcium aluminate hydrate compounds. Soil compressive strength gain, after 28-day cures at 22.8 °C (73 °F) from the pozzolanic reaction between lime and some clay minerals may range from negligible to 10.34 MPa (1,500 psi). Typically, a well-compacted, reactive lime-stabilized soil will achieve compressive strengths in the range of 100 to 500 psi.

(2) Uses. Lime added to soil can rapidly dry the soil; it coarsens the particle texture which often makes the soil easier to work; and it reduces the soil's plasticity, making it more workable, generally reducing the soil's strength loss when it is wetted, and often reducing adverse shrinking and swelling behavior. The pozzolanic strength gain, which is typically assessed after 28 days of curing at 22.8 °C (73 °F), can significantly improve soil strength of subgrades and can often meet the strength requirements for a stabilized subbase for flexible pavements. The requirements for stabilized bases are harder to meet with lime alone, and the addition of cement with the lime may be needed to gain the required strength. Many characteristics of lime stabilization make it very useful as a construction expedient and soil improvement additive for difficult plastic clay soils (e.g., drying, coarser texture, reduced plasticity and water susceptibility, construction platform, reduced shrink-swell behavior) rather than for structural strength alone.

(3) Durability. Lime stabilization should provide sufficient durability to accomplish the required objectives under the anticipated exposure conditions.

(a) Moisture. Lime-stabilized soils generally retain over two-thirds of their strength when exposed to water and have performed well in structures exposed to water (e.g., levees, canals, and dams and as expedient (lime-stabilized clay surface) military airfields in Latin America). However, a few clays have shown poor strength retention when soaked in the laboratory. Consequently, some soaked strength tests or the optional wet-dry test (ASTM D 560) limits in TM 5-822-14/AFJMAN 32-1019 may be checked if strength when exposed to soaking or wetting and drying is a critical design parameter.

(b) Seasonal frost exposure. Lime-stabilized materials generally expand and lose strength when exposed to freezing and thawing. As cycles of freezing and thawing increase there is a progressive decrease in the strength of the lime-stabilized material. Generally, the first winter is the critical exposure as extended curing in subsequent seasons will provide additional strength, and there are data to suggest these materials may heal autogenously under favorable curing temperatures. TM 5-822-14/AFJMAN 32-1019 has specific testing criteria and limits based on ASTM D 560 that must be met if the lime-stabilized material is to be exposed to freezing and thawing. Because of the relatively slow rate of pozzolanic strength gain in lime stabilization, adequate time for curing must be allowed prior to the stabilized layer's being exposed to freezing. Consequently, the lime-stabilized material must be in place well in advance (e.g., perhaps 30 days) prior to the onset of freezing weather which shortens the construction season for some areas. Alternatively, it must be protected from freezing (e.g., by placement of overlying pavement layers), and the temperature maintained high enough to allow pozzolanic reactions to occur. Additional assistance on problems with lime-stabilized materials under seasonal frost exposure is available from the Army Cold Regions Research and Engineering Laboratory, 72 Lyme Road, Hanover, NH 03755.

(c) Leaching. There is some limited evidence that soils stabilized with low levels of lime may have the benefits of lime stabilization reduced by leaching over time. The problem appears to be relatively rare and generally associated with low levels of lime stabilization (e.g., 3 percent and less). In general, this should not be an issue for lime stabilization levels for airfield pavements as their strength and durability requirements would normally require lime contents above those where leaching has been a reported problem.

(d) Carbonation. Atmospheric carbon dioxide can react with lime to form calcium carbonate which can adversely affect lime-stabilization reactions. Proper and prompt mixing, storage, compaction, and curing procedures that minimize the exposure of the lime-stabilized soil to atmospheric carbon dioxide avoids the problem. Reported problems have been with highly weathered materials in Africa that were poorly compacted and cured.

(e) Sulfate attack. Lime-stabilized materials are susceptible to sulfate attack if sulfates are present in the soil or water in contact with the stabilized material or if they are present in materials that are being stabilized. The sulfate attack reactions are expansive and highly disruptive. Technical guidance on this problem is incomplete. If lime stabilization is contemplated where sulfates are present, the HQUSACE (CEMP-ET), appropriate Air Force MAJCOM pavements engineer, or Naval Facilities Engineering Service Center should be consulted for up-to-date guidance on this difficult issue.

(4) Suitable Soils. Clayey soils with a plasticity index of 12 or more are generally best suited for lime stabilization. Organic soils and clays containing some iron compounds do not respond well to lime stabilization, and some highly weathered soils may require a larger than expected dosage of lime stabilizer to be effective.

k. Portland-Cement Stabilization. Type I portland cement and, more rarely, Types II, I/II, and III meeting the requirements of ASTM C 150 may be mixed with soils or aggregates to provide a cohesive cemented material often referred to *as soil-cement, econocrete, lean concrete base*, etc.

(1) Mechanisms. When mixed with water, portland cement develops cementing compounds that bind the soil and aggregate particles together. Unlike lime, there is no necessary chemical reaction with the soil particles themselves. Portland cement contains free lime as one of its constituents so the same cation exchange and pozzolanic reactions with clayey soils will occur with portland cement, but these are minor effects compared with the dominant formation of the conventional portland-cement hydration compounds that serve to bind the particles together.

(2) Uses. Portland-cement stabilization can provide a material with compressive strengths from a few MPa (few hundred) to well over ten MPa (several thousand psi), depending on amount of stabilizer and soil properties. These higher-strength stabilized materials are often referred to as *econocrete, lean concrete*, etc. with cement contents in the range of 134 to 223 kg/m^3 (225 to 375 lb/yd^3). Such high cement content and high-quality stabilized mixes are usually proportioned and placed with the same techniques as conventional concrete. In general, cement stabilization of fine-grained soils provides a lower strength than cement stabilization of coarse-grained soils. The reactions of portland cement are faster than pozzolanic stabilizers such as lime. A major drawback for cement stabilization is the formation of shrinkage cracks which can reflect up through surfacing layers. This is usually a severe problem with cement-stabilized bases under asphaltic concrete surfaces, but it has also occurred with concrete surfaces placed directly on high-strength cement-stabilized layers. To minimize problems with reflective cracking, the Air Force limits the allowable content of portland cement in stabilized bases in flexible pavements to a 4-percent maximum. A double application of curing compound is often sprayed on cement-stabilized bases to reduce the chance of reflective cracking in overlying portland-cement concrete surfaces in rigid pavements. Portland-cement stabilization is most often used for a relatively high-strength layer that may provide a construction platform, an all-weather construction surface, or a significant structural layer within the pavement. It is also probably the most expensive of the common soil stabilizers. Materials stabilized with portland cement should be placed and compacted within 2 hours of the mix water coming into contact with the cement.

(3) Durability.

(a) Seasonal frost exposure. Cycles of freezing and thawing can damage cement-stabilized materials so TM 5-822-14/AFJMAN 32-1019 has specific testing criteria and limits based on ASTM D 560 that must be met if the cement-stabilized material is to be exposed to freezing and thawing. Adequate curing time in the field must also be available prior to the onset of freezing. Additional assistance on problems with cement-stabilized materials under seasonal frost exposure is available from the Army Cold Regions Research and Engineering Laboratory, 72 Lyme Road, Hanover, NH 03755.

(b) Carbonation. As with lime, atmospheric carbon dioxide can react with portland cement to form calcium carbonate which can adversely affect portland cement-stabilization reaction products. Proper and prompt mixing, compaction, and curing procedures that minimize the exposure of the stabilized soil to atmospheric carbon dioxide avoid the problem. Reported problems have been with highly weathered materials in Africa that were poorly compacted and cured.

(c) Sulfate attack. Cement-stabilized materials are susceptible to sulfate attack if sulfates are present in the soil or water in contact with the stabilized material or if sulfates are present in materials that are being stabilized. The sulfate attack reactions are expansive and highly disruptive. If the soils or aggregates being stabilized contain clay minerals, sulfate resistant cements (Type II and V) will not prevent sulfate attack. If cement-stabilization is contemplated where sulfates are present, the HQUSACE (CEMP-ET), appropriate Air Force MAJCOM pavements engineer, or Naval Facilities Engineering Service Center should be consulted for up-to-date guidance on this issue.

(4) Suitable Soils. The most economical materials for cement stabilization will generally be well-graded sandy gravels or gravelly sands with a spectrum of particle sizes. Fine materials, coarse materials, or poorly-graded materials will often require uneconomically high cement contents to achieve adequate stabilization. Sticky materials such as CH clays may be difficult or impossible to mix adequately with the cement stabilizer. Organic soils and some acidic sands respond poorly to cement stabilization.

l. Pozzolan and Slag Stabilization. ASTM C 618 classifies pozzolans as Type N (natural pozzolans), Type C (high-lime-content fly ash, a byproduct of burning lignite or subbituminous coal), or Type F (low-lime-content fly ash, a by product of burning bituminous or anthracite coal). These materials are not normally cementitious by themselves, but when combined with calcium hydroxide (lime), they will form cementitious, pozzolanic bonds. Granulated blast furnace slag is a by-product of iron production which can be ground to produce a slag cement. ASTM C 989 provides requirements and grade classifications for this material. Neither material has been used extensively as a stabilizer by the military, but their use is expanding in the construction industry. TM 5-822-14/AFJMAN 32-1019 provides guidance on fly ash (the most commonly available pozzolan) stabilization. Slag is not addressed in the manual, and HQUSACE (CEMP-ET), appropriate Air Force MAJCOM pavements engineer, or Naval Facilities Engineering Service Center should be consulted for current guidance on use of this material in military construction.

(1) Mechanisms. Pozzolans and ground granulated blast furnace (GGBF) slag react with hydroxides to form cementitious bonds. Lime or occasionally portland cement are mixed with these materials to provide the hydroxide activator. Some Class C fly ashes contain sufficient free lime (calcium hydroxide) to be self-cementing, but the military has no experience at present using these materials as a stabilizer without the addition of lime or portland cement. Properly cured lime-fly ash mixes often have compressive strengths of 3.45 to 6.89 MPa (500 to 1,000 psi) with appreciably higher long-term

strengths. If more rapid strength gain is needed, addition of 0.5 to 1.5 percent portland cement can be used as an activator for the fly ash and as contributor to early-age strength.

(2) Uses. Pozzolans and slags gain strength more slowly than portland cement, but are more economical, have less shrinkage and shrinkage cracking, and longer working times than portland cement. Typical fly ash-stabilized mixes will use 2-1/2 to 4 percent lime with 10 to 30 percent fly ash. Coarser soils and aggregates require less stabilizer than fine-grained soils. Some slag mixes used overseas have 8 to 20 percent GGBF slag mixed with 1 percent lime.

(3) Durability. Because of the slower strength gain of these materials, it is crucial that sufficient time be allowed between their placement and the onset of freezing weather. These chemical reactions almost cease below 4.4 °C (40 °F) so this curing period must include moderate temperatures to assure adequate curing of these materials. They can be vulnerable to freezing and thawing damage, so TM 5-822-14/AFJMAN 32-1019 requires laboratory freeze-thaw testing after 28 days curing. Additional assistance on problems with lime-pozzolan or slag-stabilized materials under seasonal frost exposure is available from the Army Cold Regions Research and Engineering Laboratory, 72 Lyme Road, Hanover, NH 03755.

(4) Suitable Soils. Granular materials are effectively stabilized with these materials. Because of their relative economy compared to portland cement, they are particularly effective with poorly graded materials where they can effectively function as a filler more efficiently than the more expensive portland cement. Many clays are naturally pozzolanic so there is little value in adding another pozzolanic material like fly ash. These are usually best handled with lime alone. However, for clays that do not develop pozzolanic reactions with lime or for silty materials that do not contain sufficient clay minerals to react with lime, pozzolanic and slag stabilizers offer an economical and effective alternative to portland cement.

m. Bituminous Stabilization. Asphalt cement (AASHTO PP6, ASTM D 3381, or ASTM D 946), emulsified asphalt (asphalt emulsified with water, ASTM D 977 and D2397), or cutback asphalt (asphalt dissolved in a solvent, D 2026, 2027, and 2028) may be mixed with a soil or aggregate to provide a water resistant, cohesive stabilized material. The mix design for bituminous stabilized materials in a military airfield subbase or base course will be done using a conventional Marshall mix design. Binder contents for subgrade stabilization are often estimated on the basis of empirical equations and then adjusted during construction in the field to achieve the desired results. TM 5-822-14/AFJMAN 32-1019 provides detailed guidance on bituminous stabilization requirements and procedures.

(1) Mechanisms. Asphalt coats the soil and aggregate particles being stabilized and binds it into a water-resistant, cohesive material. Both strength and waterproofing are provided. No chemical reactions are involved. Asphalt-cement stabilization requires no curing other than cooling. Liquid asphalts require different amounts of curing depending on the emulsifying agent or solvent used and the atmospheric conditions. The emulsion must break and the water must either evaporate or drain off for the emulsified asphalt to be effective. Similarly, the solvent in cutback asphalts must evaporate. Premature compaction of liquid-asphalt stabilized materials before adequate water or solvent evaporation may cause very slow curing and leave the stabilized material too soft. The asphalt droplets in an emulsified asphalt may have either a negative electric charge (anionic emulsion) or a positive electric charge (cationic emulsion) that can be matched to the aggregate charge (e.g., an anionic emulsion (negatively charged droplets) used with limestone aggregate (positive charge)).

(2) Uses. Asphalt stabilization provides cohesion to bind individual particles into a mass and can provide significant waterproofing. Asphalt cements are generally mixed with a higher quality

aggregate at an asphalt plant to produce a structural quality subbase or base course stabilized material. The liquid asphalts (emulsified and cutback asphalts) may be plant mixed but are often in situ mixed for less severe loading such as in the subgrade or the subbase or for lighter load applications. As a general rule, the local paving grade asphalt cement will be appropriate for the binder for asphalt-cement stabilization. For liquid asphalts, the highest possible viscosity liquid asphalt that can be handled in the field and mixed with the soil or aggregate being stabilized should be used.

(3) Durability. Water may displace asphalt particles on a soil or aggregate particle in a process known as stripping. Some aggregates have a strong affinity for water and tend to be particularly difficult to coat with asphalt. They are prone to stripping and may prove impossible to coat with liquid asphalt. Additions of lime or liquid antistrip agents or changing the charge of an emulsified asphalt may help combat these problems. Potential moisture problems and effective countermeasures should be a fundamental part of a bituminous stabilization laboratory evaluation and mix design.

(4) Suitable Soils. Bituminous stabilization is most effective with granular materials as excess fines or plastic fines may make it impossible to properly mix the materials and require high binder contents. As the plasticity index increases past 6 and the fines (percent passing the No. 200 sieve) increases above 12 percent, problems with bituminous stabilization increase. In general, the plasticity index should be below 10 and the fines should be less than 30 percent. As the plasticity and percent fines increase, liquid asphalt become better stabilizing agents than asphalt cement. The plasticity of a material to be stabilized can be reduced by adding lime.

n. Nontraditional Stabilizers. A wide variety of special, and often proprietary, stabilizers are actively marketed. These materials have seen very little use or testing by the military, and no guidance is currently available. Many, but not all, proprietary stabilizers that have been evaluated by the military have not lived up to the manufacturer's claims, and no proprietary stabilizer should be used on a military airfield without first evaluating it in the laboratory and in independent field trials. HQUSACE (CEMP-ET), appropriate Air Force MAJCOM pavements engineer, or Naval Facilities Engineering Service Center should be consulted prior to using any of these nontraditional stabilizers.

(1) Types: Nontraditional stabilizers include a wide variety of acids, salts, electrolytes (often a sulfonated oil), polymers, enzymes, natural resins, cation exchange agents, lignins, and polymers among others. Claimed benefits include strength gain, reduced water susceptibility, improved compaction, reduced dusting, reduced plasticity, and better soil texture.

(2) Evaluation. The claimed benefit of any stabilizer should be evaluated quantitatively so that the cost-effectiveness of including the material on a specific project can be determined. It is important to identify what soil property is being changed by the stabilizer and develop a quantitative scheme for evaluating this property. For example, electrolytes reduce a clay mineral's ability to hold water so they have a potential role in dealing with expansive soils. A swelling test with and without the stabilizer is appropriate to evaluate this stabilizer's effectiveness, whereas a strength test would provide no information on the electrolyte's effectiveness. Experience with some of these materials has found that often the amount of the stabilizer needed is higher than the manufacturer's suggested dosage.

3. PORTLAND-CEMENT CONCRETE. Portland-cement concrete is the surfacing for rigid pavement. It carries load through bending and is the major structural component for supporting load. Unreinforced concrete is generally the most serviceable and cost-effective surfacing for military airfields and will be used in most circumstances.

a. Reinforcing. Reinforcement may be added to concrete pavement to accomplish specific purposes, but reinforcing is the exception rather than the rule for military airfield pavements. Reinforcing concrete pavements usually adds cost and complicates construction so it is used only where its added value balances these negative factors. Conventional reinforcing steel is added to keep cracks tightly closed and to slow deterioration of the cracks. Therefore, it is useful wherever cracking cannot be avoided (e.g., odd-shaped slabs, extra-large slabs, etc.). Because reinforcing slows the deterioration of cracks, a relatively small empirical reduction in pavement design thickness is allowed by the material for reinforcing up to 0.5 percent. Continuously reinforced concrete pavements use much more steel (0.6 percent and more) which added to resist deterioration in cracks developed from environmental stresses. The steel is continuous, and the pavement has no joints. It provides a joint-free, smooth pavement, but repairs to these pavements are often difficult. Fiber reinforcing products are actively marketed. Steel fibers can significantly reduce the required pavement thickness, but there are concerns that the fibers pose a foreign object damage (FOD) on military airfields with current finishing techniques. Plastic fibers are of no particular value for military airfields. Their primary advantage for conventional concrete appears at present to be resistance to plastic shrinkage cracking, but proper construction and curing should handle this concern without adding plastic fibers at additional expense to the military. As noted later, these fibers have been found useful in concrete exposed to exhaust from vertical and short take off aircraft like the Harrier. Prestressed pavements are very efficient and produce the most structural capacity for any given cross section of concrete pavement. The design and construction of prestressed pavement is more sophisticated than conventional pavements, but prestressing construction technology has been evolving and is more cost-effective today than in past years. More details on these various reinforced pavements and their design is provided in subsequent chapters.

b. Constituents. Portland-cement concrete is composed of portland cement, aggregates, water, and various additives. Portland cement must meet the requirements of ASTM C 150, and the various types of portland cement are described in Table 9.1. Type I cement will be the most common cement, although Type II, Type I/II, and more seldom Type V may be used in areas with sulfate exposures. Type III cement might be encountered where its rapid strength gain is necessary or in cold weather concreting where its higher heat of hydration is useful. Cements may be specified to be low alkali when problems with alkali-aggregate reactions are anticipated, but such cements may not always be readily available and may be expensive. Addition of fly ash is very common in modern concretes, and the addition of ground granulated blast furnace slags is beginning to be used more often. Both may be used as economical partial replacements for portland cement in the concrete mixture and can be used to provide other desirable characteristics such as enhanced workability, lower permeability, sulfate resistance, protection against alkali-aggregate reaction, etc. Aggregate quality requirements in TM 5-822-7/AFM 88-6, Chapter 8, for military airfield pavements are appreciably tighter than those used in ASTM C 33 which is the most commonly specified concrete aggregate requirement for the concrete industry. The tighter requirements reflect the military's concern over potential FOD hazards to aircraft on airfield pavements. These tighter restriction were adopted by the military in the 1950's after severe problems with popouts developed on new airfield pavements at Selfridge AFB. Air entrainment is crucial for protecting the concrete matrix against damage from freezing and thawing and will be used in all military airfield pavements unless clearance not to do so is first obtained from the HQUSACE (CEMP-ET), appropriate Air Force MAJCOM pavements engineer, or Naval Facilities Engineering Service Center. Air entrainment causes some loss in strength, but it also enhances workability. Therefore, proper mixture proportioning can use this enhanced workability to reduce the water-cement ratio and thereby negate the strength loss from air entrainment. The proper dosage of air-entraining admixture to achieve the targeted air content is affected by factors such as the amount of carbon (measured as loss on ignition) in fly ash or the temperature. Therefore, all air entrainment for military airfield concrete will be provided by liquid admixtures added at the plant. This allows the dosage to be adjusted to reflect specific mixture characteristics and environmental fluctuations at the project site. Air entraining admixtures that are interground with the cement and designated as Type IA, Type IIA, etc. are not suitable for this use as they do not provide the flexibility of adjusting admixture dosage to reflect changing mixture and site conditions. A number of other admixtures besides those for air-entrainment are available to accomplish specific tasks (primarily retarders, accelerators, and those for enhanced workability at a given water-cement ratio). Use of these is generally at the discretion of the engineer doing the mixture proportioning for a specific project or of the contractor who must deal with a specific site problem. The engineer responsible for the mixture proportioning is responsible for selection of admixtures and concrete materials that are compatible and cause no adverse interactions. If the contractor elects to use an admixture (e.g., a retarder because of lengthy haul times), then he or she is responsible for selecting an admixture compatible with the concrete mixture and which has no adverse effect on the fresh or hardened concrete mixture.

c. Special Air Force Requirement. During the 1980s and 1990s, newly placed concrete airfield pavement on Air Force bases had widespread problems with excessive spalling derived primarily from construction related problems, part of which sprung from the common use of concrete mixtures with poor workability. To partially address these problems, the Air Force now requires a well-graded concrete aggregate be used for all their airfield pavements with specific limitations depending on anticipated placement methods (i.e., slipform, with form-riding equipment, or by hand). Specific requirements and details are contained in the Air Force Concrete Mix Design Handbook and will be conformed to for all Air Force pavements unless a waiver is obtained from the Air Force MAJCOM pavements engineer.

d. Durability. Properly proportioned and placed, portland-cement concrete is a highly durable material. Protection against freezing and thawing is achieved by ensuring adequate strength gain before the concrete is first allowed to freeze (crucial issue in cold-weather concreting), using aggregates that are resistant to freezing effects (avoiding aggregates that are prone to produce popouts and D-cracking), and providing adequate air entrainment to protect the concrete matrix. Special precautions are needed when concrete will be exposed to sulfates or if the concrete mixture contains certain aggregates susceptible to reactions between the portland cement alkalis and some aggregate minerals (most commonly certain specific forms of silica and more rarely certain dolomitic materials). Details on these durability issues and guidelines on selecting appropriate levels of air entrainment are provided in TM 5-822-7/AFM 88-6, Chapter 8. The water-cement ratio in military airfield paving mixtures is limited to a maximum of 0.45. This requirement enhances durability by keeping the concrete permeability low as well as improves strength when compared to using higher water to cement ratios in the concrete mixture.

e. Design Strength.

(1) Test Method. Military airfield pavements are designed on the basis of the third point, flexural beam test (ASTM C 78). Thickness design is based on fatigue relationships from full-scale field tests that characterized the test pavement with the flexural test determined in this manner. Other test methods (e.g., center-point flexural beam or splitting tensile test) give numerically different values from this test and are therefore not suitable substitutes. Pavement thickness design is based on classical fatigue analysis, and the results are very sensitive to the specific value of flexural strength used in the design. Consequently, it is important that military airfield pavement design define the concrete strength consistently with the fatigue relationship used in the design procedure. Consequently, all military airfield design will be based on the ASTM C 78 flexural strength.

(2) Correlations. There are no unique relationships between different concrete strength tests (third-point flexural beam, center-point flexural beam, compressive, splitting tensile, etc.), and all such tests are indices of strength rather than an inherent material property. There are many published relationships that allow estimation of one strength test result as a function of another test (e.g., estimate

third-point flexural strength from the concrete compressive strength). However, the variation of the data upon which such relations are based is quite large and the results too inaccurate to allow the use of such relations reliably for military airfield pavement design. The different tests respond differently to changes in the concrete mixture. For example, flexural tests are much more sensitive to inclusion of crushed aggregates in the mixture than are compressive strength tests. It is possible to develop very good correlations between the different tests if the correlation is based on tests on the specific concrete mixture and the same materials are used in the laboratory as will be used in the field mixture. However, simply changing an aggregate source can change the correlation. Correlations are allowed for quality control testing of military concrete pavements during construction, but the correlations must be developed for the specific concrete mixture being used on the project, and the mixture constituents used during construction must be the same as used to develop the correlation in the laboratory.
